20

Materials Selection and Design

ASM INTERNATIONAL ®

The Materials Information Company

Publication Information and Contributors

Materials Selection and Design was published in 1997 as Volume 20 of *ASM Handbook*. The Volume was prepared under the direction of the ASM International Handbook Committee.

Volume Chair

The Volume Chair was George E. Dieter.

Authors and Contributors

- **Peter Andresen** General Electric Corporate Research and Development Center

Foreword

Handbooks published by ASM International have long been the premier reference sources on the properties, processing, and applications of metals and nonmetallic engineering materials. The fundamental purpose of these handbooks is to provide authoritative information and data necessary for the appropriate selection of materials to meet critical design and performance criteria. *ASM Handbook,* Volume 20 takes the next step by focusing in detail on the *processes* of materials selection and engineering design and by providing tools, techniques, and resources to help optimize these processes. Information of this type has been provided in other handbook volumes--most notably in Volume 3 of the 9th Edition *Metals Handbook*--but never to the impressive scope and depth of this handbook.

Volume 20 reflects the increasingly interrelated nature of engineering product development, encompassing design, materials selection and processing, and manufacturing and assembly. Many of the articles in this volume describe methods for coordinating or integrating activities that traditionally have been viewed as isolated, self-contained steps in a linear process. Other articles focus on specific design and materials considerations that must be addressed to achieve particular design and performance objectives. As in all *ASM Handbook* volumes, the emphasis is on providing practical information that will help engineers and technical personnel perform their jobs.

The creation of this multidisciplinary volume has been a complex and demanding task. It would not have been possible without the leadership of Volume Chair George E. Dieter. We are grateful to Dr. Dieter for his efforts in developing the concept for this volume, organizing an outstanding group of contributors, and guiding the project through to completion. Special thanks are also due to the Section Chairs, to the members of the ASM Handbook Committee, and to the ASM editorial and production staff. We are especially grateful to the more than two hundred authors and reviewers who contributed their time and expertise to create this extraordinary information resource.

George Krauss

President, ASM International

Michael J. DeHaemer

Managing Director, ASM International

Preface

All engineers who are concerned with the development of products or the design of machines and structures must be knowledgeable about the materials from which they are made. After all, the selection of the correct material for a design is a key step in the design process because it is the crucial decision that links the computer calculations and the lines on an engineering drawing with a working design. At the same time, the rapid progress in materials science and engineering has made a large number of materials--metals, polymers, ceramics, and composites--of potential interest to the designer. Thus, the range of materials available to the engineer is much larger than ever before. This presents the opportunity for innovation in design by utilizing these materials in products that provide greater performance at lower cost. To achieve this requires a more rational process for materials selection than is normally used.

Materials engineers have traditionally been involved in helping to select materials. In most cases, this is done more or less in isolation from the actual design process. Sometimes the materials expert becomes involved only when the design fails. In the past ten years, mostly in response to the pressures of international competitiveness, new approaches to product design and development have arisen to improve quality, drive down cost, and reduce product cycle time. Generally called concurrent engineering, it uses product development teams of experts from all functions--design, manufacturing, marketing, and so forth--to work together from the start of the product design project. This opens new opportunities for better material selection. It also has resulted in the development of new computer-based design tools. If materials

engineers are to play an important future role in product development, they need to be more familiar with the design process and these design tools.

Thus, Volume 20 of *ASM Handbook* is aimed at two important groups: materials professionals and design professionals. As a handbook on materials selection and design, it is unique. No other handbook deals with this subject area in this way, bridging the gaps between two vital but often distant areas of expertise. The Handbook is divided into seven sections:

- The Design Process
- Criteria and Concepts in Design
- Design Tools
- The Materials Selection Process
- Effects of Composition, Processing, and Structure on Materials Properties
- Properties versus Performance of Materials
- Manufacturing Aspects of Design

Emphasis throughout is on concepts and principles, amply supported by examples and case histories. This is not a handbook of material property data, nor is it a place to find detailed discussion of specific material selection problems. Other volumes in the *ASM Handbook* series often provide this type of information.

Section 1, "The Design Process," sets the stage for the materials engineer to better understand and participate in the product design process. The context of design within a manufacturing firm is described, and the role of the materials engineer in design is discussed. Emphasis is placed on methods for conceptual and configuration design, including the development of a product specification. Methods for creative generation of conceptual designs and for evaluation of conceptual and configuration alternatives are introduced. Learning to work effectively in cross-functional teams is discussed.

Section 2, "Criteria and Concepts in Design" deals with design concepts and methods that are important for a complete understanding of engineering design. The list is long: concurrent engineering, including QFD; codes and standards; statistical aspects of design; reliability in design; life-cycle engineering; design for quality; robust design (the Taguchi approach); risk and hazard analysis; human factors in design; design for the environment (green design); safety; and product liability and design.

Section 3 considers "Design Tools." This section provides an overview of the computer-aided engineering tools that are finding wide usage in product design. This includes the fundamentals of computer-aided design, and the use of computer-based methods in mechanism dynamics, stress analysis (finite element analysis), fluid and heat transfer analysis, and electronic design. Also considered are computer methods for design optimization and tolerance analysis. Finally, the section ends with discussions of the document packages necessary for design and of methods for rapid prototyping.

Section 4, "The Materials Selection Process," lays out the complexity of the materials selection problem and describes various methodologies for the selection of materials. Included are Ashby's material property charts and performance indices, the use of decision matrices, and computer-aided methods. Also discussed are the use that can be made of value analysis and failure analysis in solving a materials selection problem. The close interrelationship of materials selection and economic issues and processing are reinforced in separate articles.

Section 5, "Effects of Composition, Processing, and Structure on Materials Properties," is aimed chiefly at the design engineer who is not a materials specialist. It is a "mini-textbook" on materials science and engineering, with a strong engineering flavor and oriented chiefly at explaining mechanical properties and behavior in terms of structure. The role that processing plays in influencing structure is given emphasis. The articles in this Section cover metallic alloys, ceramics, engineering plastics, and composite materials. The Section concludes with an article on places to find materials information and properties.

Section 6, "Properties versus Performance of Materials," features articles that attempt to cross the materials/design gap in a way that the designer will understand how the material controls properties and the materials engineer will become more familiar with real-world operating conditions. Again, emphasis is mostly on mechanical behavior and includes articles on design for static structures, fatigue, fracture toughness, and high temperature. Other articles consider design for corrosion

resistance, oxidation, wear, and electronic and magnetic applications. Separate articles consider the special concerns when designing with brittle materials, plastics, and composite materials.

Section 7, "Manufacturing Aspects of Design," focuses on the effects of manufacturing processes on the properties and the costs of product designs. The section contains articles on design for manufacture and assembly (DFM and DFA), general guidelines for selecting processes, modeling of processes, and cost estimation in manufacturing. Individual articles deal with design for casting, deformation processes, powder processing, machining, joining, heat treatment, residual stresses, and surface finishing. Articles also deal with design for ceramic processing, plastics processing, and composite manufacture.

This Handbook would not have been possible without the dedicated hard work of the chairmen of the sections: John R. Dixon, University of Massachusetts (retired); Bruce Boardman, Deere & Company; Kenneth H. Huebner, Ford Motor Company; Richard W. Heckel, Michigan Technological University (retired); David A. Woodford, Materials Performance analysis Inc.; and Howard A. Kuhn, Concurrent Technologies Corporation. Special thanks goes to several individuals who did work well beyond the normal call of duty in reviewing manuscripts: Serope Kalpakjian, John A. Schey, and Charles O. Smith. I wish to thank all of the busy people who agreed to author articles for the Handbook. The high rate of acceptance, from both the design community and the materials community, is a strong indicator of the importance of the need that *ASM Handbook,* Volume 20, fills.

George E. Dieter

- **Dan Zhao** (1996-) Essex Group Inc.

Previous Chairs of the ASM Handbook Committee

- **R.J. Austin** (1992-1994) (Member 1984-1996)
- **L.B. Case** (1931-1933) (Member 1927-1933)
- **T.D. Cooper** (1984-1986) (Member 1981-1986)
- **E.O. Dixon** (1952-1954) (Member 1947-1955)
- **R.L. Dowdell** (1938-1939) (Member 1935-1939)
- **J.P. Gill** (1937) (Member 1934-1937)
- **J.D. Graham** (1966-1968) (Member 1961-1970)
- **J.F. Harper** (1923-1926) (Member 1923-1926)
- **C.H. Herty, Jr.** (1934-1936) (Member 1930-1936)
- **D.D. Huffman** (1986-1990) (Member 1982-)
- **J.B. Johnson** (1948-1951) (Member 1944-1951)
- **L.J. Korb** (1983) (Member 1978-1983)
- **R.W.E. Leiter** (1962-1963) (Member 1955-1958, 1960-1964)
- **G.V. Luerssen** (1943-1947) (Member 1942-1947)
- **G.N. Maniar** (1979-1980) (Member 1974-1980)
- **J.L. McCall** (1982) (Member 1977-1982)
- **W.J. Merten** (1927-1930) (Member 1923-1933)
- **D.L. Olson** (1990-1992) (Member 1982-1988, 1989-1992)
- **N.E. Promisel** (1955-1961) (Member 1954-1963)
- **G.J. Shubat** (1973-1975) (Member 1966-1975)
- **W.A. Stadtler** (1969-1972) (Member 1962-1972)
- **R. Ward** (1976-1978) (Member 1972-1978)
- **M.G.H. Wells** (1981) (Member 1976-1981)
- **D.J. Wright** (1964-1965) (Member 1959-1967)

Staff

ASM International staff who contributed to the development of the Volume included Scott D. Henry, Assistant Director of Reference Publications; Steven R. Lampman, Technical Editor; Grace M. Davidson, Manager of Handbook Production; Bonnie R. Sanders, Chief Copy Editor; Randall L. Boring, Production Coordinator; Kathleen S. Dragolich, Production Coordinator; and Amy E. Hammel, Editorial Assistant. Editorial assistance was provided by Nikki DiMatteo,

Kelly Ferjutz, Heather Lampman, and Mary Jane Riddlebaugh. The Volume was prepared under the direction of William W. Scott, Jr., Director of Technical Publications.

Conversion to Electronic Files

ASM Handbook, Volume 20, *Materials Selection and Design* was converted to electronic files in 1999. The conversion was based on the first printing (1997). No substantive changes were made to the content of the Volume, but some minor corrections and clarifications were made as needed.

ASM International staff who contributed to the conversion of the Volume included Sally Fahrenholz-Mann, Bonnie Sanders, Marlene Seuffert, Gayle Kalman, Scott Henry, Robert Braddock, Alexandra Hoskins, and Erika Baxter. The electronic version was prepared under the direction of William W. Scott, Jr., Technical Director, and Michael J. DeHaemer, Managing Director.

The Role of the Materials Engineer in Design

Bruce Boardman, Deere and Company Technical Center; James C. Williams, General Electric Aircraft Engines; Peter R. Bridenbaugh, Aluminum Company of America Technical Center

Introduction

THE ROLE of the materials engineer in the design and manufacture of today's highly sophisticated products is varied, complex, exciting, and always changing. Because it is not always the metallurgical or materials engineer who specifies the material, this *ASM Handbook* on materials selection and design is prepared to benefit all engineers who are involved with selecting materials with their related processes that lead to a ready-to-assemble manufactured component. This article discusses the various roles and responsibilities of materials engineers in a product realization organization and suggests new and different ways in which materials engineers may benefit their organization. Insights into use of the remainder of this Volume are also offered.

Materials selection specialists have been practicing their art since the beginning of recorded time. The first caveman, searching for food, required an implement that would not break during use. Although wood, stone, and bone were the only structural materials available, there were still choices: hard wood versus soft wood, and hard stones and flint, which would sharpen when broken, versus soft stones. While prehistoric man learned only from experience, learning nevertheless took place, and the art of materials selection became a valued skill within the community. As other materials, such as copper and iron, became available, the skill became almost mystical, with knowledge passed down from father to son, until the middle to late 19th century. By then the blacksmith had replaced the alchemist. At this point, the blacksmith had become the local expert in materials selection and shaping and was recognized as a valuable and enabling member of the community.

The role of the materials selection expert has evolved. Today when we think of materials selection specialists, we think of those who have been formally trained as metallurgical or materials engineers. But as discussed below, there are many more engineers involved in materials selection than those with the title metallurgist, materials engineer, or materials scientist. Modern engineered materials are now available that have attractive but complex properties. Therefore, it is becoming essential to develop a much closer working relationship between those who design a component and those who advise the designer on materials selection. In fact, the most efficient structural designs are now generated by incorporating, from the beginning, the complex properties of modern engineered materials into the design synthesis step (matching form to function).

The actual selection of a material to satisfy a design need is effectively performed every day in literally dozens of different ways by people of many different backgrounds. The selection process can range from simply re-specifying a previously used material (or one used by a competitor) through finite element analyses or modeling routines to precisely identify property requirements. Additionally, the selection may be done by someone formally trained in metallurgy and materials science or by designers themselves. There is no unique individual role when it comes to materials selection.

Today, the selection of the material and its processing, product design, cost, availability, recycleability, and performance in final product form have become inseparable. As a result, more and more companies are forming integrated product development (IPD) teams to ensure that all needed input is obtained concurrently. Whether it is used in a small company (which frequently, from lack of resources, is forced to work in the IPD mode) or a large company (who may have to create a "skunk works"), the IPD approach has been shown to lead to a better result and to achieve this result faster. The integration of material, process, and product design relies on individuals who are trained in materials selection and can work in a team environment. Often, it is the materials specialist, familiar with the frequent, conflicting needs of design, production, and marketing, who can assume the role of mediator to focus on the final product. We hope that this point will be made clearly in this Volume.

Attempting to define a single role for the individual who actually selects a material for a design is not possible. That individual frequently assumes roles that cross many engineering and manufacturing disciplines. Starting with the initial design and material choice, through prototype manufacture and testing, and continuing to final production, the materials

selection specialist is an essential team member. As more companies shrink their in-house, captive manufacturing and assembly operations, the role of the materials selection function may increasingly be outsourced, along with the actual manufacturing activity. This possibility can create opportunities for the materials selection specialist, but it can also create risk for the "virtual manufacturers."

Worldwide, the vast majority of manufacturing firms are small and cannot afford the luxury of a formally trained materials scientist or materials selection specialist. Rather, they have individuals trained in many areas, one of which is materials. In a smaller enterprise, these individuals actually select materials as a part of their daily design activity. Whether that training was gained as a part of another degree program, as part of a community college associates program, on the job, or as the result of a series of ASM International's Materials Engineering Institute courses, the result is the development of an individual trained in the many and varied facets of materials selection. For most products and materials applications this practice works quite well. However, for high-performance products, where understanding the subtleties of materials performance can be the defining difference, this practice can lead to a less than optimal result. The emergence of agile manufacturing and rapid response scenarios, coupled with ongoing developments in new and tailored materials, further specializes the critical function of materials selection.

Before proceeding into detail about the many roles of the materials engineer, it is appropriate to summarize the content of the remainder of this Volume to help guide readers to the portions most important to their specific interests. The volume is divided into seven instructional sections, which are summarized in Table 1 and discussed further in the following paragraphs.

Table 1 Overview of the Sections in *ASM Handbook*, Vol 20, *Materials Selection and Design*

Section title	Summary
1. The Design Process	This section offers insights into the several roles that must be played by the materials selection expert. It also reviews the process and methods that may be applied to enhance and improve the effectiveness of the design process.
2. Criteria and Concepts in Design	This section goes into detail on many of the "soft" issues related to design, process, safety, manufacturability, and quality. These issues are not historically a part of the design and material selection process, because they do not relate to the quantifiable properties (e.g., strength or toughness) or attributes (e.g., wear or corrosion resistance) that determine the ability of a material to perform the desired function. Nevertheless, they are of critical importance, because parts and assemblies must be made with well-understood variance, consistent processing, and the expectation that the part will perform safely and reliably in the ultimate customer's application.
3. Design Tools	This section details the tools associated with a state-of-the-art design process. Included are discussions on paper and paperless drawings, adding tolerances, computer-aided drafting and computer-aided design, rapid prototyping, modeling, finite element methods, optimization methods, and documenting and communicating the design to others.
4. The Materials Selection Process	This section begins the details of what steps and methods are actually required to properly select a material and its corresponding manufacturing process. Topics included are an overview of the process, technical and economic issues, the Ashby materials selection charts, use of decision matrices, computer-aided materials selection, the relationship between materials properties and processing, and the use of value analysis and failure analysis.
5. Effects of Composition, Processing, and Structure on Materials Properties	The science of materials selection is introduced in this section as the relationships between different families of materials (e.g., metals, ceramics, plastics) are discussed. Additionally the effects of thermal and mechanical processing on performance properties of materials are discussed. Sources of materials data are also listed in this section.
6. Properties versus Performance of Materials	This section details and discusses the actual properties needed for specific general types of design (e.g., structural, optical, magnetic, electronic) as well as accepted design processes and methodology for prevention of several common performance needs (e.g., corrosion, fatigue, fracture toughness, high

	temperature, wear, oxidation). Additionally there is discussion relating to design with brittle materials, plastics, and composite materials, and for surface treatments.
7. Manufacturing Aspects of Design	This section discusses what may be the most important aspects of a successful design: how the conceptual ideas are cost effectively converted into hardware. The majority of commonly used manufacturing processes are discussed in detail in a series of separate chapters, but ultimately, the designer and materials selection expert must merge these thermal and mechanical processes into a description of the properties and attributes of the final part. Techniques for computer-based modeling and costing are also discussed. Additionally, there is discussion about the effect of processing on several of the common nonmetallic materials and the control of residual stresses resulting from manufacturing. Finally, this section includes a discussion on designing for ease of assembly of the many parts that may be involved in a final product, ready for delivery to the ultimate customer.

The Role of the Materials Engineer in Design

Bruce Boardman, Deere and Company Technical Center; James C. Williams, General Electric Aircraft Engines; Peter R. Bridenbaugh, Aluminum Company of America Technical Center

The Design Process

Section 1 of this Volume shows that the process of materials selection during design can take many paths. As already suggested, the task may simply be to design a "new" part that is nearly identical to an existing part and is expected to be used in similar ways. In this case, it may be possible to use the same material and processing as were used for the existing part. Alternatively, the task may be to design and select material for a new part for which there is no prior history. Obviously, this is a much more complex task and requires knowledge of loads, load distributions, environmental conditions, and a host of other performance factors (including customer expectations) and manufacturing-related factors.

In addition to a knowledge of the required performance characteristics, the materials selector must be able to define and account for manufacturing-induced changes in material properties. Different production methods, as well as controlled and uncontrolled thermal and mechanical treatments, will have varying effects on the performance properties and the cost of the final part or assembly. Hence, the materials specialist must also work with the value engineering function to achieve the lowest cost consistent with customer value. Often, it is by relating the varying effects of manufacturing processes to customer needs that one manufacturer develops a product that has an advantage over another, using essentially the same material and process combinations.

While the effects of manufacturing-induced changes to performance properties are covered in a later section (as well as in other *ASM Handbook* Volumes), it is critical to understand and accept that the choice of manufacturing processes is frequently not under the direct control of the materials selection expert. In fact, by the time the concept and initial configuration of a design is committed to paper, or to a computer-aided design (CAD) system, the manufacturing processes and sequence of processes required to produce a product cost effectively are normally fixed. They are no longer variables that can be controlled without redesign.

The above approach generally follows the path that George Dieter refers to as a "process first approach" in his article "Overview of the Materials Selection Process" in this Volume. Unfortunately, it has been common for designers, inadvertently, to create parts with geometric features that place severe restrictions on the selection of manufacturing processes, with even less freedom remaining for material selection (Table 4 in Dieter's article demonstrates this point). The use of "design for manufacturability" concepts and IPD teams is beginning to eliminate this undesirable practice. Until the IPD approach is in common use, an alternative, referred to as a "materials first approach," may be useful. The materials first approach depends on a thorough understanding of the service environment and advocates choices based on properties that satisfy those performance needs (Table 3 in Dieter's article provides a useful starting point). Similarly, overly restrictive selection of the material independently limits the manufacturing processes available. This is all the more reason to use IPD methods.

As suggested above, the use of a cross-functional IPD team to translate the desired performance requirements into a design concept usually yields the best result most quickly. Such a team contains the expertise to decide between the use of steel sheet, machined forgings, nonferrous castings, or reinforced polymers as well as to select the processing and joining

methods. Table 2 summarizes many common specialties required to define materials, processes, and manufacturing methods for making cost effective parts and assemblies that meet the customer's expectations. These decisions are not, by themselves, sufficient to ensure a successful design, but the use of cross-functional teams to concurrently consider design, materials, manufacturing processes, and final cost provides superior customer value. Obviously, no individual design exercise will contain one member from each specialty; in many practical cases, each member can represent multiple specialties.

Table 2 Typical specialties involved during an "ideal" materials selection process

General area	Specialty
Materials science	Metals
	Plastics
	Ceramics
	Coatings
	Chemistry
	Electrochemistry
Processing	Forging
	Casting
	Welding
	Hot forming
	Cold forming
	Molding
	Machining
	Sintering
	Heat treatment
Cost analysis	Purchasing (supply management)
	Process engineering

	Industrial engineering
	Life cycle costing
Design Quality assurance	(Specific to application)
	Inspection
	Statistics
	Reliability
	Field test
	Customer
Other	Marketing
	Legal
	Environmental

The Role of the Materials Engineer in Design

Bruce Boardman, Deere and Company Technical Center; James C. Williams, General Electric Aircraft Engines; Peter R. Bridenbaugh, Aluminum Company of America Technical Center

Criteria and Concepts in Design

Material selection involves more than meeting minimum property requirements for strength, fatigue, toughness, corrosion resistance, or wear resistance. There are numerous options for product design and materials selection, and frequently they cannot be quantified. This precludes the use of mathematical optimization routines and shifts the emphasis to experience. Experience is essential in dealing with these "soft issues" related to qualitative non-property considerations.

The design must be producible. This means robust processes must be selected that have known statistical variation and will yield features or complete parts that lie well within the specification limits. This design for manufacturability approach is becoming popular, is an integral part of an IPD team's tool box, and has been demonstrated to be effective in improving quality and reducing cost.

Designing to minimize the total costs to the consumer during the expected product life (the life cycle cost) is yet another challenge. These costs include raw material, production, use, maintenance (scheduled or otherwise), and disposal or recycling costs. Some of these cost elements are unknown. This is where the combination of the art and skill of engineering faces its most severe test.

Similar issues arise when the safety, product liability, and warranty cost exposure aspects of product design and material selection are concerned. In many cases, alternate designs or materials could be chosen with no measurable difference.

However, there are also many cases where a particular design and/or material choice could prevent an undesirable product failure mode. An understanding of how a part, assembly, or entire structure can fail and the ramifications of that failure is essential in providing a safe and reliable design. A well-known example is the failure of one material in a ductile mode while another fails in a brittle mode. The former could provide that extra margin of safety by giving a warning that there is an impending failure while the latter fails catastrophically without warning. Knowing the ways a product can fail and the safety ramifications of each failure mode will go a long way to minimizing the consequences of failure if the product is used in a manner that exceeds the design intent. Failure mode and effects analysis (FMEA) can help in this regard.

Product success requires that the appearance and function of the product must meet the customer's approval. Normally these are design factors, but material selection and surface finish can be equally important. Consumers' tastes often change with time; for instance, current camera customers prefer a dull or matte black finish instead of brightly finished ones. Numerous materials-related solutions to accommodate this change in buying patterns were proposed, including anodizing, painting, and changing the substrate material from metal to plastic.

The camera example leads into a discussion of designing for the environment. The growing environmental and regulatory demand to consider the entire life cycle of a product could require the manufacturer to recover and recycle the product and process waste materials. This places renewed emphasis on considering all options. Changing the materials or the manufacture of the camera mentioned above involves designing an environmentally friendly product. Changing from chromium plating appears to be environmentally friendly, but today's chrome plating units are being constructed to operate in a zero discharge mode, so there is no obvious gain from eliminating the chrome. The anodizing process can be just as clean. Paint, on the other hand, is suffering severe scrutiny over both emissions during the painting process as well as subsequent mishandling by the consumer. And, changing the camera body to plastic is not necessarily a good solution because the recycling infrastructure is not yet adequate on a global level to effectively reclaim the material.

Another design factor is the repairability of a product. Automobiles are not intended to have accidents, but they do. Design and material selection only for initial cost and performance factors has led to the widespread use of one-piece plastic parts that are not repairable in many cases. Any product that costs more to repair than the owner finds acceptable will eventually suffer in the marketplace.

The second Section of this Handbook, "Criteria and Concepts in Design," provides significant additional detail about factors that must be considered during the conceptual stage of design. While many of these factors are not quantifiable, they affect the ultimate cost and ability of the design to satisfy customer expectations. Often, it is the materials engineer who is best equipped to integrate and account for these soft issues, which can be one of the deciding factors in the marketplace. Unfortunately, the pressure of design schedules can squeeze the time allotted for a thorough selection of material and process. The materials engineer must guard against this.

Bruce Boardman, Deere and Company Technical Center; James C. Williams, General Electric Aircraft Engines; Peter R. Bridenbaugh, Aluminum Company of America Technical Center

Design Tools

Once the concept and geometry of a part or assembly have been determined, the designer proceeds to the detailed manufacturing design phase. The output from this phase is a physical blueprint or electronic CAD file from which the part will be manufactured. This output contains input for the materials engineer in the form of material selection and processing notes that will guide the manufacturing activity and ultimately may evolve into formal material and processing specifications.

Section 3, "Design Tools," contains numerous articles relating to the functions required to pass from the conceptual stage to a detailed and optimized design. These articles introduce concepts for CAD, tolerancing, optimizing, documenting, and prototyping. A common thread between all of these aspects is that the designer requires sets of validated material and processing properties. Again, the materials engineer is an important resource. While there are numerous sources of basic materials data, few sources take into consideration the inherent differences between manufacturing facilities. It is the materials engineer, familiar with the required manufacturing processes and how they individually and collectively affect

the ultimate properties of the material, who leads the process of translating handbook data into anticipated product performance.

The need to produce a prototype part that accurately represents the future parts, including manufacturing process capability, is another factor that complicates the design process. While a prototype can be machined from a block of wrought metal, the properties of this first part will not be the same as those of the production parts if casting, forming, or powder consolidation processes are ultimately used to produce the required shape. The machined prototype will be useful for testing, fit, design functionality, and the determination of service loads, but it will provide little information about ultimate fatigue life, fracture toughness, or other environmental needs. Driven by this need, new methods of rapid prototyping continue to be developed. In a very few cases, techniques are available to quickly produce accurate prototypes that equal final production parts. Continuing with the example of machined versus cast parts, a replica of the part can be machined from expanded polystyrene and the lost foam casting method can be used to produce a "real" casting. This casting possesses all of the significant characteristics of the yet-to-be manufactured production parts. More details of these technologies can be found in the article "Rapid Prototyping" in this Volume. The materials engineer will often be asked to evaluate the degree to which the prototype can be expected to represent the production parts. Failure to include this comparison step can result in retro design under duress, schedule delays, and increased cost.

Bruce Boardman, Deere and Company Technical Center; James C. Williams, General Electric Aircraft Engines; Peter R. Bridenbaugh, Aluminum Company of America Technical Center

The Materials Selection Process

Ultimately, the design reaches the stage where final material selection is required. At that time, knowledge of both mechanical and environmental requirements is essential. During the conceptual design stage, only general data were required about materials properties, materials processing effects, and performance parameters. These broad descriptions need to be refined into specific performance requirements, including the processing steps that will ensure this performance. The materials engineer provides guidance based on knowledge of the properties of the base materials and knowledge of the relationships between the material processing and the final properties.

The materials engineer's knowledge of the processes available within the manufacturing facility and the property changes due to the mechanical or thermomechanical processes can simplify the choices between cost, manufacture, environment, and many other issues. Section 4, "The Materials Selection Process," provides details on many of the issues and steps required to finally arrive at the optimal material selection.

The Role of the Materials Engineer in Design

Bruce Boardman, Deere and Company Technical Center; James C. Williams, General Electric Aircraft Engines; Peter R. Bridenbaugh, Aluminum Company of America Technical Center

Effects of Composition, Processing, and Structure on Materials Properties

Few product lines require a thorough knowledge of all the different materials, compositions, structure, and processing relationships contained in Section 5. However, materials engineers must know which of these to apply to their operations and have general knowledge about the others. In many cases, the materials and process content of a product can be used to differentiate it in the marketplace. Therefore, it is important for the materials engineer to possess the education and background to become expert in new materials and material processes as they emerge so that the company's new products will be competitive.

Bruce Boardman, Deere and Company Technical Center; James C. Williams, General Electric Aircraft Engines; Peter R. Bridenbaugh, Aluminum Company of America Technical Center

Properties versus Performance of Materials

Up to this point, the subject of performance has been referred to only in passing or as something that is known and will be satisfied by the material and processing combination chosen. Obviously, that is a gross oversimplification.

Section 6 addresses the more significant relationships between properties and performance. For simplicity, these subjects are presented individually. In reality there are usually several limiting, and often competing, property-related performance criteria. Bridges and boilers, for example, require strength, modulus, fatigue, fracture, corrosion, thermal expansion, and so on. It is the role of the materials engineer to integrate these many factors into a successful product.

Detailed discussion of the methods used to determine the minimum materials properties required to meet desired product characteristics is not included here. In general, the methods for determining the minimum required performance properties are well beyond the scope of this Volume, or perhaps any single handbook. Fortunately, the vast majority of products designed are derived from existing products, so the materials engineer has a good idea of service conditions and product requirements. An accurate and complete understanding of a customer's intended use of a product is essential to the design and manufacture of a successful product. This information is the heart of the product design specification discussed in the article "Conceptual and Configuration Design of Products and Assemblies" in Section 1.

Also missing from Section 6 is any reference to methods for testing new or prototype parts, assemblies, or products in service-based conditions. Since Wohler's pioneering explanation of fatigue in railroad axles over one hundred years ago, there has been continuous advancement in the understanding of service environments, recording of service conditions (loads, strains, strain rates, corrosion, temperature, etc.), and accelerated laboratory testing methods to understand the effect of these conditions. From Wohler's simple axle test unit, to laboratory-sized material property test coupons, to full-scale automobile or airplane test beds, there has been a competitive need for something other than placing a product in the hands of the consumer and waiting (possibly years) to learn if it was underdesigned (premature failure and safety or liability issues), overdesigned (too heavy or expensive), or appropriately designed. Adding to the complexity is the fact that many consumers do not have similar or well-defined operating envelopes, resulting in large variations in service loads and lifetimes. Dealing with this uncertainty is one of the major challenges for a designer.

The Role of the Materials Engineer in Design

Bruce Boardman, Deere and Company Technical Center; James C. Williams, General Electric Aircraft Engines; Peter R. Bridenbaugh, Aluminum Company of America Technical Center

Manufacturing Aspects of Design

Section 7, "Manufacturing Aspects of Design," introduces articles on manufacturing-related factors besides properties, including cost. As previously stated, the manufacturing processes capable of producing a specific part design are restricted, if not fixed, at the time of conceptual design. Combine this with the fact that, for most parts, costs are related to manufacturing and assembly, and it becomes apparent that choosing the "best" design is highly dependent on choosing the "best" manufacturing method. Since this decision is made early in the process, it becomes important for designers to avail themselves of the manufacturing expertise provided by the materials engineer.

Once the manufacturing process has been identified, there is still the need to optimize the process, determine its capability, and understand the effect(s) that the process will have on a material and its properties. Computer modeling is making significant contributions to our understanding of the effects of processing on properties, as well as which steps in the processing sequence are most important to control in order to consistently produce high-quality parts that meet the design intent. The articles "Design for Quality" and "Robust Design" in Section 2 provide additional detail on the needs and methods used for process control. It is worth noting that, in almost every example, quality improvements also lead to

cost reductions by reducing rejections, downstream rework, inventory requirements, warranty costs, and disappointed customers.

Section 7 provides detail on methods for optimizing the majority of manufacturing processes for several specific material classes. Probably the most challenging, as well as the most needed, are modeling methods for predicting what will happen on a microstructural basis during manufacturing operations such as heat treatment, forging, and casting. Only through an understanding of the time-temperature profile, and its relationship to non-isothermal cooling and/or solidification of a material, can the materials engineer predict final microstructures, including any transformation and/or thermally induced stresses.

Overview of the Design Process

John R. Dixon, University of Massachusetts (Professor Emeritus)

Introduction

THE ROLE OF ENGINEERING DESIGN in a manufacturing firm is to transform relatively vague marketing goals into the specific information needed to manufacture a product or machine that will make the firm a profit. This information is in the form of drawings, computer-aided design (CAD) data, notes, instructions, and so forth.

Figure 1 shows that engineering design takes place approximately between marketing and manufacturing within the total product realization process of a firm. Engineering design, however, is not an isolated activity. It influences, and is influenced by, all the other parts of a manufacturing business.

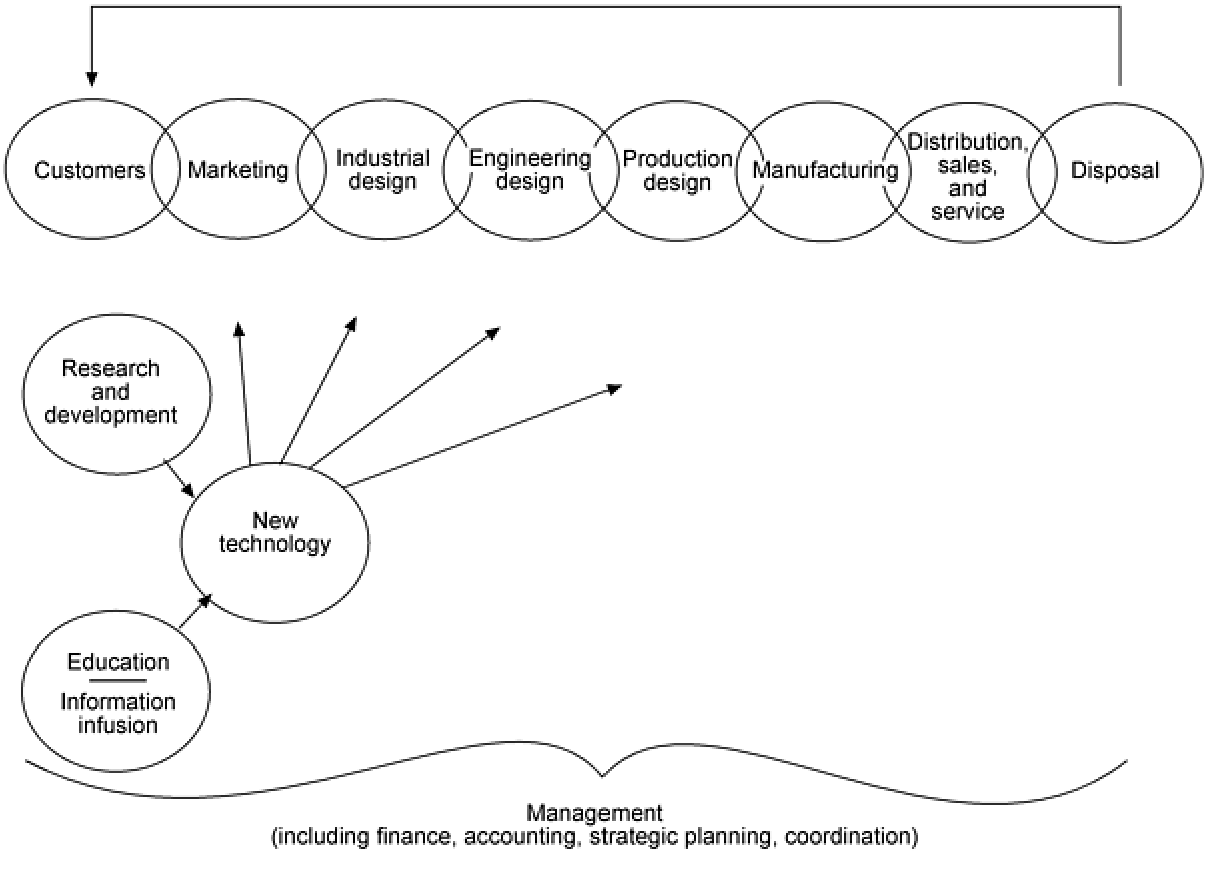

Fig. 1 Engineering design as a part of the product realization process

In the past, the interrelatedness of design with other product realization functions was not sufficiently recognized. New design processes and methods involve the use of cross-functional teams and constant, effective two-way communications with all those who contribute to product realization in a firm.

A discussion of engineering design benefits from distinguishing between parts and assemblies. Though a few products consist of only one part--a straight wrench or paper clip, for example--most products are assemblies of parts. The process of designing assemblies is described in the article "Conceptual and Configuration Design of Products and Assemblies" in this Volume.

Distinguishing between special-purpose assemblies and standard components is also helpful. A standard component is an assembly that is manufactured in quantity for use in many other products. Examples are motors, switches, gear boxes, and so forth.

As assemblies are designed, a repeated (or recursive) process takes place in which the product is decomposed into subassemblies and finally into individual parts or standard components. (See the section "Engineering Conceptual Design" in this article.) Then to complete the design, the individual parts must be designed, manufactured, and assembled. The process of designing parts is described in the article "Conceptual and Configuration Design of Parts" in this Volume.

The design of a part involves selection of a material and a complementary manufacturing process. The majority of parts used in products today are either injection molded plastics, stamped ferrous metals, or die-cast nonferrous metals. Of course, many other material-process combinations are also in use. Some parts are made by a sequence of processes, such as casting followed by selective machining. Materials and process selection are described in the Sections "The Materials Selection Process" and "Manufacturing Aspects of Design" in this Volume.

The above paragraphs point out several important and unique requirements imposed on the engineering design process. An obvious one is that parts must be designed for manufacturing as well as for functionality, a requirement that has generated a body of knowledge called design for manufacturing (DFM). Another obvious requirement is that to obtain a final product, parts must be assembled. This has fostered the special field of design for assembly (DFA). Though it is not so obvious, a consideration overriding both DFM and DFA is that assemblies and parts should be designed in a way that results in the minimum total number of parts possible (Ref 1). A smaller part count almost always will result in lower total product cost when all costs are considered, including costs of materials, tooling, processing, assembly, inventory, overhead, and so forth.

Of course, engineering designers must design products that not only can be economically manufactured and assembled, but they also must function as intended. This requires selecting and understanding the physical principles by which the product will operate. Moreover, proper function requires special attention to tolerances. These two considerations are called designing for function and fit. However, designers must consider a myriad of other issues as well: installation, maintenance, service, environment, disposal, product life, reliability, safety, and others. The phrase design for X (DFX) refers to all these other issues (Ref 2).

Designing for DFM, DFA, minimum parts, function, fit, and DFX is still not all that is required of the engineering designer. Products also must be designed for marketing and profit, that is, for the customer and for the nature of the marketplace. Designers, therefore, must be aware of what features customers want, and what customers consider to be quality in a product. In addition, marketing considerations must include cost, quality, and, increasingly important, time--that is, when the product will reach the marketplace.

Designers also should recognize that the processes by which parts and products are made, and the conditions under which they are used, are variable. Designing so that products are robust under these variabilities is another design requirement.

Designing a complex product or even a relatively simple one with all these requirements and considerations in mind is a tough and complex task. Therefore, finding creative, effective solutions to the many problems that are encountered throughout the process is essential to competitive success. Creative problem solving is especially important early in the design process when conceptual alternatives are generated, and choices are made that essentially fix the nature and character of the product. Creative problem solving in a design context is discussed in the article "Creative Concept Development" in this Volume.

A great deal of varied knowledge is needed to perform design competently and quickly. Thus design is usually a team effort involving people from marketing, several branches of engineering, and manufacturing. The formulation,

organization, and operation of such design teams are discussed in the article "Cross-Functional Design Teams" in this Volume.

The remainder of this article presents an overview of the engineering design process. Though the process is extremely complex, distinct stages of design activities can be identified and described (Ref 3). The first stage is how marketing goals, often vague or subjective, are translated into quantitative, objective engineering requirements to guide the rest of the engineering design process.

Overview of the Design Process

John R. Dixon, University of Massachusetts (Professor Emeritus)

From Marketing Goals to Engineering Requirements

The goal of this first stage in the engineering design process is to translate a marketing idea into specific engineering terms. Accomplishing this translation involves an understanding and communication among marketing people, industrial designers, engineering designers, and customers.

Industrial Design. The industrial design process creates the first broadly functional description of a product together with its essential visual conception. Artistic renderings of proposed new products are made, and almost always physical models are developed. Models at this stage are usually very rough, nonfunctional ones showing only external form, color, and texture, though some also may have a few moving parts.

Though practices vary, it is strongly advised that industrial design be a cooperative effort of the industrial designers and engineers, as well as materials, manufacturing, and marketing people. Industrial designers consider marketing, aesthetics, company image, and style when creating a proposed size and shape for a product. Engineering designers, on the other hand, are concerned with how to get all the required functional parts into the limited size and shape proposed. Another issue requiring cooperation may be choosing materials for those parts that consumers can see or handle. Both design engineers and manufacturing engineers, of course, are concerned with how the product is to be made within the required cost and time constraints.

The phrase *product marketing concept* describes fairly well the results of industrial design. The product marketing concept includes all information about the product essential to its marketing. On the other hand, the design at this stage should contain as little information as possible about engineering design and manufacturing in order to allow as much freedom as possible to the engineering design phases that follow. Such a policy is called *least commitment,* and it is a good policy at all stages of product realization. The idea is to allow as much freedom as possible for downstream decisions so that engineers are free to develop the best possible solutions unconstrained by unnecessary commitments made at previous stages.

A least commitment policy, for example, means that materials should not be specified this early in the design process unless the material choice has clear marketing implications. This often happens for those parts of the product that customers see and handle.

The Engineering Design Specification. The engineering design specification, also called the product design specification (PDS) (Ref 4), is described in detail in the article "Conceptual and Configuration Design of Products and Assemblies" in this Volume. Though different products require different kinds of information in their specification,

essential categories are common to all. Regardless of how it is organized, an engineering specification in one way or another must contain information in two major categories:

- *In-use purposes* are related to the anticipated users and misusers (i.e., the customers) of the product including the primary intended purpose(s) to which users will put the product, any unintended purposes to which the product may be put (given that human beings behave the way they do), and any special features or secondary functions required or desired.
- *Functional requirements* are qualitative or quantitative goals and limits placed on product performance, the environmental and other conditions under which the product is to perform, physical attributes, process technologies, aesthetics, and business issues like time and cost.

Though the initial engineering design specification should be as complete and accurate as possible, it must also be recognized that a specification is never fully completed. Indeed, a specification is normally subjected to a certain amount of change throughout the design process. However, if changes cause significant redesign, they often can be very expensive and time consuming and affect the final product quality. Moreover maintaining the connection between engineering characteristics and customer requirements is crucial.

Engineering Stages

A design is information. As a product is designed, the information known and recorded about it increases and becomes more detailed. Though no formal theoretical foundation exists for identifying specific stages of design information content, some stages are intuitively obvious (Ref 3) and include:

- *Stage 1:* the product marketing concept
- *Stage 2:* the engineering (or physical) concept
- *Stage 3:* for parts, the configuration design
- *Stage 4:* the parametric design

The information contained in a product marketing concept is described in the section "From Marketing Goals to Engineering Requirements" in this article. The other stages are discussed in sections that follow.

Some references (e.g., Ref 5) expand the conceptual stage into two separate stages called conceptual and embodiment design and then include the configuration design of parts as a part of detail design.

Guided Iteration

For all of the stages of engineering design, that is, stages 2, 3, and 4 listed above, the problem solving methodology employed is called guided iteration (Ref 3). The steps in the guided iteration process, illustrated in Fig. 2, are formulation of the problem; generation of alternative solutions; evaluation of the alternatives; and if none is acceptable, redesign guided by the results of the evaluations. This methodology is fundamental to design processes. It is repeated hundreds or thousands of times during a product design. It is used again and again in recursive fashion for the conceptual stage to select materials and processes, to configure parts, and to assign numerical values to dimensions and tolerances (i.e., parametric design). See Fig. 3.

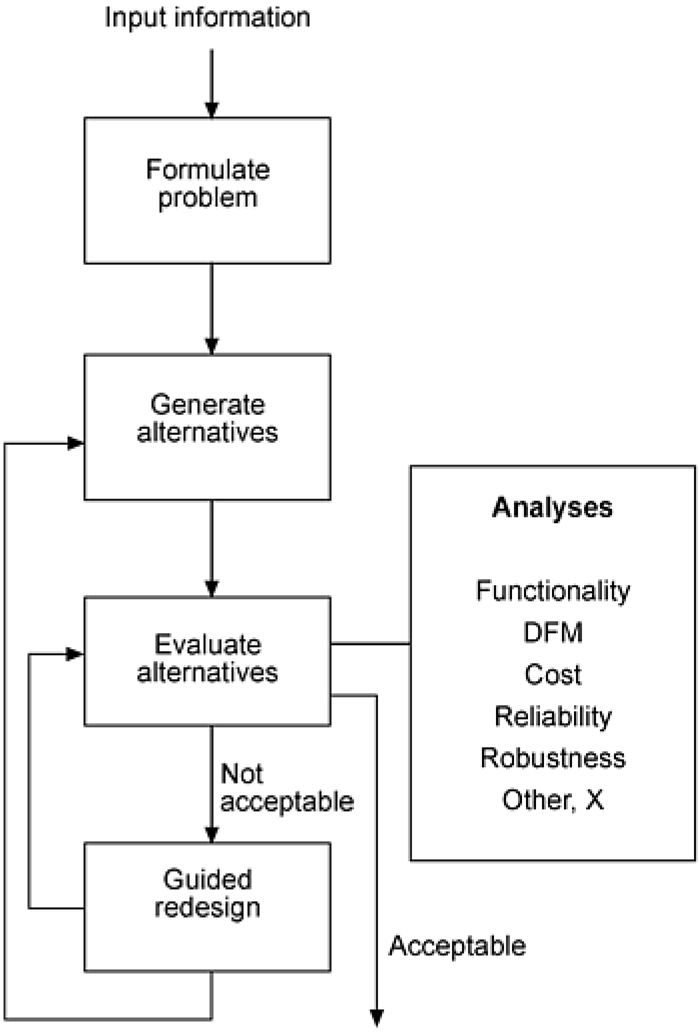

Fig. 2 Guided iteration methodology

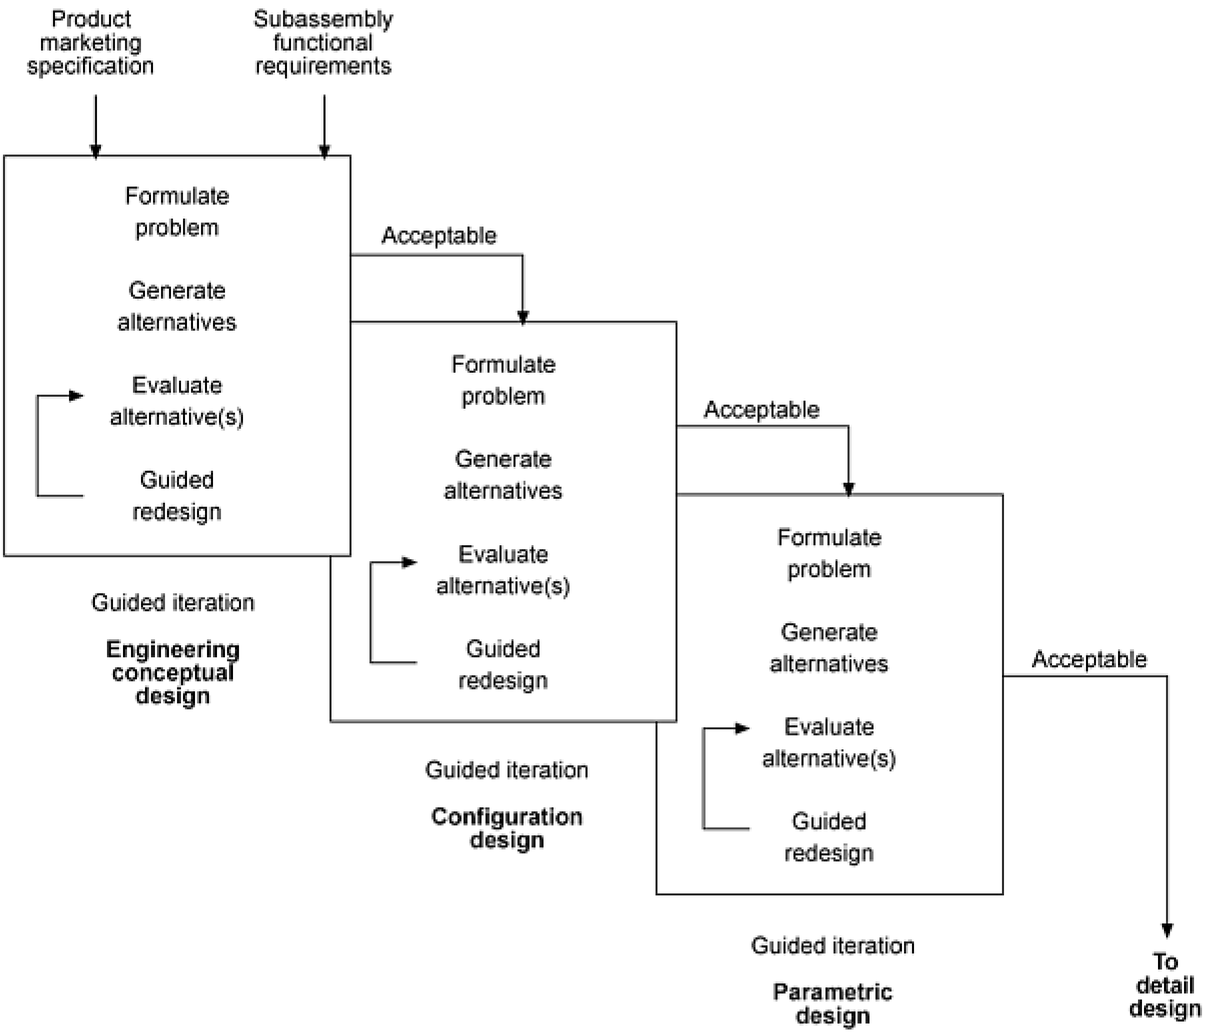

Fig. 3 Guided iteration used for conceptual, configuration, and parametric design

The action of a designer that adds to the information content of the design is a decision based on evaluation results. Some say, therefore, that design *is* decision making. This statement is true to some extent, but it does not illuminate how design decisions are made. They are made by guided iteration. That is, the additional information needed to advance the design is made explicit in a problem formulation. Alternative ways of providing that information are generated, and the alternatives are evaluated. Finally a decision is made about the acceptability of the alternatives. Thus decision making in design, repeated over and over again in all stages, is to accept, revise, or reject a proposed alternative.

It is important to note how critical the generation of alternatives and their evaluation is to the decision about acceptability. If an alternative has not been considered, it cannot be evaluated and accepted. If the evaluations performed are incorrect, careless, or have failed to consider all the issues, then a poor decision may be made. All the steps in guided iteration must be well done every time they are done in order to obtain the best possible design result.

Engineering Conceptual Design

With an engineering design specification prepared to the extent that is feasible, the next stage of design is to determine the physical concept by which the product will function. (Hopefully, the concept has not been dictated by the specification in violation of the least commitment policy.) The physical concept includes the physical principles by which the product will work and an abstract physical embodiment that will employ the principles to accomplish the desired functionality.

As a very simple example of the meaning of these terms, suppose the required function is simply to support a load over an open space. One physical principle derived from beam theory is that longitudinal tensile and compressive stresses within a bending member can support a transverse load. The physical embodiment that uses this effect is a long, slender member of uniform cross section; here it is called a beam. Note in this example how the physical principle is integral to the embodiment. If only purely tension or compression stresses were used to support the load, an embodiment called a truss, which employs only tension and compression, might have resulted. In other words, though there is not usually a unique embodiment for implementing a physical concept, a concept and its embodiment are inextricably linked.

When a product is more complex, it consists of an assembly of subassemblies and parts. Then the physical concept is not so simple as in the above examples, and the embodiment must identify a set of principal functional subassemblies. For example, for an automobile, the subassemblies identified might be the engine, drivetrain, frame, body, suspension system, and steering system. The physical principles by which a product will work are specified by including sufficient information in its embodiment about how each of these functional subassemblies will interact with all the others to accomplish the required product functions.

The term *decomposition* is generally used to describe the part of the design process that identifies the subassemblies comprising a product or larger assembly. That is, in the conceptual design of an automobile, it could be decomposed into the engine, drivetrain, frame, and so forth.

Decomposition can be performed in two ways. (a) It can be done first purely in terms of functions. Physical embodiments are selected to fulfill the functions. (b) Alternatively, it can be done directly in terms of physical embodiments with the functions remaining more or less implicit. Most design is done as in (b). However, there are very good reasons for proceeding as in (a), that is, in function-first fashion (Ref 5, 6). In the automobile, for example, the function of the engine is to convert a source of on-board energy to rotational mechanical power. This function need not be provided by the usual internal combustion engine; instead it could be provided by an electric motor, a turbine powered by compressed gas, human-powered pedals, and many other alternatives. In the case of an automobile, the available alternative sources of power are very familiar. In a new, less-familiar product, however, the advantage of function-first decomposition is that it stimulates designers to consider many ways of fulfilling a given function instead of choosing the most common embodiment that comes to mind.

For an initial embodiment, it is usually sufficient to perform only one level of functional or physical decomposition, but all subassemblies thus created will ultimately, as a part of their own conceptual design, be decomposed again and again. For example, a lawn mower engine may be decomposed into, among other things, an engine block and a carburetor. Then in turn, the carburetor may be decomposed into, among other things, a float and a cover. Thus the process of conceptual decomposition repeats (or recurs) until no new subassemblies are created, that is, until only parts or standard components are obtained. See Fig. 4.

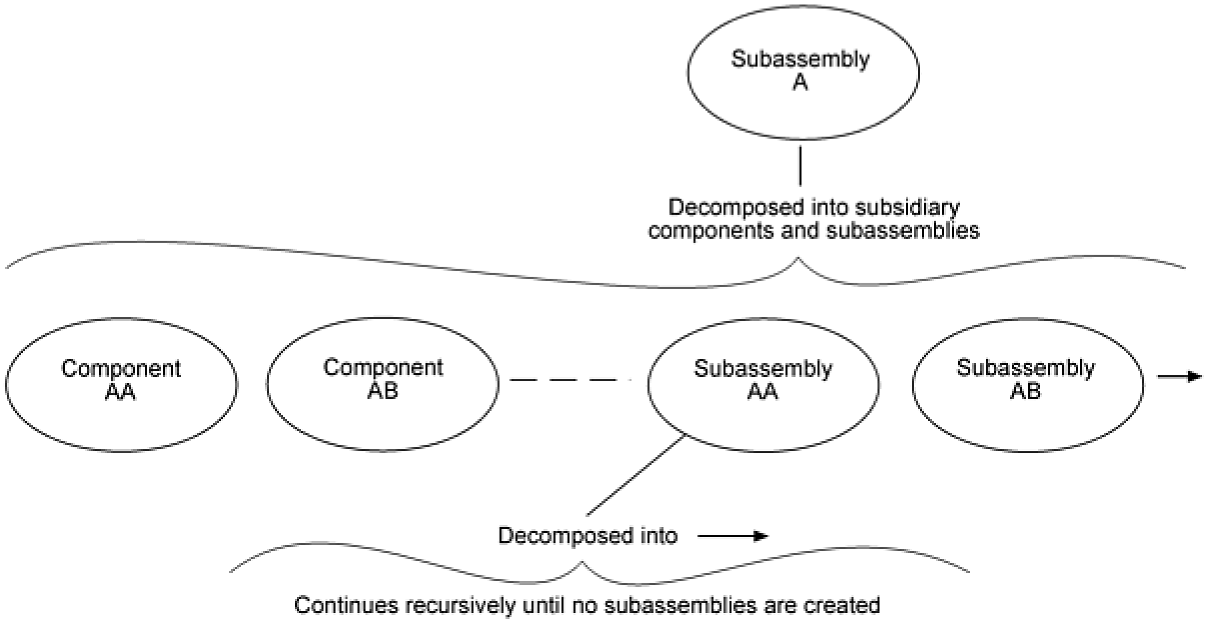

Fig. 4 Model of recursive decomposition

Generating Conceptual Design Alternatives. A large number of alternative physical concepts should be generated for evaluation in terms of the requirements because the selection of the best possible conceptual alternative is a crucial step in obtaining the best possible solution. Nonoptimal choices at this stage are extremely costly in time and money if they have to be corrected later. Unfortunately, there is a human tendency, strong in some designers and design organizations, to pass quickly through the engineering conceptual stage by considering only the one or two possible conceptual solutions that are most familiar to the people involved. This procedure very often ignores other possible solutions that may be superior; that is, ones that may be found by business competitors who are more thorough.

Evaluating Conceptual Design Alternatives. Evaluation of proposed conceptual designs is a crucial step. There is a significant difference between having a design and having the best competitive design (Ref 7). This distinction is often missed by people in marketing, management, and manufacturing.

Evaluation must be incisively and knowledgeably done, and all the issues must be considered as thoroughly as possible. Here again, the tendency in some firms is to perform only quick, subjective evaluations. Unfortunately, a common evaluation process used is, "I like this one best!" However, the design decision can be only as good as the evaluations performed, and good evaluation methods are available. See, for example, Ref 4.

Guided Redesign of Conceptual Alternatives. All of the methods available for comparison and evaluation of physical concepts indicate in general, qualitative terms which alternatives are best. In addition, and at least as important, the methods also illuminate the specific characteristics of proposed alternatives that are weak or strong. Thus evaluation directs the attention of designers to the changes or refinements that are needed to improve the alternatives. After such improvements are made, the alternatives can be reevaluated and then redesigned.

After evaluation and redesign, if none of the generated alternatives is acceptable, the search for new alternatives must be resumed. This search, too, can now be guided by the evaluation results. Thorough evaluation develops a great deal of useful information about the design. In particular, after evaluation, designers know why the alternatives generated so far are unacceptable, and thus they know why different principles, technologies, materials, or manufacturing processes are needed. Such knowledge is important in guiding the renewed search for concepts that will have a better chance of fulfilling the requirements of the engineering design specification.

It is important to appreciate that the engineering conceptual design process, from development of an engineering specification through generation of alternatives, evaluation of alternatives, to guided redesign, essentially must be repeated for each subassembly that is created as the product is decomposed and through as many levels of decomposition as needed to get to individual parts or standard components. Each subassembly has its own special functionality and

engineering requirements, which are not the same as those of the product as a whole. For large products, the complexity that results from all these design processes inside design processes, and so forth can be astounding. Keeping track of all the interactions is a monumental task, especially as changes are made that may propagate throughout the design. Thus clear, written documentation is essential throughout the process, and this documentation is particularly critical for effective and efficient teamwork.

Design of Assemblies Compared to Design for Assembly. Discussion so far has been about design of assemblies. Design for assembly (DFA) involves mainly the design of parts so that they can be handled easily and inserted properly into place during the assembly process; these concepts are addressed in the article "Design for Manufacture and Assembly" in this Volume. Design for assembly does involve some design of assembly issues, such as the paramount issue of designing for the minimum number of parts. Also, if the assembly is to be done automatically, assemblies should be designed so that all parts are insertable from a single direction.

There are, however, issues in design of assemblies that have little to do with design for assembly. One of these is called stack-up, meaning the way tolerances can add up in an assembly. (See the article "Dimensional Management and Tolerance Analysis" in this Volume.) Designers obviously must be aware of such issues: establishing tolerances requires attention to both functionality and manufacturability.

Overview of the Design Process

John R. Dixon, University of Massachusetts (Professor Emeritus)

The Configuration Design of Special-Purpose Parts

As described in the preceding section, the engineering conceptual design process decomposes a product into layers of nested subassemblies and ultimately into standard components and special-purpose parts. Often an enormous number of special parts have to be designed, manufactured, and assembled into a subassembly for final assembly into the product. This section contains a discussion of the first stage in the design of these parts: designing their configuration.

Is this Part Necessary? The starting place for designing a part is to try to eliminate the part. Readers are referred to Ref 8 by Boothroyd and Dewhurst for a relatively easy method for determining whether a proposed part is actually needed as a separate part. As pointed out above, one complex part is almost always less expensive overall than two or more simpler parts. However, this general rule may have exceptions and must be examined. The added complexity, for example, may delay production while the more complex tooling is being made (Ref 9).

If a part is necessary and a standard part can be used, then it is usually more economical to specify the standard part instead of designing and manufacturing a special-purpose part.

What is a Configuration? Ultimately, designers must determine exact numerical values for the dimensions and tolerances of parts, that is, perform parametric design. However, before this step can be done, parts are configured. A part configuration specifies the features of a part (see the bulleted list below) and their arrangement and connectivity, but the part configuration does not specify exact dimensions. The configuration can and should be evaluated as a configuration before its final dimensions and tolerances are established.

Features of parts include:

- *Walls* of various kinds (flat, curved, tapered, and so forth)
- *Add-ons* to walls, such as holes, bosses, notches, grooves, and ribs
- *Solid elements,* such as rods, cubes, tubes or spheres
- *Intersections* among the walls, add-ons, and solid elements

As with engineering conceptual design, designing a part configuration is done by guided iteration.

Formulating the Problem. Designing a part requires an engineering design specification for the part. The functions and other requirements for a part are not, in general, the same as those of the subassembly or product into which the part will be assembled. However, the engineering specification of a part will contain the same types of information as listed in the section "From Marketing Goals to Engineering Requirements" in this article.

Each part in a product is important to the whole, but each part also has a life (e.g., a functionality) of its own. Products and to some extent their subassemblies have a wide variety of unique functions, but there are only a relatively limited number of (mostly technical) functions for parts to perform. These include, for example, supporting forces, providing a barrier, providing a passage, providing a location, aiding manufacture, and adding strength or stiffness. Since reducing the number of parts is always an important goal, it is always helpful to combine as many such technical functions as possible into a single part.

The Configuration Requirements Sketch. Designing a part can be done only by sketching, whether on paper or in a CAD system. To begin, a designer must know the interactions that the part has with other parts and subassemblies. These interactions include forces (loads and available support areas), energy or material flows, and physical matings or other spatial requirements (e.g., certain spaces may be unavailable to the part). A sketch that shows these interactions to approximate scale is a very helpful starting place and is called a configuration requirement sketch.

Generating Alternative Configuration Solutions. There may be dozens or even hundreds of possible part configurations. Often too many exist to consider generating all the possible ones for evaluation. Thus the generation of alternatives must be limited by qualitative physical reasoning and by reasoning about manufacturability.

Qualitative essentially means reasoning without numbers though orders of magnitude of numbers are certainly involved. Thus qualitative reasoning fits configuration design evaluation well because configurations are themselves largely without numbers. Nevertheless, even without numbers, the basis of qualitative reasoning is still rooted in fundamental physical principles. Qualitative reasoning is far more objective and useful than guesses or feelings. It can be used to generate configurations that, once dimensions are added, will make efficient use of materials, avoid common failure modes, promote or restrict heat transfer, and so forth.

It should be remembered that, though designers are ultimately responsible for decisions made during design, others are available for input all along the way. This is one advantage of cross-functional teams, and experts and consultants from outside the team also can be called in.

Materials at the Configuration Stage. At this point in the part design process, it is necessary to decide upon a manufacturing process and at least a class of materials (e.g., aluminum, thermoplastic, steel). However, unless the information is needed for evaluation of the configurations, selection of the exact material (e.g., the particular aluminum alloy or thermoplastic) should be postponed consistent with least commitment until the parametric stage. Consultation with materials and manufacturing experts is, of course, strongly advised. It should also be remembered that some material choices have marketing implications as well. Other factors, such as recycling concerns and existing business relationships, also may be relevant.

Evaluating Design for Manufacturability at the Part Configuration Stage. In addition to qualitative physical reasoning about functionality, effective part configurations are strongly influenced by manufacturing issues. In stamping, injection molding, and die casting, for example, the part configuration is strongly related to die costs (Ref 3).

Design for manufacturability guidelines is determined by the physical nature of the manufacturing process involved. Descriptions of a number of manufacturing processes are presented in the Section "Manufacturing Aspects of Design" in this Volume. For assembly, also see especially Ref 1 and 8.

In considering DFM guidelines, designers should remember that reducing part count is an overriding concern. Thus complications that reduce part count are generally preferable to simplified designs with more parts. Of course, when part count is minimum, then making parts easy to manufacture is desirable.

Redesigning. The evaluations for functionality (including material use) and for DFM will guide the redesign of prospective configurations.

Tolerances at the Configuration Stage. Determining tolerances of part designs so that the parts will both function well and be manufacturable also has important implications at the configuration stage. Increasing the number and tightness of specified tolerances causes a corresponding increase in the cost and difficulty of manufacturing.

Overview of the Design Process

John R. Dixon, University of Massachusetts (Professor Emeritus)

Methods for Parametric Design

Evaluations of concepts and configurations are based primarily on qualitative reasoning about physical principles and manufacturing processes. In parametric design, however, numerical computations become much more important. The attributes of parts identified at the configuration stage become the design variables for parametric design, and their values must now be determined. These values are mostly, though not exclusively, numerical. Relative processing costs (as distinguished from tooling costs) are sensitive to the exact values assigned so that relative processing costs must now be considered along with functionality as a part of parametric design (Ref 3).

Most parametric design methods can be applied to special-purpose parts and to standard parts and standard assemblies. A number of powerful methods are available for the parametric design of components and small assemblies, including guided iteration, optimization (see the article "Design Optimization" in this Volume), and statistical methods (see the articles "Statistical Aspects of Design" and "Robust Design" in this Volume).

Tolerances at the Parametric Stage of Design. At the configuration stage, the concern is with reducing the relative tightness and number of tolerances that must be assigned to obtain the required functionality. At the parametric stage, actual tolerance values are assigned. Not only do the values strongly influence functionality, they also have a strong influence on processing costs.

Why Methods for Parametric Design Are Needed. At the parametric design stage, the tendency in practice is to avoid the use of formal methods. Experienced designers tend to rely on experience and what has worked previously. If experience has resulted in general knowledge and understanding that can be applied in new situations and it works, then that is fine. However, the slow adaptation of Taguchi's approach (Ref 10, 11) (or some method) of robust design by United States industry was an important factor enabling foreign competitors to design and produce reliable products that captured a number of important markets (see the article "Robust Design" in this Volume). The lesson is that experience that merely works does not necessarily work well enough to beat competitors who are continually learning new and better methods.

Of course, some dimensions are determined exactly by manufacturing considerations, space or weight concerns, and other such limits.

Guided Iteration for Parametric Design of Components. As with engineering conceptual and configuration design, parametric design problems for components can be solved by the general method of guided iteration. The specific methods used to implement these steps in parametric design are different from the methods used in conceptual and configuration design.

Problem formulation in parametric design requires identification of the design variables, including their range of allowed values; identification of the performance parameters whose values will be computed or measured to evaluate the performance of trial designs; the performance criteria to be included in the evaluation; and the analysis methods that will be used to compute values for the evaluation parameters.

Generation of alternatives in parametric design requires selecting an initial design, that is, an initial set of values for the design variables. Consideration of DFM issues may guide or limit these values.

Evaluation in parametric design requires computation of the values for the performance parameters as well as selection and implementation of a method for evaluating the overall quality of the trial design. Since multiple evaluation criteria usually exist, this step requires considering how to obtain an overall evaluation from the separate evaluations of each criterion.

Redesign in parametric requires that new values be selected for the design variables so that a new trial design can be evaluated. Obtaining the new values is guided by the evaluations of the preceding trial or trials.

Reference 3 discusses this subject in detail for interested readers.

Optimization Methods for Parametric Design. Optimization is a well-developed field of study that is the subject of entire courses and books. Excellent texts and reference books on optimization are available for use by designers; an example is Ref 12. The more technically advanced manufacturing firms will likely have optimization experts with which designers and design teams can consult. Computer programs are also available, for example, the optimization software programs Optdes and OptdesX (trademarks of Design Synthesis, Inc., East Provo, UT).

Though there are exceptions, in general, optimization methods are useful when the following conditions are met. The design variables are all numeric and continuous. In this case, optimization methods are likely to be effective and efficient. If not, optimization can still possibly be used, but some adaptations will be required. A single function (called the "criterion function" or "objective function") can be written in terms of the design variables that express the overall quality or goodness of a trial design. Often this single function is cost, though in some cases it can be weight, efficiency, robustness, or some other performance factor.

Suboptimization. In complex, realistic parametric design problems, an appropriate criterion function often cannot be readily formulated to meet the conditions required by optimization techniques. Nevertheless, sometimes certain subparts of problems can be solved by optimization. This is called suboptimization.

Suboptimization can be effective and helpful with a stipulation. One cannot in general optimize a whole problem solution by dividing it up into subproblems, each of which is suboptimized separately. Suboptimization of all the subparts of a system does not in general lead to optimization of the whole system. The degree to which the subsystems are coupled is the degree to which suboptimization is suboptimal. Still, suboptimization can be advantageous in situations where any adverse effect from a suboptimized section on the whole system is negligible or acceptable.

Statistically Based and Taguchi Approaches for Parametric Design. Methods from the field of statistics and design of experiments (Ref 13, 14) also can be used to assist performing parametric design in some cases. Only the so-called Taguchi approach (Ref 10, 11) is introduced here because it is fairly easily applied and because its use is now fairly common. Moreover, it has a good record of successful application.

Robustness. The overall evaluation criterion in Taguchi's techniques is called robustness. Robustness refers to how consistently a component or product performs under variable conditions in its environment and as it wears during its lifetime. The variable conditions under which a product must function may include, for example, a range of temperatures, humidity, or input conditions (e.g., voltages, flow rates). Robustness also refers to the degree that the performance of a product is immune to normal variations in manufacture, that is, to variations in materials and processing.

Noise Factors. The terms noise or noise factors are commonly used for the uncontrollable variable conditions of environment, wear, and manufacture. Thus another way to describe robustness is to say that it is the degree to which the performance of a product is insensitive to noise factors.

Control Factors. Noise factors, which the designer cannot control, are not to be confused with the design variables, whose values the designer can control. Design variables are called control factors in the Taguchi approaches. Though designers have no control over the noise factors, the ranges over which noise factors vary are usually reasonably predictable.

Strategies to Achieve Robustness. To achieve robustness in the face of the environmental and other noise factors, two different strategies may be followed. One strategy is to design the product so that the performance of sensitive parts is insulated from the noise conditions (e.g., provide thermal or vibration insulation). Alternatively, steps might be taken to remove or reduce the source of a noise (e.g., eliminate the cause of temperature variations or the source of vibrations). Both insulating the part or product from the noise and eliminating the source of the noise are called "reduce the noise" strategies.

A second design strategy is to accept the noise but reduce its consequences. In this approach, the product is designed so that its lifetime performance is as insensitive to the noises as possible. For example, instead of thermally insulating the part or parts whose performance is sensitive to temperature, those parts can be designed so their performance is not significantly impaired by the expected temperature variations.

Often, of course, both "reduce the noise" and "reduce the consequences" strategies may be used simultaneously, but reducing the noise is usually a considerably more expensive solution.

Taguchi techniques have a built-in trade-off methodology for selecting the set of control factors that results in the best combination of performance and robustness given the conditions of noise in manufacturing and use. The methodology maximizes the signal-to-noise ratio. Though it is a reasonable criterion, designers using the Taguchi methods have no control over it. Nevertheless, the Taguchi techniques have a very good track record for producing excellent overall results.

A disadvantage of the Taguchi method is that only a few values of the design variables over a limited range can be considered. Another disadvantage is that in many cases, experimentation is required to obtain the performance results. When the cost and time required for experimentation are large, the disadvantage is obvious. Where analysis and/or simulation can be used instead of experimentation, they usually will be both quicker and less expensive. Moreover, the use of statistical methods and proper design of experiments can, in most cases, make experimentation more efficient, and these methods can be applied to analytical models and numerical simulations as well as to hardware.

Using the Taguchi approach is not the only statistical approach to achieving robust designs that also perform well (Ref 13, 14). Robustness (that is, variability of performance) often can be included when using guided iteration and optimization for parametric design.

Additional information about the Taguchi methods is provided in the article "Robust Design" in this Volume.

Best Practices of Product Realization

This section very briefly describes a number of the practices, called best practices, used by successful firms to achieve the goals of quality, cost, time-to-market, and marketing flexibility (Ref 15).

Traditionally, cost was considered of paramount importance, and no one would argue that cost is unimportant. However, in the 1980s, quality, defined very broadly, became equally or possibly more important. Unfortunately, in many firms, quality was rather narrowly viewed as exclusively related to manufacturing or production instead of to design and the rest of the product realization process. This limited view results in a serious error because it ignores the fact that many factors determining quality are largely decided in the design stages, especially the early design stages. For a good discussion of quality issues, see Ref 16.

What Business Are You Really In? In some (especially older) manufacturing firms, a strong cultural bent exists toward the belief that the business of the firm is to manufacture things, specifically the things that constitute their current product or product line. However, the business of such a firm is not really a particular product or product line. Rather, their business is the service that these products perform for customers. For example, the business of a company manufacturing pencils is not making pencils; it is providing the service that pencils provide their users. That is, the business of such a firm is to provide the service that enables people to record their thoughts and other information onto hard copy.

A firm manufacturing pencils may never decide to manufacture ballpoint pens, word processors, or speech recognition systems, but at least viewing their business as a service provider reveals who their competitors are (not just other pencil manufacturers) and who they may be in the future. It also gives the firm an incentive for inventing the next popular thought-recording product, even if it is only a better pencil. Thus manufacturing firms should determine and become conscious of what service their products perform for customers, and what the customer values about that service and the way it is provided.

Sources of New Ideas. There are four primary sources of ideas for new or revised products in firms: customers, employees, benchmarking, and new technology.

Competitive manufacturing businesses require constant feedback from the customers who buy, sell, repair, or use the products of the company. If a design engineer is looking for positive new ideas as well as for shortcomings of current products, then he or she must get out personally and talk to the customers throughout the design process, and after. Design engineer communication with customers through field trials, field observations, focus groups, and interviews is important to excellent design results.

Employees in the factory, shops, and offices are also an extremely valuable source of new ideas for products and product improvements. Good practice requires that there must be a believable, financially rewarding, well understood, and low threshold (easy to use) mechanism for employees to get their new product, product improvement, and process improvement ideas heard and seriously considered.

Benchmarking (Ref 17, 18) also stimulates engineers and others in a firm to see and discover new product ideas and new ways of viewing both design and manufacturing. Benchmarking can emcompass studies of both competitor and noncompetitor products and processes.

Keeping abreast of new technologies and methodologies in materials, manufacturing, design, engineering, and management is another important source of ideas for new and improved products. Coupling new technological information with the search for new or improved product ideas is an essential part of the product development process that is not, strictly speaking, engineering design defined here, but it is important if engineering designers are to produce the best possible products for a company.

Cross-Functional Teams. It would be difficult to overstate the importance of cross-functional teams and teamwork to the implementation of effective, modern design practices and methods. The close cooperation of different disciplines is especially important to realizing the benefits of DFA and DFM and to ensuring that designs are consistent with marketing and business considerations. In this Volume, the topic of cross-functional teams is discussed in detail in the article "Cross-Functional Design Teams." It is also covered in Ref 19.

Focus on Quality. The most competitive companies recognize that quality is crucial to competitiveness and that quality cannot be built into or inspected into a product unless it is first designed into a product. Time-to-market is also recognized as a critical factor in profitability, and development times can be significantly shortened through appropriate management and engineering design approaches (e.g., concurrent design and design for manufacturing). See the article "Concurrent Engineering" in this Volume. Finally, competitive firms know that quality, time-to-market, and cost are all interrelated. None should be sacrificed for the other.

The most competitive firms tend to have established metrics (i.e., measurements) that indicate their performance regarding quality, cost, and time-to-market. One way to help establish such metrics is through competitive benchmarking. See Ref 17 and 18.

Competitive benchmarking involves a detailed look at the products and processes (both design and manufacturing processes) of the very best competitors of a company. Competing products can be purchased, taken apart, and analyzed for cost, performance, and manufacturability. Out of this process, metrics can be established for the products and processes of a company, and performance can be measured against these metrics.

Concurrent Engineering, Design for X (DFX), and Design for Manufacturing (DFM). Concurrent design attempts to organize the product realization process so as to have as much information and knowledge available about all the issues in the life of a product at all stages of the design process. This is also referred to as design for X, where X stands for the customer, robustness, manufacturing (including tooling, assembly, processing), environment, safety, reliability, inspectability, maintenance and service, shipping, disposability, and all the other issues in the life cycle of the designed object and its production (Ref 2).

Design for the Customer. Quality function deployment (QFD) (Ref 20) is a method for deriving the desired engineering characteristics of a product from customer input or of transforming customer inputs into engineering requirements. A technique for implementing QFD, called the house of quality (Ref 20), is generally used to perform the product or design evaluation and to guide the redesign for improved customer satisfaction.

DFA and DFM. The importance of DFA and DFM to product realization has already been indicated. However, lip service to DFA and DFM is not sufficient. There is much to know about both of them, and the firm has to acquire and apply that knowledge to their processes.

Design for Robustness. As with DFA and DFM, design for robustness requires more than lip service. The knowledge of what it is and how to do it actually must be brought into a firm and used if its benefits on product quality are to be realized.

Physical Prototyping Policies. Reducing the number of planned prototypes (e.g., from three to two) will save a great deal of time (Ref 21) because design engineers, who know ideas will get tested in prototypes, are prone to take risks in their initial designs. But the product realization process is not the time to take risks. Risky ideas should be developed and tested in the laboratory before they are incorporated into product development programs.

Strategic Use of Computational Prototyping and Simulations. Modern computational methods employing computers make it possible to reduce or even eliminate more expensive and more time-consuming physical prototyping. Computer-aided design, solid modeling, finite element methods, and many kinds of simulation programs are used by best practice firms to improve quality and reduce design and development time. See the articles "Computer-Aided Design" and "Rapid Prototyping" in this Volume.

Exacting Control of Processes. The previous idea of quality assurance was to inspect parts and assemblies after they had been produced. The new best practice is to control processes so rigorously that inspection is unnecessary. Methods of statistical process control (SPC) have been developed for this purpose and are in widespread use (Ref 22).

Intimate Involvement of Vendors. Dozens, hundreds, or even thousands of vendors may be involved in the manufacture of certain products and machines. Previous practice was to prepare specifications that vendors must meet with their products and that were used to obtain competitive bids from a number of competing vendors. The present practice is to employ only one or two vendors and to involve them in the product design, especially as it relates to the parts and subassemblies to be supplied by the vendor.

Conceptual and Configuration Design of Products and Assemblies

Kevin N. Otto, Massachusetts Institute of Technology; Kristin L. Wood, The University of Texas

Introduction

COMPETITIVE DESIGN of new products is the key capability that companies must master to remain in business. It requires more than good engineering, it is fraught with risks and opportunities, and it requires effective judgment about technology, the market, and time. Several recent business decisions give insight to these claims:

- To avoid losing market share, all U.S. commercial airplane manufacturers have offered contracts to deliver aircraft at prices that are below current cost (Ref 1). The companies are betting that they can remain profitable through improvement of their products and processes.
- In the early 1980s, Sony offered an improved magnetic videotape recording technology, the Betamax system. Although it offered better magnetic media performance, it did not satisfy customers, who rather were more concerned with low cost, large selection of entertainment, and standardization.
- In 1996, both Ford and Toyota launched new family sedans. Three years earlier, each had torn apart and thoroughly analyzed each other's cars. Ford decided to increase the options in its Taurus, matching Toyota's earlier Camry, while Toyota decided to decrease the options in its Camry, matching Ford's earlier Taurus.

There is clearly a need to apply statistically sound methods to evaluating the intended customer population for a product. It is equally important to design into the product what is required to meet customer demands, applying rigorous methods for incorporating the best technologies.

This article describes an integrated set of structured methods (Fig. 1) that were developed to address these needs. The methods start with identifying the customer population for the product and developing a representation of the feature demands of this group. Based on this representation, a functional architecture is established for the new product, defining what it must do. The next step is to identify competitive products and analyze how they perform as they do. This competitive benchmarking is then used to create a customer-driven specification for the product, through a process known as quality function deployment. From this specification, different technologies and components can be systematically explored and selected through functional models. With a preliminary concept selected, the functional model can be refined into a physically based parametric model that can be optimized to establish geometric and physical targets. This model may then be detailed and established as the alpha prototype of a new product.

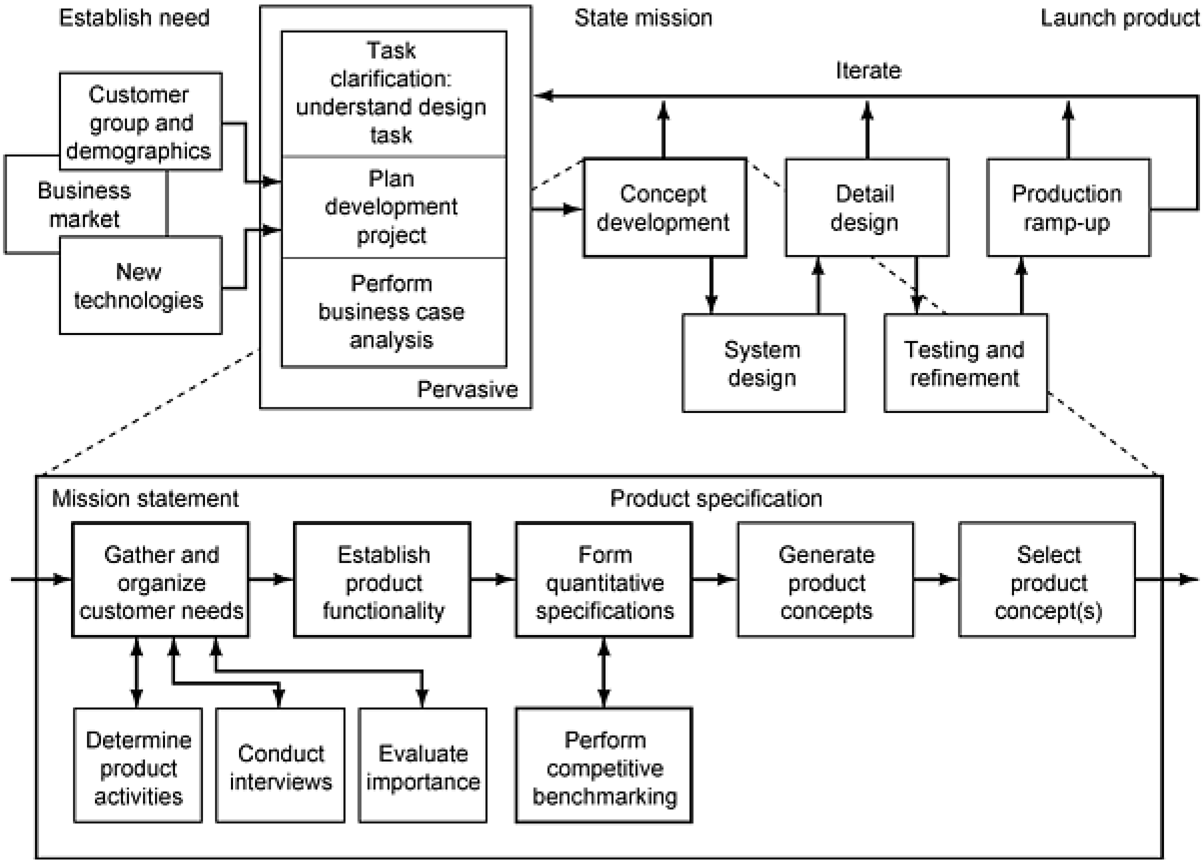

Fig. 1 The concept and configuration development process. "Pervasive" activities occur throughout product development.

Conceptual and Configuration Design of Products and Assemblies

Kevin N. Otto, Massachusetts Institute of Technology; Kristin L. Wood, The University of Texas

Task Clarification

Conceptual and configuration design of products, as depicted in Fig. 1, begins and ends with customers, emphasizing quality processes and artifacts throughout. Intertwined with the focus on customers and quality are a number of technical and business concerns. We thus initiate the conceptual design process with task clarification: understanding the design task and mission, questioning the design efforts and organization, and investigating the business and technological market. Task clarification sets the foundation for solving a design task, where the foundation is continually revisited to find weak points and to seek structural integrity of a design team approach. It occurs not only at the beginning of the process, but throughout.

Mission Statement and Technical Questioning

A mission statement and technical clarification of the task are important first steps in the conceptual design process. They are intended to:

- Focus design efforts
- Define goals
- Define timelines for task completion
- Provide guidelines for the design process, to prevent conflicts within the design team and concurrent engineering organization

The first step in task clarification is usually to gather additional information. The following questions need to be answered, not once but continually through the life cycle of the design process (Ref 2):

- What is the problem really about?
- What implicit expectations and desires are involved?
- Are the stated customer needs, functional requirements, and constraints truly appropriate?
- What avenues are open for creative design?
- What avenues are limited or not open for creative design? Are there limitations on scope?
- What characteristics/properties must the product have?
- What characteristics/properties must the product not have?
- What aspects of the design task can and should be quantified?
- Do any biases exist in the chosen task statement or terminology? Has the design task been posed at the appropriate level of abstraction?
- What are the technical and technological conflicts inherent in the design task?

It is surprising how often a great deal of time (and money) are wasted because no one took time at the front end of a project to really understand the problem. To obtain this understanding, the design of any product or service must begin with a complete understanding of the customers' needs, as discussed in the section "Understanding and Satisfying the Customer" in this article.

The tangible result of technical questioning is a clear statement of the design team's mission. Following is a sample template for a mission statement (Ref 3):

Product description	**One concise and focused sentence**
Key business or humanitarian goals	Schedule
	Gross margin/profit or break-even point
	Market share
	Advancement of human needs
Primary market	Brief phrase of market sector/group
Secondary market	List of secondary markets, currently or perceived

Assumptions	Key assumptions or uncontrolled factors, to be confirmed by customer(s)
Stakeholders	One- to five-word statements of customer sets
Avenues for creative design	Identify key areas for innovation
Scope limitations	List of limitations that will reign back the design team from "solving the world"

The mission statement should not be used as a mere statement of "parenthood." Instead it should be used as a "passport," "calling card," and "banner," stating the design team's intentions. When interviewing customers, meeting with potential suppliers, or carrying out design reviews, members of the design team should make the mission statement the lead item of discussion.

Business Case Analysis: Understanding the Financial Market

Technical questioning is only one side of the proverbial design coin. Understanding the business market represents the other side, especially to complete the mission statement. During any conceptual and configuration design effort, a product's market must be clarified through the development of a business case analysis. A number of financial assessment techniques exist at varying levels of detail. Two notable generic techniques are the "Economics of Product Development Projects" (Ref 3) and the Harvard business case method (Ref 4, 5, 6). This section explains how the Harvard business case method can be used to understand the potential impact of product development. A summary is shown in Table 1. Application of the methodology is described below for a simple mechanical product: a fingernail clipper.

Table 1 Summary of the Harvard business case method

Process step	Description
1. Problem statement	What market problem are you addressing, fixing, improving, making more efficient, etc.? This should be limited to one sentence, two at the most. Only one problem can be addressed. If the problem is complex, with many interrelated subproblems, the problem should be clarified and refined to the basic (atomic) or kernel problems.
2. Assumptions	Discuss any limiting assumptions made in preparing the business case proposal, such as product costs, direction of the industry/department, etc. This step provides a clear statement of the scope of work.
3. Major factors	List, briefly, major factors of the environment that affect the decision. This may be the state of the business (capital constraint), critical business needs or directions (strategies), etc.
4. Minor factors	List, briefly, factors that should be considered, but that do not seem to have a significant effect on the problem
5. Alternatives	List concrete or hypothesized alternatives (minimum of three) to address the problem or opportunity defined by the problem statement, assumptions, and major factors. Two or three sentences should be sufficient. Under each alternative list the advantages and disadvantages of each.
6. Discussion of alternatives	Review each of the alternatives with respect to the stated problem, assumptions, major and minor factors. Compare alternatives and discuss the relative merits of each (in terms of cost savings/avoidance, cycle time reduction, increase in quality, and head count reduction). From this discussion, a clear leader among the alternatives (i.e., the most feasible alternative) should be identified.

7. Recommendation	State your recommendation. There should be no need to defend it; this should have been covered in the last section. If needed, elaborate on the recommendation to add clarity.
8. Implementation	Describe the implementation plan. Include resource requirements: financial, human, space, etc. Describe the time frame requirements, controls, and measurements that will be needed to ensure that goals are met. Measurements should be tied directly to solving the problem, and adequate tracking mechanisms should be used to quantify the success of the project. Contingency plans should be developed that address any high-risk aspects of the solution.

Fingernail clippers are widely used by several markets: consumers (the primary market), professional salons, and domestic pet manicurists. Assume that a company seeks to improve its current product offering for the consumer market, in order to increase its market share in a complementary product line, fingernail polish. The mission is to design a fingernail clipper for comfortable use by either the left or right hand. It is assumed that comfort, low cost, reliability (consistently remove nails with a simple finger force throughout the product's life), and storage compactness are the driving market needs (to be confirmed or revised through customer interviews). The corporation also seeks only a 30% gross margin, since the goal is to increase the market share of fingernail polish.

A number of solutions exist for addressing both the technical and process issues associated with a fingernail clipper product development. A business case may be derived for each of the possible solutions. However, the intent during the early stages of conceptual and configuration design is not to study all possible alternatives in detail, but rather to determine whether a minimal benefit to the business will be realized by improving the clipper (i.e., comfort, cost, reliability, and compactness). As such, this example concentrates on steps 5 and 6 of the Harvard business case method (Table 1), where only one generic alternative is considered. A device solution (i.e., a new, generic, hypothetical clipper design) is the alternative considered, emphasizing the possibilities of reduced cost and higher reliability through compactness and fewer components.

These possible benefits call for a "break-even" financial analysis for the clipper problem. This analysis answers the question: "Is the hypothetical clipper with less material (compactness) and fewer components feasible as a business venture?" It begins with a summary of the current costs for fingernail clipper development (Table 2), as projected from the current product. Because these costs continually change with new technology and market forces, the actual costs have been multiplied by a random factor. The important issue is the cost of the current clipper operation relative to the cost of the hypothesized solution. The cost projections are based on 750,000 clippers, with a product distribution of 80% small clippers, for fingernails, and 20% large clippers, for toenails. The average cost for this distribution is $0.31 per product for fabrication, $0.17 for labor, and $0.23 for engineering time.

Table 2 Current costs scenario (fingernail clipper example)

Category	Projected cost, $	Cost per product, $/clipper
Labor costs		
Small clipper		
Assembly	60,000	0.10
Handling	36,000	0.06
Large clipper		
Assembly	16,500	0.11

Handling	10,500	0.07
Total	**123,000**	**0.17**
Fabrication costs		
Small clipper		
Materials	96,000	0.16
Piece-parts	72,000	0.12
Tooling	6,000	0.01
Large clipper		
Materials	30,000	0.20
Piece-parts	21,000	0.14
Tooling	4,500	0.03
Total	**229,500**	**0.31**
Subtotal (ongoing costs)	**352,500**	. . .
Engineering costs		
Total	**173,600**	**0.23**
Total costs	**526,100**	**0.71**

For the purpose of comparison, the adopted concept for this analysis is a "generic," hypothesized clipper with reduced parts. It is assumed that suitable component and fabrication technology exists for this concept. Such a device would require fewer materials and components and less assembly and labor, but tool costs would potentially increase due to higher precision in the cutter alignment. Based on this new concept, Table 3 lists the expected costs for 750,000 products (same distribution of small and large clippers), again multiplied by a random factor). One-time development (engineering) costs account for $187,000 (increase in tooling design), and projected ongoing fabrication and engineering costs account for $231,000 ($154,500 fabrication plus $76,500 labor), compared with current product ongoing costs of $352,500.

Table 3 Proposed costs scenario (fingernail clipper example)

Category	Projected cost, $	Cost per product, $/clipper
Labor costs		
Small clipper		
Assembly	30,000	0.05
Handling	30,000	0.05
Large clipper		
Assembly	9,000	0.06
Handling	7,500	0.05
Total	**76,500**	. . .
Fabrication costs		
Small clipper		
Materials	66,000	0.11
Piece-parts	24,000	0.04
Tooling	24,000	0.04
Large clipper		
Materials	21,000	0.14
Piece-parts	9,000	0.06
Tooling	10,500	0.07
Total	**154,500**	. . .
Subtotal (ongoing costs)	**231,000**	. . .

Engineering costs		
Total	**187,000**	**0.25**
Total costs	**418,000**	. . .

It is then necessary to compare the current and proposed costs, to determine the payback period and cost savings. Table 4 shows the results of this break-even analysis. The payback period is 6 months, with a potential savings of $121,500 for 750,000 products. These results are extremely encouraging. Significant cycle time and cost savings may be achieved for the business if a suitable fingernail clipper concept can be developed. Because of these potential savings, the project should be carried to the next stage: conceptual design and prototype.

Table 4 Break-even cost analysis (fingernail clipper example)

Issue	Analysis result
Estimated payback period for development costs	6 months
Projected savings for first 100,000 products	$16,200
Projected cost savings for next 650,000 products	$105,300
Expected average cycle time savings for each 100,000 product lot	38% of current work days

Implications. While only a subset of the Harvard business case method is illustrated above, the potential impact is impressive. A "go/no-go" decision may be made early in the product development process, provided that financial information exists for the current market and projected costs can be readily assumed for hypothesized concepts. Such decisions should be made in parallel with technical and industrial design clarifications. Also, they should continually be reviewed and updated as new information becomes available, especially as concrete product configurations are derived.

A critical aspect of the Harvard business case method is that cost data are needed in order to predict a product's potential return on investment of a product. If an entirely new product or family of products is under development, cost data may not exist. The Harvard business case method can still be applied if data can be obtained from a similar or analogous product, or from very rough estimates of preliminary product layouts.

Understanding and Satisfying the Customer

Having clarified the business opportunity, a firm should determine whether there is actual demand for a new or revised product. Too many technology development initiatives are undertaken with no basis for market acceptance other than management belief. The "technologist's problem" (the belief that if the developer thinks the technology is valuable, everyone else should also) is unfortunately very common in the engineering community. Akia Morita, founder of Sony Corporation, once boasted that, "Our plan is to lead the public to new products rather than ask them what they want. The public does not know what is possible, we do" (Ref 7). One result is products such as the Betamax. While the technology-push approach can and does sometimes work, it is also clear that considering the customer's desires will pull product development into better directions and amplify success.

It is important to recognize that "the customer" is only a statistical concept. There are countless potential buyers. Several tasks, discussed below, must be completed in order to develop a statistically valid customer needs list.

Gathering Customer Need Data

Reference 8 is an excellent management science reference on customer requirements. Reference 9 provides a total quality management perspective.

Some of the techniques for constructing a list of customer needs include using the product, circulating questionnaires, holding focus group discussions, and conducting interviews.

Using the Product. The design teams goes to the locations where their or their competitor's product is used, and they use the product as the customer would. If customer tasks can be easily understood and undertaken by the design team, and the design team is small, then this approach is effective. It is costly, though, for projects with either large design teams or highly skilled customer tasks that require training. Further, it does not address the need to document customer needs.

Questionnaires. The design team makes a list of criteria that they consider relevant to customers' concerns, and customers rank the product on these criteria. Alternatively, the design team forms a list of questions for customers to answer. The problem is that what the design team considers most important is not necessarily what customers consider most important.

Focus Groups. In a focus group discussion, a moderator facilitates a session with a group of customers who examine, use, and discuss the product. Usually this is done in the design team's environment, typically in a room with a two-way mirror so that the design team can observe the customers during the session. This session can be video- or audiotaped for later examination.

Interviews. Sometimes a design team asks an interviewer to discuss the product with a single customer, typically in the environment where the product is used by the customer. Again, the interview can be video- or audiotaped for later examination.

Griffin and Hauser (Ref 10) found that interviews are the most effective technique for uncovering information per amount of effort. They also report that for consumer product design projects, properly interviewing nine customers for one hour each uncovers over 90% of customer needs. Assuming a homogeneous market, interviews beyond the ninth subject tend to uncover very few new customer needs.

Using an interview sheet with canned questions does not work well for eliciting customer needs. It is much better to state nothing other than the single request, "Walk me through a typical session using the product." Typically the interview starts with the customer approaching the product in storage, before even using it. Where is it stored? What must the customer do to obtain it from storage and prepare it for use? How is it unpacked from the box and assembled? Ideally, when the customer does any motion or thought processing at all, the customer should describe it to the interviewer. This

should be continued through the product use, followed by cleanup and re-storage. Here are some useful questions for prompting conversation during silent moments (Ref 3):

- What do you like or dislike about this product?
- What issues do you consider when purchasing this product?
- What improvements would you make to this product?

If a company is contemplating the development of a new product (e.g., a new technology with no existing products on the market), the above questions work well as a starting point. Because the customer cannot walk through the use of an actual product, an analogous device should be used, even a blob of clay, so that customers can manipulate a substance when describing their desires.

Here are some general hints for effective customer interviews (Ref 3):

- *Go with the flow.* Do not try to stick closely to any interview guide, including this one.
- *Use visual stimuli and props.* Bring any tangentially related product, and ask about it.
- *Suppress preconceived notions about the product technology.* The customers will make assumptions about the technology, but the interviewer should avoid biasing the discussion with any assumptions about how the product will be designed or used. That leads to speculation, not facts.
- *Have the customer demonstrate.* It usually unveils new information.
- *Be alert for surprises and latent needs.* The interviewer should pursue any surprise answer with follow-up questions. This usually uncovers latent needs, needs that the customer is not consciously aware of and that are otherwise hard to uncover.
- *Watch for nonverbal information.* Words cannot communicate all product sensations.

Figure 2 shows a form for collecting customer interview data, completed for the fingernail clipper example. The first two columns are completed during the actual interviews. The first column documents any interviewer's prompts to the customer, what might have been said to get the response, if anything. The second column documents the raw data, what the customer said *in his or her own words.* No interpretation should be made by the interviewer when completing these columns.

Clipper project				
Customer data				
Customer:		Interviewer:	KNO	
Customer ID:	KNO5	Date:	9/3/95	
Willing to follow up?	No	Location:	Cambridge, MA	
Type of user:	Middle claass, white male, traveling			
Question/prompt	Customer statement	**Interpreted need**	**Weight**	**Activity**
When usually use?	In the evening in hotel			
	Keep in my shaving bag	Reasonably compact	Must	Store
How big is that?	About 3" 2" 6",and I have a lot of things in it, it is always full			
Size of things is important?	Very important, I look for the smallest size of everything			
	So I dig it out of my bag, and	Striking appearance	Nice	Prepare for filing
	carry it to the bed, where I usually clip my nails.	Lightweight	Nice	
	Spin handle and rotate simultaneously	Easy to open file	Should	
Do you file?	Yes, I file at an angle with a vertical and angular motion	File at an angle	Must	File nails
	With file between thumb and index finger, and clipper body in fist			
		Easy to close file	Should	Unprepare for filing
	Rotate file back in place			
		Easy to open clipper	Should	Prepare for clipping
	Rotate handle into position	Easy to hold clipper	Should	
	Grab in hand using thumb and index finger, with tail up against middle finger edge			
	Position nail to be cut on bottom blade	Easy to align clipper	Nice	Clipping
		Low clippering squeeze force	Nice	
	Squeeze finger and thumb to cut	Blade shape curved	Nice	
	Reposition blades and make a second cut	Clip nails	Must	
	Reposition blades for final cut	Nail falls predictably	Nice	
	Catch cut nail			
	Toss in garbage	Dispose of nails		
	Rotate handle back	Easy to close clipper	Should	Return from clipping
	Spin handle to closed position			
	Put back in bag			

Fig. 2 Customer need collection form (fingernail clipper example)

The other columns are completed as soon as possible after the interview. In the third column, customer statements from the second column are interpreted in a structured noun-verb format (though not rigidly so). When making these interpretations, it is important to express what the product must do, not how the product might do it. Positive rather than negative phrasing should be used, to keep the interpretations focused on actual needs and not on whether a product is satisfying them. Finally, the words "must" and "should" should not be used in the statements. Rather, these qualifications should be incorporated into subsequent importance ratings, which constitute the fourth column.

In the fourth column, the importance of the customer's stated needs is interpreted using five ordered ratings: *must, good, should, nice,* and *not* (Ref 11). A *must* rating is used when a customer absolutely must have this feature, generally when it

is the determining criterion in purchasing the product. *Must* ratings will act as constraints. The *not* rating is for features that the customer never uses and does not care about.

Compiling Customer Needs

From interviews or other customer data, multiple lists of customer needs must be compiled into one. The design team should transcribe each need onto an index card, then group the cards into categories to make an affinity diagram (Fig. 3).

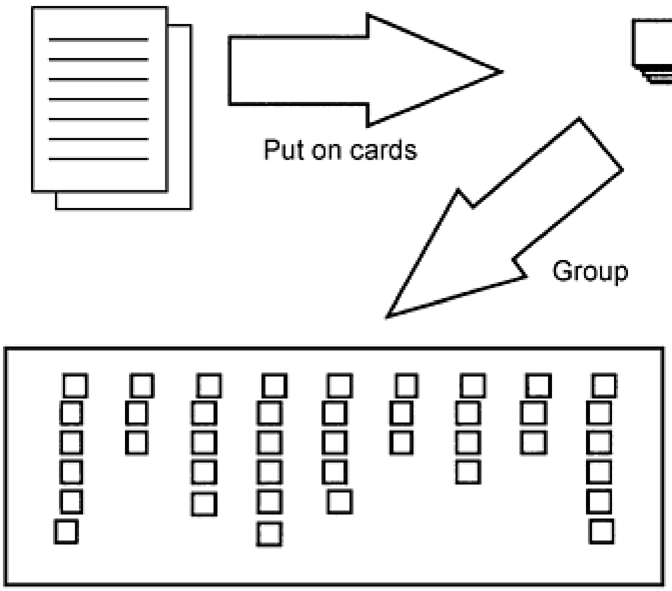

Fig. 3 Converting the set of customer needs into an affinity diagram

An alternative approach is to have a few customers sort the cards as explained above. This prevents the customer data from being biased by the design team. Next, a matrix is created in which the needs are listed down the rows and are repeated across the columns. The matrix is filled in with entries (i,j), the number of times that need i appears with need j. From this matrix, a statistical hierarchical cluster analysis can be performed, converting the matrix into a tree structure where each need is arranged next to the need statements or clusters that are "closest." The design team then parses the tree into a two- or three-level structure with exemplar labels for the branches. Reference 8 provides details. This approach is believed to be a more complete way to parse the need statements, although more costly.

Ranking Customer Needs

Once the customer needs have been compiled, numerical importance rankings must be established. A design team should take care, however, because the typical customer population will be multi-modal, with segments that have different importance weightings. Multi-modal populations present systems-level choices about which product options to offer. Methods for designing a product family to meet such demands is a subject of active research (Ref 12, 13).

A traditional approach to rating customer needs is to compare the number of subjects who mention a need to the total number of subjects. For example:

$$\omega_{CR_i} = \frac{\text{Number of times mentioned}}{\text{Number of subjects}} \qquad \textbf{(Eq 1)}$$

where ω_{CR_i} is the ith interpreted customer need importance rank. This ranking is flawed, as it includes a measure of need obviousness, as opposed to need importance. A need may not be important but may be very obvious, and so every subject mentions it. Because of this concern, the design team typically reviews the different statements in column 2 of the

customer response sheets (Fig. 2) to raise and lower the result from Eq 1. This approach is less than quantitative, takes excessive time, and is hard to justify.

A good approach to forming an importance ranking for a population is to send the list of customer needs to a random sample of customers (generally at least 100), asking them to rank the importance of each need. This approach can provide a sound statistical sample. However, any determination of statistical importance must incorporate two phases. First, a decision must be made as to whether the customer need is a *hard constraint* that must be satisfied, or an *objective* that can be traded off versus other customer needs. The former must be separated from the latter and accounted for differently by the design team.

To separate out customer needs that are hard constraints, each need is examined one at a time, and the number of *must* responses is compared to the total number of subjects. Clearly, if every subject flags the need as a *must*, then that need must be satisfied. But if only a fraction of the subjects indicate that the product must satisfy a need, a decision must be made about what fraction should be used before interpreting the customer need as a constraint.

To answer this question, statistical outlier analysis can be applied to determine when a "few" *must*s are outlier responses that are not worth flagging. A *must-confidence percentage level,* C_{must}, can be defined as the desired customer response percentage about the median needed to switch the customer need from an objective to a constraint. C_{must} is bounded between zero and one. Note that although C_{must} is a confidence percentage level, the approach here does not presume normally distributed data. No confidence intervals have been mentioned, only confidence percentages. Often engineers feel comfortable with $C_{\text{must}} = 0.999$, corresponding to three confidence intervals, when operating with normally distributed data. Such a value of C_{must} is excessive here, as it can create excessive constraints for the design team. It will force many customer needs to carry infinite importance as *must*s.

To establish whether a customer need is a constraint, tabulate the importance responses into the five categories described above. One can calculate how many subjects need to provide *must* responses for a customer need to be considered a *must:*

$$(1 - C_{\text{must}})(N - 1) < N_{\text{must}_i} \qquad \textbf{(Eq 2)}$$

where N is the total number of subjects and N_{must_i} is the number of subjects who provided *must* responses on the *i*th need. If N_{must_i} is less than the left-hand side of Eq 2, then the need becomes a constraint with a *must* importance rating. This test is very simple to implement and use.

Having separated the customer needs into *must* and *non-must* categories, relative importance ratings can now be placed on the *non-must* needs in the traditional way. As one approach, first convert the subjective importance ratings into numerical equivalents. A typical transformation used is:

Importance rating	Numerical equivalent	
	Option 1	**Option 2**
Must	9	1.0
Good	7	0.7

Nice	3	0.3
Not mentioned	0	0

This mapping is always a subjective interpretation-conversion that a design team must agree upon in order to convert linguistic customer expressions into numbers. This subjectivity is a customer modeling issue that will arise with any approach. Once the mapping is established, the importance assigned to each customer need can be calculated by the average

$$\omega_{CR_i} = \frac{\sum_j \omega_{CR_{ij}}}{\text{Number of subjects}} \quad \textbf{(Eq 3)}$$

where $\omega^{CR_{ij}}$ is the numerical importance rating for the *i*th need assigned by the *j*th customer. The result of Eq 3 can be linearly scaled to any other numerical range desired, and the information contained will remain unchanged. The variance of Eq 3 across the subject pool can also profitably serve as an uncertainty indicator to establish significant figures.

Other methods for determining importance are detailed in Ref 8. One is an anchored measure approach, whereby the customer respondent first determines the most important need, which is assigned a "10." Then each lower importance need is ranked relative to that need. Another approach is to require that the importance ranks add up to a constant figure, such as 100. This method can work in small sets of needs, but otherwise it can be confusing and cause the customer to rank low-priority needs inaccurately.

All of these direct approaches may suffer from scaling problems: it may be that customers think they know what they want, but they do not purchase accordingly. Therefore, some experts advocate a revealed preference approach, where the design team describes different product features as numbers, then asks for purchasing preferences on entire products (not features), and then uses regression analysis to fit importance coefficients from the products to the features. However, Hauser and Griffin (Ref 10) report poor results with the revealed preference approach.

Gathering Customer Use Data

A customer engages in many distinct activities when using any non-trivial consumer product. A product is purchased, transported, assembled, stored, removed for use, initialized, used in different ways in different environments, perhaps modified by the user, periodically cleaned or maintained, and disposed. Different customer use patterns should be captured and communicated to the design team, as they can give rise to different product forms. Further, capturing the customer use patterns helps to ensure that customer needs have been gathered for each different activity.

To form the possible use patterns, it is important to capture the activity sequence for each customer by completing the column 5 of the customer data sheet (Fig. 2). Typically, a sequence of customer statements will have one associated activity. *Activities* differs from *customer needs* in that activities label what the customer is doing (not the product) when a group of needs are expressed about the product. After column 5 is completed, the activities are transcribed onto index cards and sorted into another affinity diagram (Fig. 3). The number of cards for each activity can indicate how typical each is. The initial and final activities should be highlighted, so that the team can help system-engineer the environment within which the product will be used.

The affinity diagram communicates to the design team what the customer does with the product. It helps ensure that a design team is aware of all customer life cycle product needs. The activity diagram can be expanded "upstream" to capture sales, distribution, and manufacturing activities, or "downstream" to capture activities such as disposal. Incorporating such life cycle and manufacturing concerns remains an active research area.

In addition, the affinity list is useful in categorizing customer needs. Typically, customer needs are grouped into abstract categories, based on arbitrary interpretations by the design team or customers. Experience has shown that the activities list provides a more meaningful way to group customer needs.

Summarizing Customer Needs

Customer needs must be summarized into a document that the design team can reference. A sample is shown in Fig. 4. Among other items, the header information contains a brief description of a typical customer. This description should have been given to the design team from management originally or through the mission statement, but it should be refined, based on what is now known about customer needs. The customer description for the fingernail clipper is "male or female, age 20 to 60, carries clipper on the run, not employed in the beauty industry." Basically, the customer description includes the core demographic description applied when customers were selected for interviews, and any relevant product-specific information. This information is particularly important for segmented customer populations.

Clipper project		
Customer requirements		
Interviewer(s): KNO		
Date 9-7-95		
5	Number of customers	
0–5	Weighting scale	
75%	Must confidence	
Average customer		
	Male/Female, age 20-60 middle class	
	Not in the hair or nail business	
	Customer requirement	Weight
Purchase		
	Cost	4
Transport in package		
Unpackage		
Chain keys		
	Act as keychain	0
Store		
	Compact storage	4
	Non-snag storage	1
	Lightweight	2
	Striking appearance	3
Prepare to file/pick		
	Easy to open	2
Filing/picking		
	Files nails	2
	Picks nails	Must
	File rough	1
	File holds filed dust	0
	File has a picking tip	Must
Return from filing/picking		
	Easy to close file	2
Prepare for clipping		
	Easy to open clipper	4
Clip nails		
	Easy to align clipper	2
	Easy to hold clipper	3
	Body contoured to hold	3
	Curved blade shape	3
	Wide handle	2
	Low squeeze force	1
	Blade can act as pusher	1
	Blade can act as a file	1
	Clips nails	Must
	Clips toe nails	1
	Clips hangnails	1
	Sharp blade	1
	Nails fall predictably	1
	Stores cut nails	1
	Easy to clean	0
Return from clipping		
	Easy to close clipper	4
Throw away		

Fig. 4 Partial customer needs list (fingernail clipper example)

In the sample form, customer needs are listed by activity. In turn, the activities are arranged in serial order, with parallel activities ordered by importance. Within each activity group, customer needs should be similarly arranged. The numerical importance rating for each need should be included in the second column. Customer needs that are *must*s should have this indicated in the second column. The scale (0 to 1, 1 to 10, etc.) and normalization (relative to most important goal, relative to a sum, etc.) should be indicated on the top of the form, if there is no company standard.

In addition to satisfying customer needs, some products must satisfy other requirements, typically legislative or manufacturing. These can be represented as additional requirements in the customer needs list. Typically all have *must* ratings, since they must be met in order for the product to be legally sold or physically produced.

Non-customer requirements can be incorporated in the customer needs list as deemed appropriate. Alternatively, a specification sheet may be added for non-customer requirements, organizing the requirements according to topic. References 14 and 15 provide detailed examples of how to create a specification sheet.

Functional Decomposition: Modeling, Analysis, and Structure

Design teams need a representation of what the customer wants from the product, that is, a model of how the product should function in order to satisfy the customer. Functionally, all products *do something.* Products therefore accept *inputs* and operate to produce *outputs* (i.e., the desired performance). We can model any product, assembly, subassembly, or component as a *system,* with inputs and outputs that traverse a system boundary. The essence of such a model is the need-function-form definition of engineering design. In the sections below, we construct the necessary machinery for understanding and representing design function, according to a system perspective.

Why Functional Decomposition?

While methods to carry out market studies or to gather customer needs are widely accepted, methods to generate concepts are typically left to the whims of the design team. The transition from customer needs to concrete solutions is seen as more of an art than a science (Ref 16). In fact, for many consumer products, there is a tendency to seek form solutions directly based on the previous experience of the design team members. With ever-shrinking cycle times and budgets, and with ever-expanding demands for quality, this approach has a number of limitations. Most notably, the links between

customer needs and design concepts are, at best, indirect or implicit. They exist only in the minds of the designers. As such, customer needs are relegated to the criteria for evaluating concepts, not the direct catalysts for generating concepts.

Over the last 20 years, new methods for engineering design have emerged that focus on mapping customer needs to functional descriptions, or mapping these descriptions to sets of technologies that satisfy the underlying functional requirements (Ref 3, 14, 15, 17, 18). When combined, these methods have a number of intrinsic advantages:

- The emphasis is on *what* has to be achieved by a new concept or redesign, not on *how* it is to be achieved. By so doing, a component- and form-independent expression of the design task may be achieved so that the design team can comprehensively search for solutions.
- Creativity is enhanced by the ability to decompose problems and manipulate partial solutions (Ref 17). When a design task is decomposed into its functional elements, solutions to each element are more apparent due to the reduction of complexity and extraneous information.
- Functions or sets of functions may be derived or generated directly from customer needs. These functions define clear boundaries to associate assemblies or subassemblies of the final design solutions. In turn, these boundaries provide a basis for allocating resources to concurrent engineering efforts and for seeking modular concepts.
- Functional modeling provides a natural forum for abstracting a design task. Many levels of functional abstractions may be created, from a very high-level single-function statement to detailed functional statements for the subsystems of a design.
- By mapping customer needs first to function and then to form, more solutions may be systematically generated to solve the design problem. "If one generates one idea it will probably be a poor idea; if one generates twenty ideas, one good idea might exist for further development" (Ref 17).
- Needs mapped to function and then to form promote set-based concurrent engineering processes (Ref 19). Feasible regions of technology may be explicitly defined based on functional requirements. Tradeoffs may also be explored in parallel among a wide array of radical and known solutions, since a common functional description is driving the design effort directly from the voice of the customer.

The next section describes a systematic approach for establishing the functionality of a new design or redesign. The fingernail clipper provides a running example to clarify the approach.

Establishing Functionality and Product Architecture

The procedures described above yielded a clear statement of customer needs, organized to establish priorities for the design effort. Functional modeling begins the systematic process of transforming these needs into a clear specification of the design task. It also initiates the conceptual design phase, wherein an array of solutions are sought.

Phase 1: Develop Process Descriptions as Activity Diagrams. To start the functional modeling process, an important tool is to specify the *process* by which the product being designed will be functionally implemented. A process or process description, in this sense, includes three phases: *preparation, execution,* and *conclusion* (Ref 20, 21, 22). Within each phase, we network high-level user activities to show the full life cycle of a product, from purchase to recycling or disposal. As high-level activities are listed in each phase, a number of product characteristics are chosen.

Here, the process description is represented as an activity diagram (Fig. 5). This diagram clearly shows a number of process choices that will influence the final design. For example, the activities of "picking" and "filing" are process choices for improving the customer's fingernail appearance through mechanical contact. Chemical "soaking" process choices or others might be chosen as alternatives. They would lead to different activities, functional descriptions, and, ultimately, product architectures and components. Figure 5 does not include manufacturing activities such as packaging and transport, sales functions, or disposal, but depending on the scope of the design task, it could have included these activities.

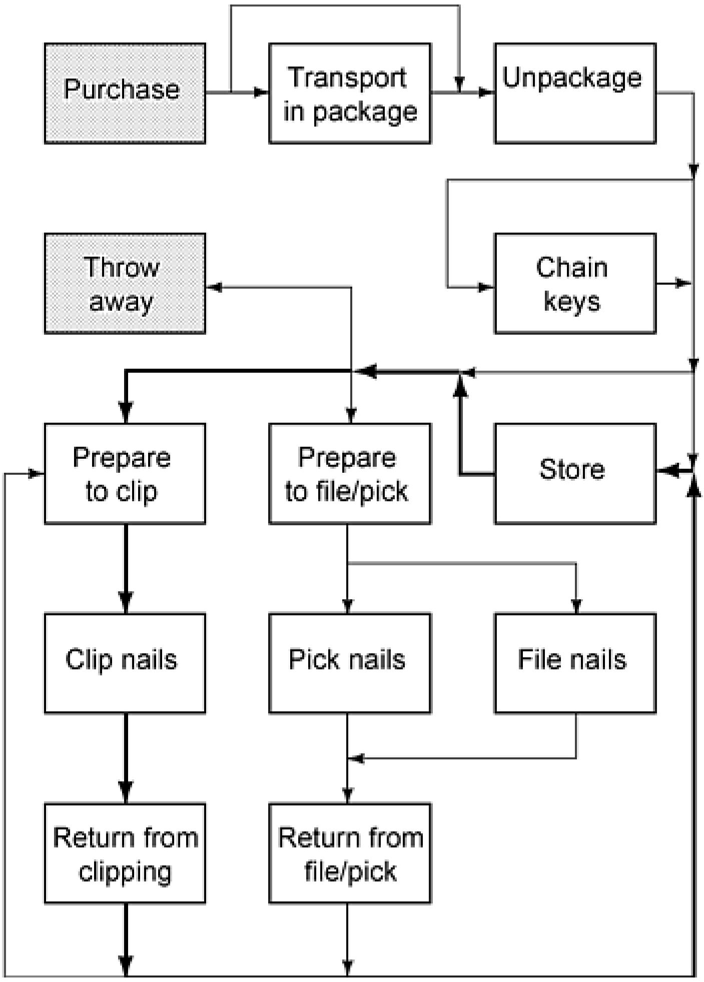

Fig. 5 Completed activity diagram (fingernail clipper example)

Phase 2: Formulate Subfunctions through Task Listing and Black Box Modeling. Using the activity diagram and the list of customer needs, a *function structure* for the product can be formulated (Fig. 6). A function structure is defined as an input-output model that maps energy, material, and signal flows to a transformed and desired state. Function structure modeling (Ref 3, 14, 15, 17, 20, 23, 24) has historically been used to create a form-independent product expression. We extend common function structure modeling to include a mapping of customer needs to subfunction sequences (called *task listing*), a method for aggregating subfunctions, and a comparison of a functional decomposition with customer needs.

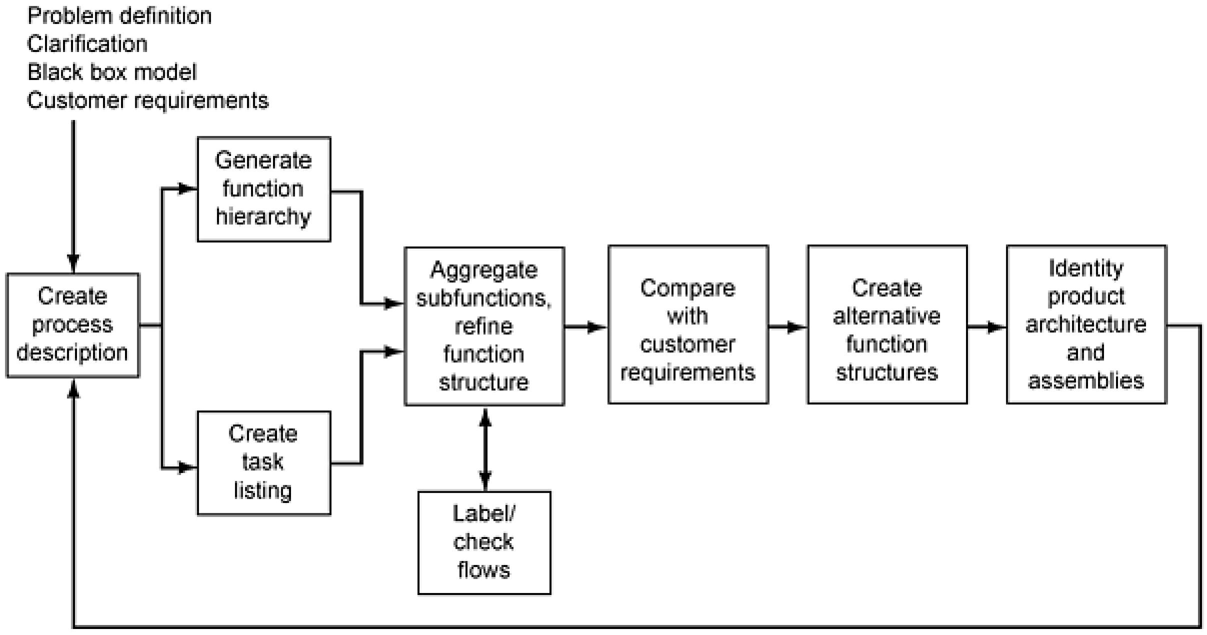

Fig. 6 Schematic representation of the function modeling and analysis process

The first step is to identify primary flows associated with the product activities. A *flow* is a physical phenomenon (e.g., material, energy, or signal) that is intrinsic to a product operation or subfunction. In the context of input-output modeling, a flow enters an operation or subfunction, is manipulated by the subfunction, and exits in a new state. For example, an operation may be to pressurize a fluid. Two critical flows for this operation are an energy to execute pressure change and the fluid material being operated upon. A list of some common energy flows is given in Table 5 (Ref 25, 26).

Table 5 Examples of common energy flows

displacement
power
deflection/strain
electricity
human force
friction force
solar energy
light
rotation
time
vibration
magnetism
pneumatic power
oscillating force
sound (acoustic)
linear force
stress
torque
heat
noise
hydraulic power
pressure

Considering the fingernail clipper example, a subset of the customer needs are:

Need	Effect	Importance
Cost	Not inexpensive	4
Compact	Not compact	4
Files well	Does not file well	2
Cuts well	Does not cut well	Must
Easy to open/close	Not easy to open/close	4
Easy to hold	Not easy to hold	3
Comfortable	Not comfortable	3
Sharp cutting surface	Not a sharp surface	3

We now translate the customer needs to energy, material, or signal flows of the product when effects are exhibited or are expected to be exhibited during product use. Cost is not an aspect of using the product, so we do not model "not inexpensive." Primary flows associated with "not compact" are the user's hands, the fingernail dimensions, and storage compartments (e.g., pants pockets, wallets, or purses). These flows are material in nature and capture capacity in terms of "volume." Primary flows for the remaining customer needs include:

- "Does not file well"--hand motion (energy), fingernail (material), fingernail roughness (signal)
- "Does not cut well"--generated cutting force (energy), finger force (energy), and fingernail (material)
- "Not easy to open/close"--hand movements (energy) and hand (material)
- "Not easy to hold"--finger force (energy) and hand (material)
- "Not comfortable"--finger force (energy) and hand (material)
- "Not a sharp cutting surface"--generated cutting force (energy) and fingernail (material)

To document the mapping of customer needs to flows, a "black box" model of the product is developed. A black box model lists all input and output flows for the primary, high-level function of the design task, stated in active verb-noun phrases. Figure 7 illustrates a black box model for the fingernail clipper task. This model must now be refined and decomposed to identify the basic product or device functions that will satisfy the overall function and needs.

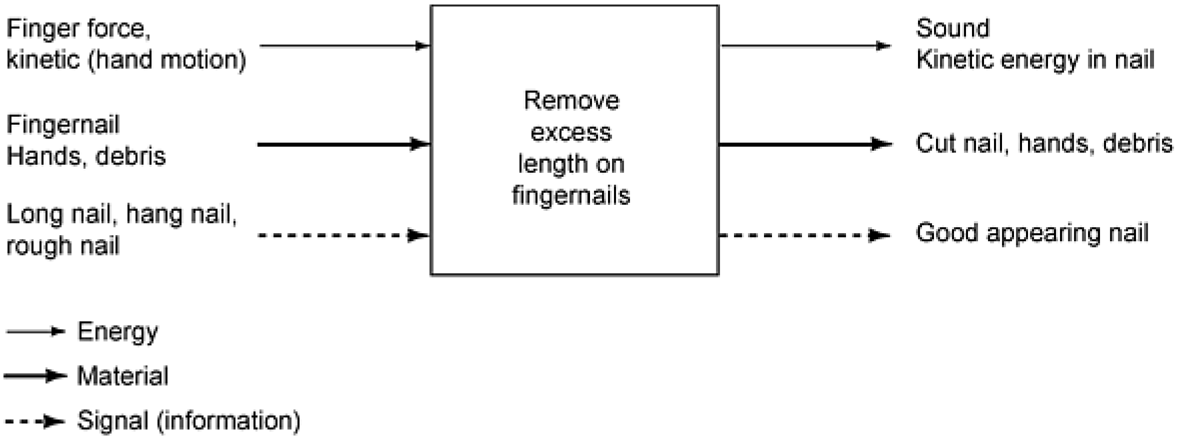

Fig. 7 Black box model (fingernail clipper example)

For each of the flows, the next step is to identify a sequence of subfunctions and specific user operations. A subfunction, in this case, is an active verb paired with a noun that represents the causal reason behind a product behavior. An operation is a specific action by the user that is needed to complete the function structure. References 17, 23, 25, and 26 provide lists of appropriate verbs and nouns to use in functional analysis, and Table 6 summarizes typical classes of engineering functions. A useful approach for generating subfunctions is to trace the flow as it is transformed from its initial creation state to its final expected state when it leaves the product's system boundary. This approach may be executed by *playacting* the flow (becoming the flow) or brainstorming a hierarchy of functions that must process the flow.

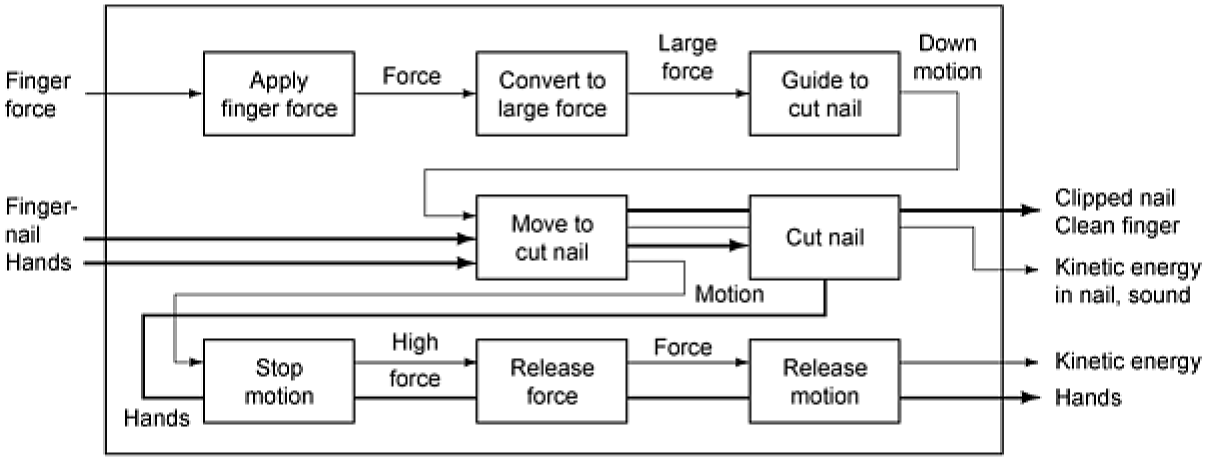
Table 6 Basic device/product function (active verb) classes

Function class	Definition	Basic functions	Alternatives (synonyms)
Channel	To cause a direction of travel or path for a material or energy	Import	Input, receive, allow, form entrance
		Export	Discharge, eject, dispose, remove
		Transport	Channel, lift, move
		Transmit	Conduct, convey, transfer
		Stop	Insulate, resist, protect, shield
		Guide	Direct, straighten, steer
Store/supply	To accumulate or provide material or energy	Store	Collect, contain, reserve
		Supply	Fill, provide, replenish
Connect	To join two or more flows (materials or energies)	Couple	Connect, assemble, join

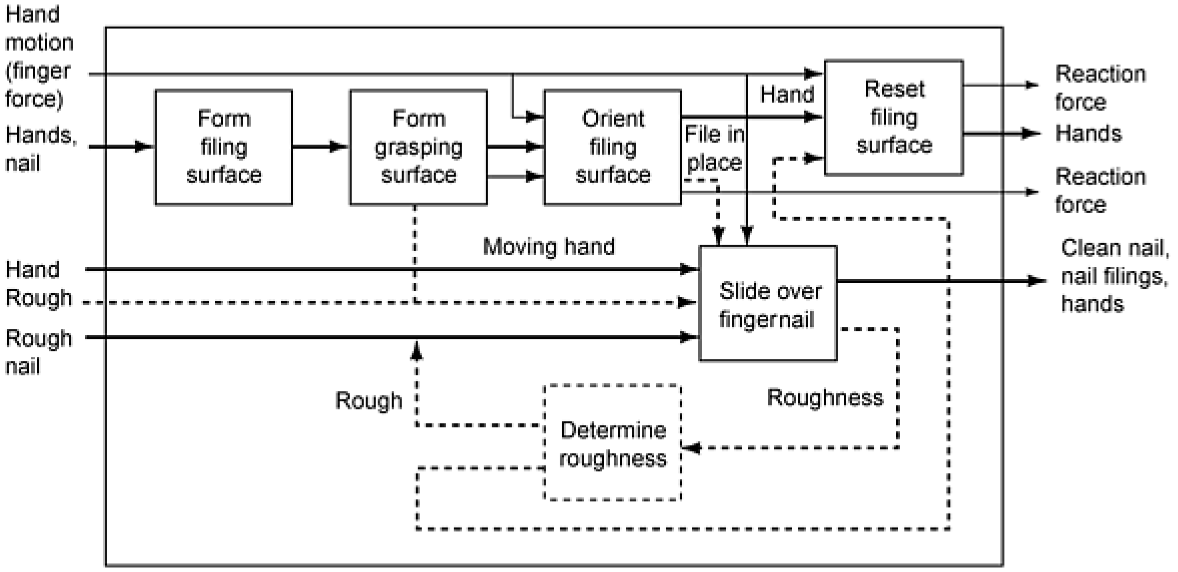
	energies)	Mix	Add, pack, blend, combine, coalesce
Branch	To cause a material or energy to no longer be joined or mixed	Branch	Divide, diverge, switch, valve
		Filter	Strain, filtrate, purify, percolate, clear
		Separate	Release, detach, disconnect, disassemble, release, subtract
		Remove	Polish, cut, sand, drill, lathe
		Distribute	Scatter, disperse, diffuse, empty
		Dissipate	Absorb, dampen, dispel, diffuse
Control magnitude	To alter or maintain the size or amplitude of material or energy	Actuate	Start, initiate
		Regulate	Control, allow, prevent, enable, disable, limit, interrupt
		Change	Increase, decrease, amplify, reduce, normalize, multiply, scale, rectify
		Form	Compact, crush, shape
Convert	To change from one form of flow type to another (e.g., one energy type to another energy type)	Convert	Transform, gyrate, liquefy, solidify, evaporate, condense, integrate, differentiate, process
Support	To secure firmly a material or energy path into a defined location	Stabilize	Steady
		Secure	Attach, mount, hold, fasten, lock
		Position	Orient
		Translate	. . .
		Rotate	Turn, spin
		Allow degrees of freedom	Constrain, unsecure, unlock
Signal	To provide information to, within, or out of the system boundary	Sense	Perceive, recognize, discern, check, locate, verify

	Indicate	Mark
	Display	. . .
	Measure	Calculate, compare, count
	Clear	. . .

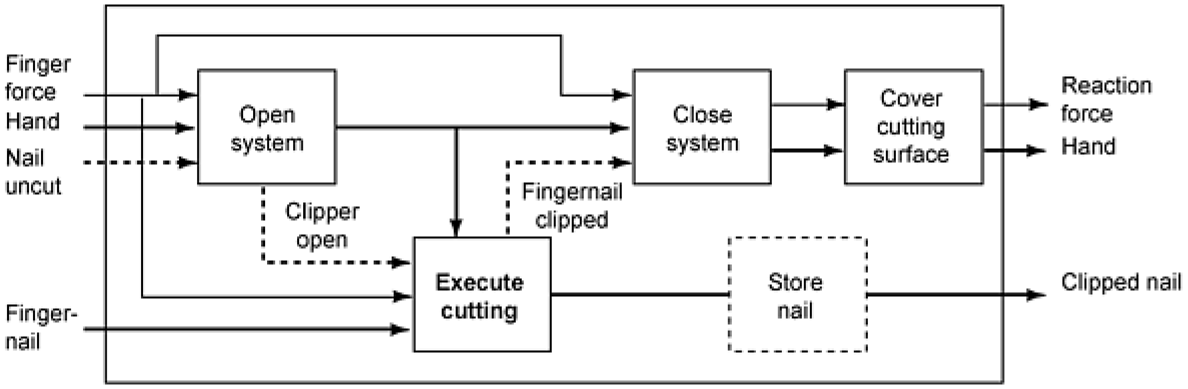
For example, a customer need, expressed in the customer's voice, may exist for "cuts nail well." A suitable flow for addressing this need is a force flow that ultimately acts on the nail material flow. Through playacting these flows, a subfunction sequence may be of the form: capture force, apply force, transform to larger force, transmit force as motion, guide motion, cut material, stop motion, release force, dampen reaction to force, etc. Figure 8 illustrates task lists for three sets of customer needs, and the corresponding flows.



(a)



(b)



(c)

Fig. 8 Task lists for three sets of customer needs (fingernail clipper example). (a) Customer needs: cuts well, easy to hold, comfortable. Flows: finger force, nail, hands. (b) Customer need: file well. Flows: nail, hand motion, roughness signal. (c) Customer need: opens and closes easily. Flows: nail, hand

Phase 3: Aggregate Subfunctions into a Refined Function Structure. The subfunctions for the full set of customer needs are aggregated (combined) to represent the functions of the entire product. This step is accomplished by appropriately connecting flows between each sequence and adding subfunctions that interact or provide control states.

Aggregation and refinement of the function structure ends when two criteria are met:

- The subfunctions are "atomic" (i.e., they can be fulfilled by a *single, basic* solution principle that satisfies the function).
- The level of detail is sufficient to address the customer needs.

The first criterion provides a basis for choosing the depth of functional analysis (e.g., a subfunction of "control motion in three dimensions" should be refined to "control motion in three rotations and translations"--six total functions--since a single, basic form solution in fingernail clipper technology does not provide 3D control). The second criterion ensures that time is not wasted refining a function structure to the level of miscellaneous and secondary product components, such as fastening.

For the fingernail clipper design effort, an aggregated function structure is shown in Fig. 9. Notice that subfunctions and flows are combined for overlapping or redundant functionality from Fig. 8. User functions are listed outside of the system boundary for clarity.

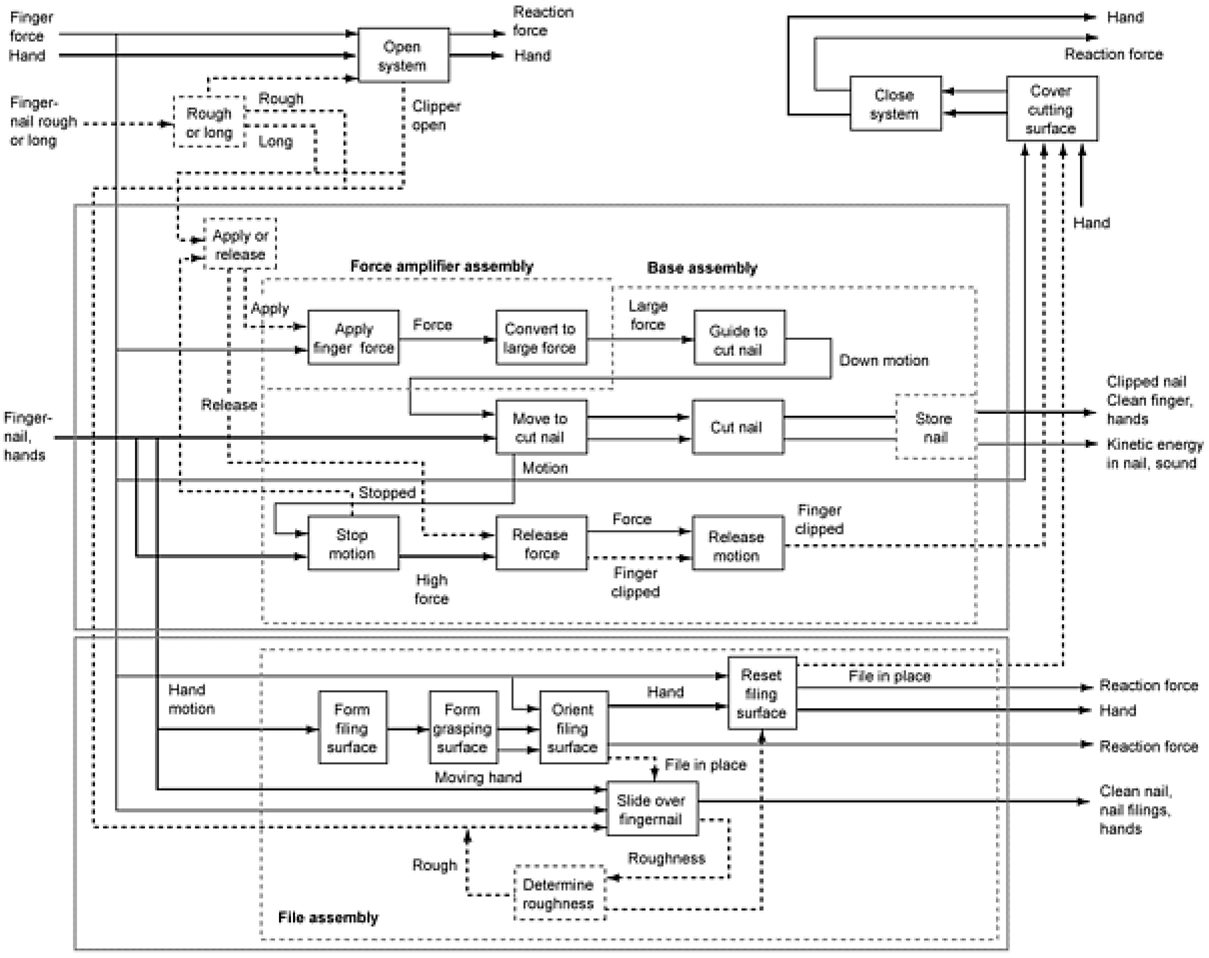


Fig. 9 Refined function structure (fingernail clipper example)

Phase 4: Validate the Functional Decomposition. Once the design team has completed the subfunction aggregation, functional modeling and analysis comes to a closure through two verification steps:

1. All major flows between the subfunctions are labeled and checked according to their state of transformation. This ensures validity and continuity, perhaps leading to the addition of further functional representations. Table 7 lists the pertinent questions, checks, guidelines, and actions

implemented at this stage.

2. The customer needs list is reviewed, and the subfunction or sequence of subfunctions is identified that satisfies each customer need. Needs not covered by the function structure require further analysis, and subfunctions not satisfying a need require confirmation of their incorporation. This verification typically adds more subfunctions to the network, while simplifying or removing others that really do not apply.

Table 7 Function structure organization and flow checks

Question	Check/guideline/action
Are physical laws maintained?	For example, validate conservation of mass and energy.
What is the new state of flow for each subfunction? Is this state valid and correct?	Label input/output states.
Are system and subsystem (assembly) boundaries clearly shown?	Define system boundary from process description or activity diagram. Subsystems (assemblies) starting point--define as a group of functions where the energy flow does not change (e.g., no relative motion).
Are all functions (noun) form-independent?	If not, the function should be generalized.
Are the subfunctions atomic? Can each subfunction be replaced by a device or structure that only performs that function?	Refine subfunction into a set of atomic subfunctions, without adding unnecessary detail.
Does an alternative ordering or placement or number of subfunctions exist?	If so, develop alternative function structures or subfunction structures.
Are all subfunctions product or device functions?	If not, the subfunction(s) is a user function (not performed by the product). Convert the subfunction to the device functions that must support the user function. If leaving the user function in the function structure adds clarity, double box it to show a distinction.
Are certain functions included as "wishes"?	If so, place a dashed box around the function to show that it is auxiliary or secondary.
Are certain functions "prolific, " meaning that they affect or are affected by flows of many other subfunctions (e.g., "support impact loads")?	If so, place a ground symbol on the subfunction and include only primary flows through it.
Is the entire function structure sequential (i.e., the subfunctions are connected one after another in a dependent sequence or chain)?	If so, product parallelism (assemblies/subsystems) have not been identified. All of the customer needs are dependent. Parallelism of functions that do not directly depend on one another should be separated.
Do redundant functions exist?	Remove or combine redundant functions.
Do functions exist outside the system boundary?	If so, they should be clearly distinguished and maintained for clarity only, such as a user function.

Consider the following validation for the fingernail clipper task:

Need	Effect	Validation (applicable subfunction(s))
Cost	Not inexpensive	Not applicable (criterion for evaluating design concepts)
Compact	Not compact	Apply finger force, form filing surface, form grasping surface, cut nail
Files well	Does not file well	Form filing surface, form grasping surface, orient surface, slide over nail
Cuts well	Does not cut well	Convert to large force, cut nail
Easy to open/close	Not easy to open/close	Guide to nail, move to cut nail
Easy to hold	Not easy to hold	Apply finger force release force, release motion
Comfortable	Not comfortable	Apply finger force
Sharp cutting surface	Not a sharp surface	Cut nail

The subfunctions listed for the validation combine to represent the customer need. For example, "compact" will ultimately be governed by the solution principles chosen for the "apply finger force" subfunction. The size of these solution principles determines the overall compactness of the final fingernail clipper. This customer need will need to be balanced with "cuts well" and the "cut nail" subfunction, since a minimum size will be needed to cut a nail.

Phase 5: Establish and Identify Product Architecture and Assemblies. With the functional decomposition verified, it becomes important to identify product assemblies that can be addressed by individual designers or cross-functional design teams. The key elements of this phase are to define collection of functions (chunks) that will form assemblies in the product and to clarify the interactions and interfaces between these chunks. By so doing, a product team will have a basis for choosing between *modular* and *integral* architectures (Ref 3, 27). They will also have a basis to choose parallel design tasks for the product development, where only the interaction and interface information need to be shared continuously among the subteams.

A simple process for establishing the product architecture and assemblies includes the following steps:

1. Using the functional decomposition of a product, cluster the subfunctions or elements in the function structure. Dashed boxes around the clusters of subfunctions and a title will serve as an appropriate representation. These clusters are chosen by identifying parallel subfunction chains (each parallel track is a candidate cluster), subfunction chains that have common energy types as flows, and subfunction chains that have only simple interactions with each other.
2. Create a rough spatial layout (block diagram with a reference frame) for the product. This layout is meant to show the relative position of each cluster in order to clarify spatial interactions and interfaces (the boundaries between clusters).
3. Define interactions, interfaces, and performance characteristics between each cluster. Four types of interactions exist as flows across interfaces: spatial (geometry), energy, information, and material. These

interactions represent what must be shared across interfaces within the performance requirements.

Figure 9 shows the application of the first of these steps to the fingernail clipper. Three primary assemblies are identified: the base, force amplifier, and file. Important interactions include the hand flow of the user and attachments to allow relative motion for opening and closing activities. These assemblies may now be designed relatively independently, if a modular architecture is chosen. Reference 27 presents further examples, including spatial layouts.

Competitive Benchmarking

To remain competitive, a design team must compare any proposed concept with the competition. Typically a corporate group exists to tear down the competitor's product, estimate costs, plot trends, make predictions on requirements, and work with the design teams. These efforts uncover the clever things that the competition has spent effort on, uncover the principles behind how they work, and predict costs.

It may be appropriate to benchmark products before customer needs analysis and functional decomposition. Alternatively, if a team does not wish to bias these initial analyses, it can update the results with benchmarking data.

Reference 28 presents benchmarking methods and an overview of a reverse engineering methodology at a large company. Reference 29 presents an approach to benchmarking and a case study from the computer industry. Reference 30 presents a ten-step approach to benchmarking company operational practices. In this section we present a method that is focused on product design, using the customer demands and the product functions. The steps in this method are:

1. Identify design issues.
2. Identify competitive and related products.
3. Conduct an information search.
4. Prepare for product teardowns.
5. Evaluate distribution and installation.
6. Take apart and measure the assemblies.
7. Write a bill of materials.
8. Plot industry trends.

Step 1: Identify Design Issues. First, it must be clear what problems the design team is facing on the current project. If this is a new project, the technical form issues may be unknown, so it will be worthwhile to investigate the market, competitors, and competitive products. If this is a redesign project, an investigation can ask of the previous design team:

- What was difficult for you?
- What design problem did you solve that you are proud of?
- What related technologies are you interested in?

The deliverable from this step is a list of keywords with explanations about what information to gather.

Step 2: Identify Competitive and Related Products. Once the product function is known, one must examine the sales outlets for products that address those functions. For consumer products, sales outlets are typically retail stores. One must list all competitors and their different product models, and all related products in their portfolio. If a competitor has a family of products under a common product architecture (they use identical components for some aspects of each product, but different components for niche demands), one should detail this information, as it can indicate the competitor's preferred market segments.

This step should only identify the competitors, by company names and product names. The list should be screened by highlighting the particular names that appear most crucial for the design team to fully understand.

Step 3: Conduct an Information Search. The importance of an information search cannot be overstated. The wealth of information available about business operations across the globe is amazing. A design team must understand the market demand for product features and what the competition is doing to meet it. The team should gather information on the products and related products, the functions they perform, and the targeted market segments. All keywords associated with these three categories should be formed from step 2 and used in informational searches.

Most business persons are happy to discuss the market and non-competitive business units. Though most will not provide strategic information about their own companies, many people are willing to tell all about their competitors. Suppliers will usually discuss their customers, if it appears that you might provide an additional sale. Once people understand you are designing or redesigning a new product, they naturally want to get involved with new orders, and they will help you as much as they legally can. Pursuit of information beyond that point is unethical, and not necessary. Most people are happy to share information, so simple honesty and a friendly attitude can get you a long way.

Public sources of information include the library and electronic wire services. University libraries are filled with technical engineering modeling references. Also, librarians have expertise in uncovering obtuse references with limited initial information. Particular references of interest include:

- *Thomas Register of Companies.* This is a "yellow pages" for manufacturing related businesses. The Thomas Register lists vendors by product.
- *Market Share Reporter.* Published every year by International Thomson Publishers, this book summarizes the market research of Gale Research Inc. It comprises market research reports from the periodicals literature. It includes corporate market shares, institutional shares (not-for-profits), and brand market shares.
- U.S. Department of Commerce, National Institute of Standards and Technology. This U.S. government branch provides, among other things, national labor rates for all major countries. This proves very useful for determining competitors' manufacturing costs.

On the World Wide Web, databases can be searched using keywords for a small fee. In the United States, these include:

- *Lexis/Nexis.* These two databases are the most comprehensive full-text online sources of news and business information. *Lexis* provides legal information, and *Nexis* focuses on business. They both provide abstracts and full text from public news sources, including newspapers, magazines, wire services, newsletters, journals, company and industry analyst reports, and broadcast transcripts.
- *Dialog Information Services Databases.* Dialog is the world's largest online information research service, containing millions of documents. These include databases with simple abstracts as well as the full text. For the most part, the articles come from business journals and include information on company histories, competitive intelligence, new product development efforts, sales and earnings forecasts, market share projections, research and development expenditures, financial activities, demographics, socioeconomic activities, government regulations, and events that affect the business environment.

Most major manufacturers have a presence on the World Wide Web. Much information can be gathered simply and at no cost, particularly technical information. Material properties of industrial brand plastics and metals, for example, are easily found. Topical search engines are readily available.

After examining trade journals and uncovering which competitors have bragged about new innovations, it is useful to gather the patents on these new innovations. However, patent searches based on company names are difficult, since companies typically "bury" their patents by filing under the individual names of designers. Uncovering individual patents is usually done by refined topical searches. As much information as possible should be supplied to the person searching the patents.

Vendors of original equipment manufacture (OEM) components also are a valuable source of information. Cost quotes using the competition's ordering quantities are effective at uncovering OEM part costs. Usually one can also obtain unsolicited information about the competition. Persons in the industry can provide good pointers on non-obvious cost, technical, and market drivers. Overseas labor rates, shipping rates, and reliability of supply from particular geographic areas are examples of "inside knowledge" that might be uncovered from public sources when one knows what to look for. University faculty specializing in a relevant technical area can provide invaluable assistance in design or serve as design reviewers. All of these and other sources must be leveraged to determine as much as possible about what customers want, what competitors are supplying, and the dynamics of the market.

Step 4: Prepare for Product Teardowns. In the steps described above, the team establishes a list of products that are worth tearing apart and analyzing. This list should include products that can provide technical solutions to design needs. Typically, it includes the least expensive model on the market, the most expensive model, the most popular model, and models that have particular technical features.

Next, one must clarify what data are required, such as:

- Primary function
- Quantity of parts per product unit
- Dimensions

- Maximum, minimum, and average material thicknesses
- Weight
- Material
- Color/finish
- Manufacturing process, including sufficient information for a design for manufacturing analysis

Next, one should identify all tools that will be required to complete teardown. In addition, it is necessary to identify all sensors and test equipment required (e.g., camera, a videotape of the product operating, multimeter, hardness tester, optical sensor, flow meter). Typically, one documents this information in a written or electronic report, similar to professional laboratory experiments.

Step 5: Evaluate Distribution and Installation. Important factors in product development are the means used to acquire parts, contain parts and ship, distribute, and market the product. These must also be examined as a part of the benchmarking process. The packaging of the product should be examined and reported to the design team, because often it is quite expensive. Installation instructions and procedures should be examined for costs and effectiveness.

Step 6: Take Apart and Measure the Assemblies. Disassembly is the most obvious step in reverse engineering. However, to be effective, it must be coordinated with measurements. The first step is to take pictures and measurements on the whole assembly before disassembly. Then the assembly is torn down, pictures are taken in an exploded view, and the parts and assemblies are measured.

Step 7: Write a Bill of Materials. A written form should be completed that details the product. A good format is shown in Fig. 10, where the column headings are the data identified in step 4. The bill of materials should include photographs, in sequence, and an exploded-view computer-aided design drawing.

Part #		Part name	Quantity	Finish	Function	Physical parameters
A1	Arm assembly					
	001	Actuator arm	1	Chrome	Transmit finger force	2 in., shaped
					Input from finger	0.25 in. pivot
	002	Pin	1	Chrome	Pivot	0.13 in. round
A2	Cutter assembly					
	003	Blade arms	2	Chrome	Cut nails	2 × 0.44 × 0.13 in.
					Spring action	0.13 in. gap
A3	File assembly					
	004	File	1	Chrome	File nail	Scored, 1.50 × 0.25 × 0.06 in.
	005	Pivot rivet	1	Chrome	Attach file	0.19 in. rivet

Fig. 10 Reverse engineering bill of materials (fingernail clipper example)

Step 8: Plot Industry Trends. The last step is to arrange and transform the data for clear understanding of implications for the design or redesign task. This process should include:

- Categorization of the market
- Categorization of technical solutions
- Benchmarking of technical solutions
- Benchmarking of competitors

Market categorization is typically done by socioeconomic status and percentage of the market.

Technical solutions should be categorized by function structure modeling. This often poses difficulty, since competitors may include functionality that the design team chooses not to include. Nevertheless, function structure modeling can provide a means to list all known technical solutions to particular subfunctions.

Benchmarking of technical solutions and companies is more readily completed, but it requires a time history of product measurements. All technological innovations manifest themselves into the market along "S-curve" timelines, as shown in Fig. 11. As an example, consider clock speed for microprocessors. For all the different microprocessors on the market, one can plot the clock speed as a function of the time when the product was introduced. The metric values will naturally fall on an S-curve. First, the values are low and widely spaced: not much innovation is occurring in the market. Next, rapid innovation occurs, and many products are launched. The lower leg of the "S" is forming. Eventually, however, engineers cannot extract more performance. The slope of the "S" tops out, and the curve becomes flatter.

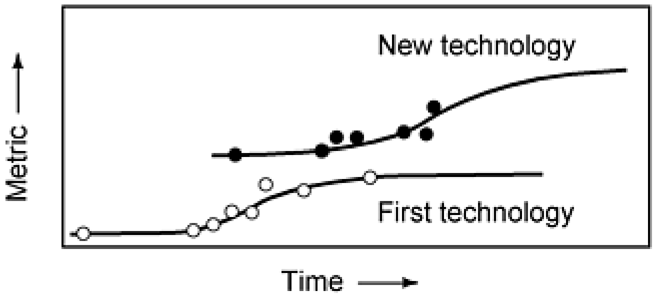

Fig. 11 Technological innovations plotted as S-curves

Industry trends are critical for a competitive company to understand. If the market is becoming more competitive, the company must understand that it needs to invest in product and process quality, or lose. If the market technology is topping out (the top of the "S"), the company needs to begin to invest in a new technology, to "jump" to the next S-curve, higher on the scale of the metric. Plotting trends provides all of this information. Clearly, trend charting of competitive data is a necessary and culminating business activity as part of product benchmarking.

Forming Quantitative Specifications

Having established the function structure/architecture and benchmarked competitive product performance, the design team must associate each subfunction with at least one line item in a product functional *specification sheet.* This sheet should give functional specifications about what the product must do, not necessarily specifications for purchasing components. The specification sheet should also rank each specification according to its importance.

The most common approaches to forming specifications are total quality management (TQM) methods (Ref 9, 31, 32), in particular quality function deployment (QFD) (Ref 33) and the house of quality (Ref 34). For the most part, these methods provide a means to agree on a proposed list of specifications and set target values on the variables. What these and other tools do not provide is a means to identify what variables should be used as specifications. How does one identify the important measurable variables?

Many researchers and practicing engineers have developed methods for forming specifications. Reference 3 contains an excellent chapter about forming product specifications and using the house of quality. Reference 34 is a classic article on the house of quality. Reference 33 is a text on QFD, complete with case studies. Reference 8 presents several methods for selecting among different variables. In all of these methods, the approach for generating variables is simply to be creative. In this section we review methods for generating and tracking specification variables.

Definition of Specifications

Typical definitions state that an engineering specification includes both a *metric* and a *value* (Ref 3). A metric is the quantity of discussion.The value is a target for the metric (either a particular number, a range, or an inequality).

These statements are easy to understand when operating with numerically real-valued metrics. It is not the case that all specifications must be real-valued, however. A specification can be generated using a collection of colors, smells, or other sets of elements that are hard to quantify.

In general, design team members subjectively interpret metrics and target values differently, based on their past experience. To be valid, a specification must have three characteristics that all team members implicitly or explicitly agree on:

- It must come from a set of different possible elements (or values).
- These elements must collectively be *comprehensive.*
- These elements must be *measurable.*

A set is comprehensive if, by knowing the value, the members of the design team can interpret the extent of achievement of the associated informal reason for setting the specification. For example, if a numerical specification of "20" for machinability is not agreed on or understood by the design team, it is not a good specification of machinability. The specification must be grounded with understood points (Ref 11), such as associating "50" with the machinability of 1020 steel.

Formal definitions of measurability exist (Ref 11), but essentially the design team must be able to order the set of values, at least partially. Otherwise, the set is no more formal than a person's subjective interpretations. It must be understood that "30" is better than or equal to "20" for example. This is not an issue with quantitative numbers, but it is with non-numeric datasets. (See the article "Computer-Aided Materials Selection" in this Volume.)

Identifying Specification Metrics

To establish an initial set of engineering specifications, a design team should begin by listing each subfunction. For each subfunction, a relevant product subsystem (either architectural assembly or physical subsystem of a redesign) is examined. From these sources, a means to "instrument" the product subsystem to measure the functional flows in and out of the sub-function should be considered. Depending on the product, this instrumentation can rely on engineering data acquisition, or it can be as simple as touch, feel, or look. A partial list for the fingernail clipper is shown in Fig. 12, with the process assumption of a mechanical cutting surface (a blade).

Subfunction	Specifications
Open system	Opening force
	Opening gap
	Opening grip area
	Opening surfact friction
Rough or long	...
Apply or release	...
Apply finger force	Fingerpoint surface friction
	Fingerpoint cupness
Convert to large force	Force gain
	Motion reduction
Guide to cut nail	Blade visibility
	Blade curvature
Move to cut nail	Open blade opening width
Cut nail	Sharpness
	Hardness
	Flatness
Store nail	Storage volume
Stop motion	Click sound
	Stop compliance
Release force	Expansion force
Release motion	...
Form filing surface	Opening friction torque
	Finger opening surface area
	Finger opening friction
	Finger pushing area
	Open alignment force
Form grasping surface	Grip area
	Grip surface friction
Orient filing surface	Filed nail visibility
Slide over fingernail	Filing surface area
	File roughness, left to right
	File roughness, right to left
Reset filing surface	Closed alignment force
Determine roughness	...
Cover cutting surface	Closed blade opening width
Close system	Closed arm force

Fig. 12 Generating metrics for subfunctions (fingernail clipper example)

This approach generally produces better results than other approaches, in that the sub-functions are more quantified than customer needs. The approach clearly relies on the creativity of the design team, but the creativity is composed of two stages: conceiving of the function structure itself and conceiving of how the flows of each subfunction can be "instrumented" for measurement on the product subsystem. It is less of a conceptual leap to generate measurable metrics for an independently generated set of subfunctions, each associated with a subsystem, than to generate measurable metrics for each customer need directly.

Next, the metrics generated must have target values assigned to them. This assignment is completed by examining the relevant customer needs associated with each metric. In general, establishing a target may require some calibration of the metric. For example, once it is understood that handle temperature is a good metric to represent comfort of the customer, it may be necessary to test different handle temperatures with customers to determine the highest acceptable temperature value.

After these steps, a relevant hierarchical set of functional specifications is completed. It can be collected into a house of quality matrix, for example, to verify and communicate how customer needs are being met. The house of quality can be used to document the product design targets of the different team members working in concert.

Ranking Specification Importance

Finally, the importance of each specification can be calculated through the house of quality. This calculation is carried out in the usual manner by inserting relationship values in the house of quality matrix to relate customer needs to engineering specifications. Then a suitable algebra is used to combine relationship ratings with customer need importance ratings, resulting in importance ratings for individual specifications.

The first step is to map customer needs to the specifications. In typical house of quality manner, the relationships are captured by a set of symbols, described below. There is always a question concerning how to make these assignments, and in this application, the problem is even more complex because of the additional *must* constraints. When some of the customer needs have *must* ratings and others do not, how can symbols be used to make importance ratings?

We propose the following system. One considers each specification one at a time and assigns symbols based on the following subjective rules:

Symbol	Meaning
Ȯ	Attaining the target on this specification will totally satisfy the customer need
○	Attaining the target on this specification will satisfy at least half of the customer need
△	Attaining the target on this specification will satisfy less than half of the customer need
(Blank)	Attaining the target on this specification will do nothing toward satisfying the customer need

The linguistic values of "half" and "nothing" define both the subjective weighting criteria and the level of resolution that the design team must take care to agree upon.

The next step is to map the *must* ratings of customer needs into *must* assignments for the specifications. The specifications with *must* ratings then act as functional constraints for the design team--they must be met.

It is not immediately clear what overall algebra is appropriate for mapping customer importance ratings (Eq 2 and 3) into importance ratings for the specifications. In particular, the means to combine *must* and non-*must* ratings is not obvious. On the other hand, it is clear that if a *must* customer need has a Ȯrelationship with a specification, then that specification deserves a *must* rating. For the remaining specifications that derive from that *must* customer need, the *must* ratings need not be treated as such, because they are already "covered" with a specification. That *must* customer need can be assigned the highest numerical importance rating in Eq 3 for use in ranking the remaining non-*must* specifications.

Given these insights, the best approach is to insist that every *must* customer need should have at least one Ȯentry in its mappings to the specifications. That specification can serve as a direct proxy measurement for the *must* customer need.

If no specification exists that can be directly mapped with an Ȯentry, the specification list should be re-examined. If the condition persists, the team must agree on the set of specifications that predominantly map to the *must* customer need. All of these specifications should then be assigned *must* ratings, keeping in mind that an excessive number of *must* ratings places excessive demands on a design team.

Once the specifications that act as constraints are identified, the subsequent specifications can be assigned numerical importance ratings. This process is usually a simple exercise of multiplication and addition. The causality values are given numerical equivalents, typically:

Symbol	Numerical equivalent	
	Option 1	**Option 2**
ȯ	9	1.0
○	5	0.5
△	3	0.3

Any *must* customer needs are assigned the maximum importance value, typically 9 out of 9 or 1.0 out of 1.0. Then the numerical importance of each specification is determined through a weighted sum across the needs:

$$\omega_i = \sum_j T_{ij}\, \omega_{\mathrm{CR}_j} \qquad \textbf{(Eq 4)}$$

where T_{ij} is a numerical equivalent taken from the table above. The results can then be linearly normalized to any selected scale.

The results for the fingernail clipper are shown and summarized in Fig. 13, the house of quality matrix for the clipper. Note the propagation of the *must* ratings onto the engineering specifications. These can now be readily modeled into hard constraints for the design team. The other numerically rated specifications become objectives that can be traded off in design decision making.

Generating Design Configurations and Form Concepts

Figure 13 illustrates a crisp, quantitative specification for product design. Its roots are grounded in customer needs, and its structure takes into account the established product functionality. However, this specification does not complete the conceptual design process. Form solutions must be generated for the decomposed subfunctions, combined into a finite set of concept variants, and then selected using the quantified specifications exemplified by Fig. 13. Other articles in this handbook document detailed methods for executing these tasks. As a preview, however, let's consider the fingernail clipper example and generate solutions that may be derived as a direct consequence of our systematic approach.

Various methods for concept generation are documented in the literature (Ref 2, 3, 14, 15, 16, 17, 18, 35). For the purpose of the fingernail clipper design, we seek to develop concepts according to a four-step process:

1. Generate as many solution principles to each of the subfunctions (Fig. 9) as possible.
2. Prune the number of solution principles using the criteria of Fig. 13.
3. Combine the remaining solution principles into a number of feasible concept variants that satisfy the entire set of product functions.
4. Identify avenues for function sharing in each concept variant to reduce part count and complexity.

Figures 14 and 15 illustrate a subset of the results from this process. The morphological matrix contained in Fig. 14 shows a breadth of form solutions to the decomposed functions. In turn, Fig. 15 shows some possible combinations into concept variants. Because the concepts are generated directly from the functional specification, the likelihood of satisfying customer needs is high. Figure 16 shows the range of fingernail clippers that are actually on the market.

Subfunction	Current	Solution principles		
Opening				
Open clipper	**Spin and flip**			
Determine rough or long				
Clip nail				
Determine apply or release				
Apply finger force	Shaped top, bent bottom	Shaped top and bottom	Hand grip	Finger holes
Convert to large force	Pivot	Linkage	Concentrate it	Pliers
Stop motion	Teeth hit	Peg		
Release force	Spring of bent body	Linear spring	Coil spring	Leaf spring
File nail				
Move file into place	Pivot out file	File on arm	Slide arm out	Flip out file
Slide over nail				
Determine roughness				
Return file in place	Pivot back file	(File on top arm)		
Closing				
Close clipper	**Flip and spin**			
Hold shut	Spring of bent body	Spring of bent body

Product Application Example

This section presents a brief example of successful product design. The product, known as Batter Up!, was an original design (Ref 36) that carved out a new market, initiating the first data point on an S-curve.

Children with disabilities need recreational opportunities and skills as part of their educational development (Ref 37). This general need led to the mission statement "to design a device and/or process that will enhance the recreational activities of students with severe mental and physical disabilities." After customer interviews at Rosedale School in the Austin Independent School District (Ref 36), the mission statement was refined to "the design of a product that would enhance tee ball for the students, while maintaining their integration in the community." The primary market for the device was thought to be educational institutions. Initial analysis showed that institutions should be able to fabricate the device themselves so that the cost would be under $100.

Customer needs analysis (10 customers) for this application gave the results shown in Fig. 17. Customers wanted a product that would guide a child's bat to hit a softball consistently and that would be adaptable to changing skill levels. Beyond these "musts," the critical needs identified were that the product should be adjustable in height for children in wheelchairs and children of various sizes, be usable without adult assistance, provide auditory stimulation for cause-effect learning, be easily storaged and transported, and be easy to build/duplicate.

Batter Up Project
Customer Needs

Interviewer(s): Seventh Inning Stretch Team
Date: 9/95
10 Number of customers
0–5 Weighting scale
75% Must confidence

Average customer:
Male/Female, age 12–21 yrs. old, student
Person with severe mental/physical disabilities

Customer need	Weight
Manufacturing	2
Easy to build/duplicate	4
Affordable	3
Set up	
Can be used in several positions	4
Useful for different grip abilities	1
Adjustable for different skills	Must
Various social settings	3
Operation	
Hits ball consistently	Must
Operates easily	3
Ball flies differently	3
User is independent	5
Resets itself	2
Stimulates sensory modes	
Visual	1
Tactile	3
Auditory	4
Store/maintain	
Compact transport/storage	4
Simple maintenance	3

Fig. 17 Partial customer needs list (Batter Up! example)

A black box model and refined function structure for this product are shown in Fig. 18. The system boundary for this functional analysis included only the operational phase, tee ball. In the function structure, notice the convergence of an external energy source and the human energy from the user. These energy flows, in addition to guidance functions, provide the primary means of satisfying the operational needs of students with disabilities.

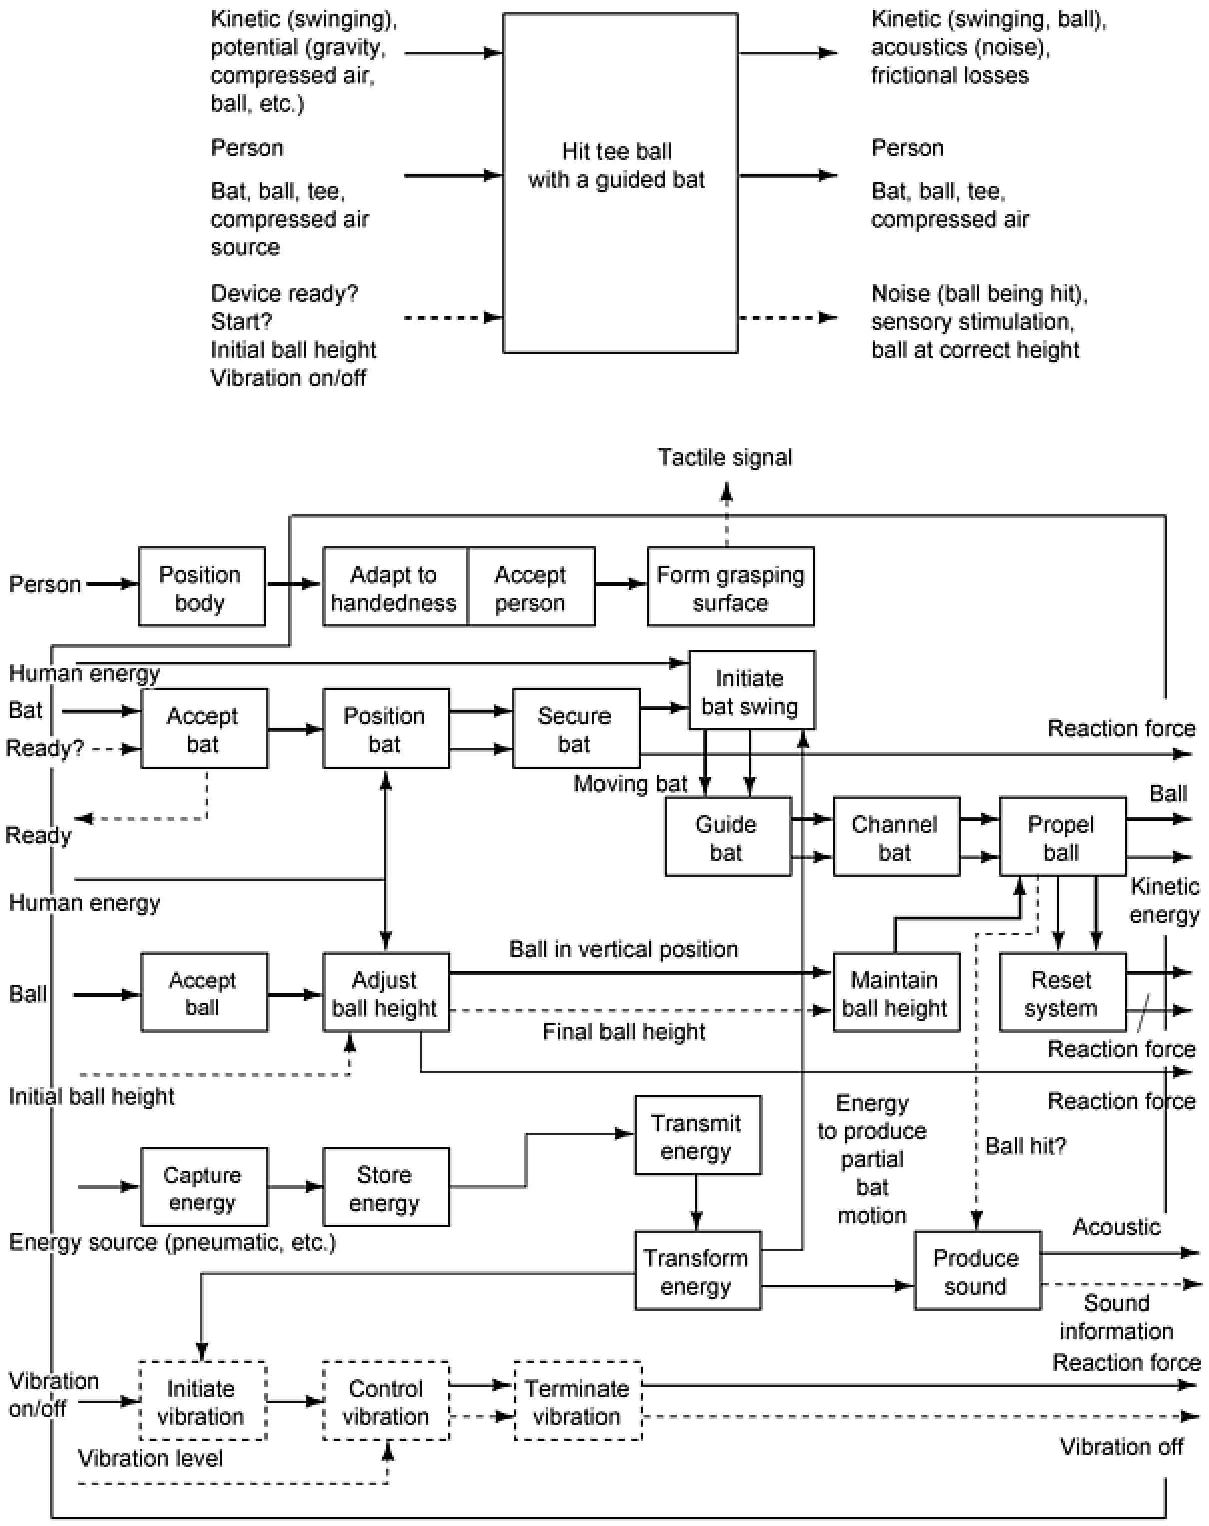

Fig. 18 Black box model and refined function structure (Batter Up! example)

A house of quality matrix for the product included measurements of the volume, mass, and number of piece parts. In addition, the length of bat grips, operating noise, range of bat height, range of handle movement, and range of bat speeds provided a quantified specification of the functions in Fig. 18.

Table 8 shows a partial morphological analysis of the main functions in the function structure. Solution principles are listed discursively according to energy domain. A wide variety of mechanical and electromechanical solutions are shown for the application, especially for the external energy source. These solution principles led to a number of concept variants.

Table 8 Partial morphological matrix (Batter Up! example)

Functions	Mechanical	Hydraulic	Electrical	Miscellaneous
Adapt to handedness	Gears, pulleys, wheels, pegs, pins	Water/air pressure	Solenoid, servo motor	. . .
Accept person	Walking, rolling to product	Riding a water wave, flying	. . .	. . .
Accept bat	Slot, groove, hole, guide rail, ridge	Fluid suction	. . .	Magnetic attraction
Position bat	Pegs, axis movement	Piston cylinder	Solenoid, servo motor	Magnets
Secure bat	Clamp, vice, belt, brace, latch	Fluid suction	Electrical charge (static cling)	Velcro, magnets, adhesion
Initiate bat swing	Conveyor, lift, mechanical impulse, catapult	Waterjet, piston cylinder	Electrical impulse	Magnetic repulsion
Guide bat	Guide rails, parallel plates, friction, loop on bat, string, hole in bat	Jet stream	. . .	Magnetic restriction/attraction
Channel bat	Human input, gravity, string	Air flow, water pressure	. . .	Magnets, explosion
Accept ball	Mount, cartridge, hoop	Tube	. . .	. . .
Adjust ball height	Jack, pegs, pulley system, lever	Air pressure	Electric current	Magnets, explosion
Maintain ball height	Clamp, mount	Air pressure, fluid suction	. . .	Magnets, adhesion
Propel ball	Loop, impact	Air suction, jet stream, water pressure	. . .	Magnetic attraction, explosion
Accept energy	Lever, four bar, crankshaft, rope	Tube, pipe, fan, windmill	Electrical inlets	Metal surfaces, panels, fuses
Store energy	Translational/rotational spring, material deformation, rubber band, pendulum, bat movement	Fluid column, compressed air (balloon, bladder)	Batteries, capacitor	Magnetic field, solar panels, chemical
Transform energy	Gears, belt/sprocket, lever, four bar, cam, rack and pinion, universal joint	Piston cylinder	Motor, generator	. . .

Transmit energy	Linkages bearings	Pipe, volume deformation	Wires, volt potential energy	Magnetic field
Initiate vibration	Button, lever, string, switch, key		Laser,	
Control vibration	Shaker, unbalanced motor, virotube, centrifuge	Pneumatic, wave machine, water pulse, bubbles	Sound waves (Bass)	Magnets
Terminate vibration	Button, lever, string, switch, key		Laser	. . .
Make sound	Chimes, bell, drums, siren, klaxon	Whistle, horn, water waves	Speaker	Chemical reaction, explosion
Stop bat	Block, slow with spring, sponge, pillow, rubber stopper, friction	Water/air resistance	. . .	Magnets
Reset function	Reapply functions: position bat, secure bat, accept ball, adjust ball height, accept energy, store energy			
Product stability	Weight, clamps, stakes, balance, strength of materials	Suction cups	. . .	Gyros, magnets, adhesion of part joints
Universal design	Global function			
Inclusion	Global function			

Figure 19 illustrates the selected concept. This concept, based on a pneumatic energy source and a guide line, was designed to make use of basic hardware in consideration of the fabrication limitations of wood shops in secondary schools. After prototype testing, this assistive device was successfully installed in the Austin Independent School District.

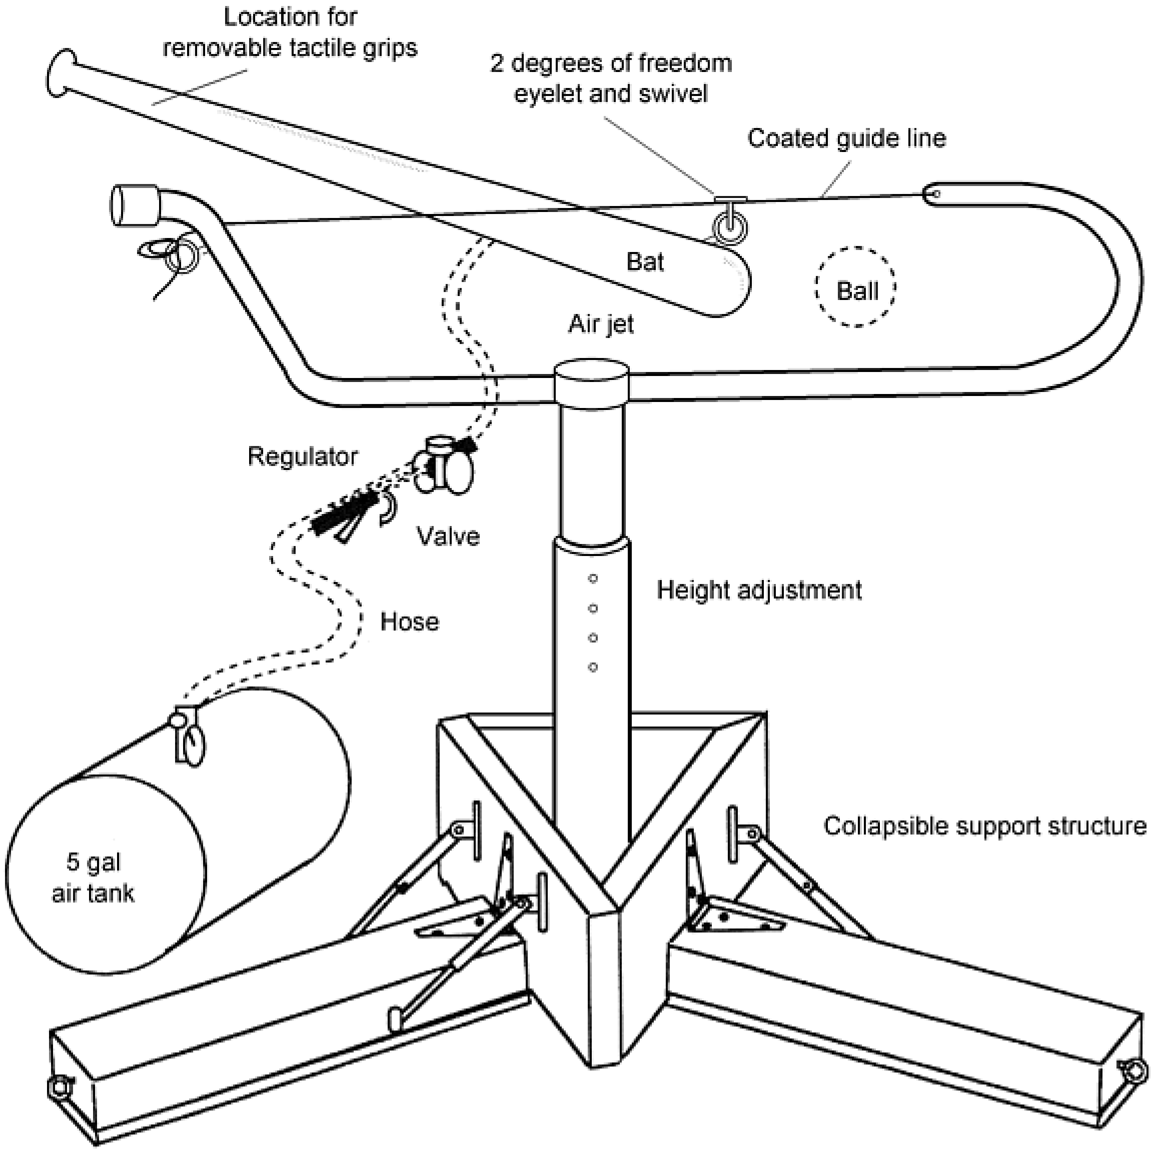

Fig. 19 Design concept for beta functional prototype (Batter Up! example)

Conclusion

Product concepts begin and end with the customer. A concise and quantified specification is essential to developing suitable concepts, and this article presents a systematic method for creating such a specification. We begin with the technical and business market, probing the design task for legitimacy. Customer needs analysis, functional decomposition, and competitive benchmarking are then presented as methods for directly mapping customer statements to functional requirements, in the context of competitors' products. Results of these methods lead to a house of quality matrix, forming the product specification and setting the playing field for concept generation. Further information is provided in the articles "Conceptual and Configuration Design of Parts" and "Creative Concept Development" in this Volume.

A common criticism of design methodology is that it is explanatory and thought-provoking, but not relevant to actual practice. This criticism is becoming an antiquated view. Leading industrial companies are constantly seeking more structured approaches to their product development processes, especially in the era of concurrent development, intensive computing, and downsizing of workforces. An effective structured method allows not just one expert to understand and complete a task, but many others as well, and it provides for all decisions to be documented in case of subsequent redesign.

Conceptual and Configuration Design of Parts

John R. Dixon, Professor Emeritus, University of Massachusetts Amherst

Introduction

PRODUCTS ARE DESIGNED by a recursive process that decomposes the initial abstract physical and functional concept of a whole product into subassemblies, and then decomposes the subassemblies further into more subassemblies, and so on until all the elements that describe the product are either individual parts or standard modules. As recursive decomposition proceeds, the description of the product--that is, the design--becomes less and less abstract and more and more detailed. Ultimately, the specific standard modules and standard parts to be used must be selected by the designer, and any nonstandard (i.e., special-purpose) parts must be designed. (A *standard module* is a product manufactured in quantity for use in a number of other products. Examples are motors, clutches, switches, pumps, and the like. A *standard part* is a part manufactured in quantity for use in a number of products. Examples are screws, bolts, brackets, beams, shafts, and the like. Most standard parts and standard modules are offered for sale through the catalogs of their manufacturers.)

This article concerns the conceptual and configuration design of *special-purpose parts*--parts that are designed and manufactured especially for use in a particular product (Ref 1). In the design of special-purpose parts, the following issues must be considered, and the discussion here is organized in terms of these issues:

- Functionality
- The relationship of the part to the whole assembly or subassembly, including their design for assembly
- The material from which the part will be made and the process by which it will be manufactured
- Developing the configuration
- Space, fit, and tolerances
- Design for manufacture (DFM)

Although these issues can be discussed separately and sequentially, designers must consider them simultaneously (or at least repeatedly and iteratively) as parts are designed. Beginning a part design, however, requires a clear understanding of the function of the part to be designed.

Part Functions

At their most abstract level, parts are initially conceived as the result of the functional or physical decomposition of an assembly or subassembly. Thus, parts contribute to the overall functionality of their parent assembly. However, unless the product consists of only one part, the function of a part is never identical to the function of the product as a whole. Parts have their own special, usually limited and highly technical, functions. Only in synergistic concert do the functions of parts produce the function of their assembly or product. Readers are referred to the article "Conceptual and Configuration Design of Products and Assemblies" in this Volume for a complete discussion of product and assembly functionality.

Table 1 is a list--comprehensive, but not necessarily complete--of functions served by parts. There are also a few examples of the types of parts and features of parts that perform the listed functions. Some parts, of course, are designed to serve more than one function.

Table 1 Functions served by parts

Function	Examples of part types or features
Transmit or support force(s) or torque(s)	Brackets, beams, struts, columns, bolts, springs, bosses, knobs
	Levers, wheels, rollers, handles
	Parts that fasten, hold, or clamp, such as bolts, screws, nails
Transmit or convert energy	
Heat	Heat fins, electric resistance heating elements
Mechanical power	Shafts, connecting rods, gears
Electricity	Wires, lightbulb elements, resistors
Provide a barrier (for example: reflect, cover, enclose, or protect)	
Light	Walls, plugs, caps
Heat	Thermal insulators, thermal reflecting surfaces
Electricity	Electrical insulators, magnetic shields

Sound	Walls, sound-absorbing wall surfaces
Control motion	Cams, grooves, slots, gears
Allow passage (of light, rods, shafts, wires, pipes, etc.)	Holes, windows, grooves
Control or regulate the passage of	
Fluids	Nozzles, orifices, pipes, ducts
Light	Shutters, wheels
Indicate	Clock hands, instrument needles, colors, embossing
Locate or guide	Grooves, holes, bosses, tabs, slots

In addition to such overall part functionality, special features are almost always designed into parts to aid in their manufacture or to reduce material cost. Examples are listed in Table 2.

Table 2 Special features designed into parts to aid manufacturing or to reduce material cost

Function	Examples of part features
Aid manufacturing	Fillets, gussets, ribs, slots, holes
Add strength or rigidity (e.g., stiffen)	Ribs, fillets, gussets, rods
Reduce material use	Windows or holes through walls, ribs that allow thinner walls, slots
Provide a connection or contiguity (so the part can be a single part)	Walls, rods, ribs, gussets, tubes

Conceptual and Configuration Design of Parts

John R. Dixon, Professor Emeritus, University of Massachusetts Amherst

Relationship of Parts to Assemblies

By performing their own limited functions, parts contribute to the functionality of their parent assembly or subassembly. However, parts are expensive, sometimes very expensive. Not only are they expensive to design--a typical part in a complex assembly can require three to four designer-months--but then the parts must be manufactured. This requires the design and manufacture of tooling as well as the cost of materials and processing. Then the parts must be assembled, either manually or with the aid of machines.

Design and manufacturing costs for parts are substantial, but they are not all the costs--and sometimes not even the largest. Parts must be stored, kept track of, and often distributed for regional or local inventories. The overhead costs associated with a given part varies depending on the nature of the part and the business, but they can be large.

The design rule resulting from these considerations is that the number of parts in a product should be minimized. Thus, after the function of a part has been articulated, the next step in the design process is to determine whether the part is *really* necessary. Can the function be eliminated, or can the function be accomplished by combining parts? For specific guidance in addressing this issue, readers are referred to the article "Design for Manufacture and Assembly" in this Volume and to Ref 2.

There is a tendency for designers to underestimate the importance of reducing part count in a product, especially when combining part functions results in parts that are very complex. Though precise calculations are not possible, all indications are--everything considered--that a single complex part is less expensive than two simpler parts. Moreover, this conclusion is generally true even when the combined part becomes extremely complex. As long as a single complex part can be manufactured and assembled, it is almost always the preferred design.

There is a proviso. If the single, more complex part is going to cause a costly time-to-market delay during tooling and production ramp-up, then the savings may not be realized. See Ref 3.

To illustrate, one firm designed a new single part that would replace eleven injection-molded parts. Not surprisingly, the new part was incredibly complex. When it came time to produce it, the extreme complexity made rapid, high-yield production impossible. Therefore, the design was modified resulting in two parts, and new tooling made. Subsequent production went very well. Fortunately in this case, the time delay required to redesign the new part, and to get new tooling, was not critical to marketing the product. Thus, in this case the net savings in tooling, manufacturing, assembly costs, and overhead created by reducing eleven parts to two were tremendous.

Design for manufacturing requires designers to know the limitations of manufacturing processes, so they will not design parts that are unnecessarily difficult or expensive to produce. As pointed out in the article "Design for Manufacture and Assembly," however, reducing part count requires that designers know not only the limitations of processes but also their full capabilities, so that savings derived from employing fewer parts, even if they are more complex, can be realized.

Material and Process Selection

Generally the design of a part cannot begin, and can never proceed very far, without a decision being made about the material and manufacturing process to be employed. This subject is covered thoroughly in the articles "Relationship between Materials Selection and Processing," and "Manufacturing Processes and Their Selection," in this Volume.

Because this subject is discussed so completely elsewhere in this Volume, it will not be discussed here. Readers should note, however, that materials and process selection is a critical and early step in the design of every part.

John R. Dixon, Professor Emeritus, University of Massachusetts Amherst

Determining the Configuration

The preliminary steps in part design have been described above: identifying the required functions of the part, determining whether the part is really necessary, and selecting the material and manufacturing process by which the part will be made. Next, designers must make decisions about how the part will be configured.

To configure means to select the elements of which an object will be composed and to arrange the relative positions and connectivity of those elements. Exact dimensions, precise shapes, and tolerances are not explicitly included in the configuration design.

The "elements" that comprise a part are called features. The types of features that can make up a part include:

- *Walls* of various kinds such as flat, curved, and so forth
- *Add-ons* to walls such as holes, bosses, notches, grooves, ribs, and so forth
- *Solid* elements such as rods, cubes, tubes, spheres, and so forth
- *Intersections* among the walls, add-ons, and solid elements

There are usually several--and sometimes many--ways a part can be configured. As always in design, it is best to proceed by first generating a number of alternatives and then evaluating, modifying, and again evaluating the alternatives before accepting one of them. In part design, the only feasible way to get started with this process is by creating sketches of alternative configurations. Because parts are usually three dimensional, this requires designers to possess good three-dimensional visualization and drawing abilities. The sketching can be done with a computer if the available modeling software supports quick generation of the alternative possibilities. At this stage in the design, sketches need not be formal and dimensions need be only approximate. The goal here is only to determine what features and arrangement of features will result in the best overall design once dimensions and tolerances are assigned.

Making sketches of a part can begin only after the space allowed for the part and the physical contacts required for it are defined, at least approximately. Thus the process begins with a sketch of the surroundings of the part. This sketch should be roughly to scale, but only roughly because the design of the surrounding parts may not be complete, or will be subject to revision. This sketch will show not only the material surroundings but also the approximate locations of external forces, flows, energy transfers, and the like that the part must accommodate. Thus sketching begins by showing the essential surroundings of the part and locates loads, possible support points or areas, heat or other energy flows, adjacent parts, forbidden spaces, and so on.

With the surroundings defined as much as is practical, the sketching of alternative part configurations can begin. Even in relatively simple cases, however, there may be far too many possible configurations for all to be considered. The generation of alternatives must be guided and limited by qualitative physical reasoning about the functionality of the part and about manufacturing issues. These two subjects are discussed in the next two sections of this article.

One way to think about a configuration is to note that it establishes the attributes of the part that will require subsequent dimensioning.

John R. Dixon, Professor Emeritus, University of Massachusetts Amherst

Qualitative Physical Reasoning to Guide Generation of Part Configuration Alternatives

Considering geometric issues only has the potential for generating a very large number of alternative configurations. The generation process must be guided and limited in a way that provides a smaller set of those alternative configurations that are the most likely to be successful. Then this smaller set can be subjected to more detailed evaluation and redesign. This guidance is provided by qualitative physical reasoning about the functionality and manufacturability of the configuration. Even though at the configuration stage of part design actual dimensions have not been determined--the sizes and spatial relationships of the features are still only approximate--knowledge of physical principles and manufacturing processes can still be applied to help create the most effective alternative designs for further evaluation.

Qualitative in this context means, essentially, without numbers--though orders of magnitude of numbers are usually involved. The basis of qualitative reasoning is rooted in fundamental physical principles. It is much, much more objective than guesses or feelings. To illustrate, the following paragraphs discuss some of the configuration issues that can be guided by qualitative physical reasoning.

Material Use. Good configurations will enable the use of as little material as possible; that is, they can use material efficiently to achieve their functionality. The I-beam configuration is a good example of material efficiency when the function is to support a load across an open space. By placing the most material away from the neutral axis of the beam, it makes maximum use of the material to carry the load.

In the case of a part whose function is to transmit a force, a very common part function, stresses in the part should be as uniform as possible throughout, and as high as is safe. Having relatively lightly stressed material in some sections of such a part is a waste of material, at least from a functional point of view in supporting forces. Thus, configurations are best that have the potential for uniformly high stresses throughout. This generally means that tension and compression are better than bending for supporting and transmitting forces.

There are exceptions to this general guideline, however, because manufacturing must also be considered. In a forging, for example, it may be that reducing the amount of material used results in the need for more dies and higher loads (to move more material greater distances and to produce the thin sections). The added dies and processing costs may be greater than the cost of material saved.

Columns can fail in compression, but mostly they fail by either lateral or torsional buckling. The latter is a special concern because it is often neglected, allowing columns to be designed that are perfectly safe in compression and even lateral buckling, but which fail (sometimes surprisingly) by twisting.

It is known from strength of materials principles that the cross-sectional second moment of area is a key to buckling resistance. For lateral buckling of a column, the minimum moment, considering a 360° realm of possibilities, is the only one that matters. Thus a configuration that has a more-or-less constant moment of inertia regardless of orientation will be the most efficient. Clearly, a round (or at least symmetrical), configuration is the most efficient.

For torsional buckling, it is the torsional second moment of area that matters. Intersections of walls increase this moment somewhat, but the most effective configuration against torsion is to create sections that are hollow. This has the effect of moving material away from the axis of twist, somewhat analogous to the logic of an I-beam. Thus if torsional buckling is a concern, a hollow symmetrical section may be most efficient.

Brackets and Trusses. A bracket is a part whose function is to support a load or loads, transferring the force to an adjacent supporting structure, usually a wall of some kind. Brackets often must be designed with spatial constraints in mind; that is, there are regions of space that may not be invaded by the bracket material. But whatever the constraints, qualitative rules can help guide the generation of effective alternatives. A few examples of such rules follow.

Tension and compression are more efficient ways to transmit forces from one place to another than is bending. When bending is required, it is best to make the "beam" as short as possible and make the cross section as much like an I-beam or box as possible.

In most trusses, loads are carried by compression and tension; thus trusses tend naturally to be efficient configurations from the standpoint of material use.

Sometimes, a trusslike structure must be designed to connect loads at oddly distributed points to supports at other locations. Configurations that have the potential for using as much tension and compression as possible (as distinguished from bending) are desirable. Thus placing members in the same directions as the loads can produce a more effective configuration.

Inside Corners. To reduce local stress concentrations, configurations that allow for rounded inside corners or that can add on fillets are best. As an added benefit, rounded inside corners almost always support ease of manufacturability.

Heat Transfer. The configuration of parts whose function involves the transfer of heat can also be evaluated, in part, by qualitative physical reasoning. Heat is transferred by conduction, convection, and/or radiation. To the extent that the heat transfer mechanism employed is conduction, configurations that result in the lowest possible temperature gradients are the best. This is accomplished by providing the potential for using a high thermal conductivity material and by providing for a suitably large, direct path. Configurations that provide opportunities for reducing contact resistances to adjacent parts involved in the heat flow are also helpful.

When convection is the primary mechanism, increasing the heat flow requires a configuration that provides large surface areas adjacent to the surrounding medium. (This is the reason fin configurations are often used.) If the configuration can help induce turbulence in the surrounding medium, that is also helpful. In the case of finlike parts, the surface area is naturally large, but designers must also consider the need for conduction of heat to the extremities of the fin. Keeping a uniformly high temperature would require a tapered fin, but this may raise manufacturing difficulties. Fins that are too long and thin cannot be manufactured easily, but this is an issue that will get sorted out during the parametric design stage.

Radiation is an important heat-transfer mechanism requiring that the heat exchanging surfaces be as large as possible, and be "visible" to each other. The materials should have the potential for being made with surfaces of high emissivity and absorptivity.

Whenever possible, of course, configurations that can make use of multiple heat-transfer mechanisms may be advantageous, but trade-offs here are not always obvious until computations can be made at the parametric design stage.

Insulating against Heat Transfer. To insulate against heat transfer, designers must try to prevent or reduce all three of the heat-transfer mechanisms: conduction, convection, and radiation. To reduce conduction, configurations that can reduce or eliminate direct paths for heat conduction, especially when the material has a high thermal conductivity, must be used.

To block convection, the circulation of the surrounding gas, usually air, must be inhibited. Most insulating materials thus create a large number of very small pockets for gas, which (if it cannot circulate to produce convection heat transfer) is a poor conductor of heat.

An interesting configuration to discuss here in the context of qualitative reasoning about configurations is the evacuated wall bottle for storing hot or cold liquids. This configuration virtually eliminates both conduction and convection through the sides and bottom by employing an evacuated chamber in which there is no material to conduct heat or air to circulate in convection. Moreover, by using very low emissivity surfaces, it reduces radiation greatly. Almost all of the heat loss from such a bottle is through the corked opening, which should therefore be kept as small as possible.

Residential windows make another interesting example of configurations that must resist heat transfer. Configurations of metal-frame windows that allow a direct metal (or even wood) path from outside to inside are poor, of course. The concept of providing an air space between two panes in such windows is based on qualitative reasoning about heat transfer: the air space is an insulator, but it does not interfere with light flow.

John R. Dixon, Professor Emeritus, University of Massachusetts Amherst

Qualitative Reasoning about Manufacturing to Guide Generation of Part Configuration Alternatives

Configurations of parts are also strongly influenced by manufacturing issues, and it is not necessary or desirable to wait until dimensions and tolerances have been established to consider manufacturing issues in part design. This is one important reason the manufacturing process must be selected early in part design, and it is also the reason designers must be familiar with manufacturing processes.

This Volume contains a number of articles describing various manufacturing processes in considerable detail, so they will not be discussed in detail again here. See also Chapter 3 in Ref 1.

The following paragraphs describe typical DFM guidelines for several of the most widely used processes. The list is by no means complete, and is intended only to indicate the kinds of issues that can be considered in guiding the generation and evaluation of part configurations.

Qualitative DFM Guidelines for Injection-Molded, Compression-Molded, Transfer-Molded, and Die-Cast Parts. Injection molding, die casting, compression molding and transfer molding are all internal flow processes, followed first by cooling and solidification, and then followed by ejection from the mold. Thus, part configurations for these processes should ideally be designed so that: (a) the internal flow can be smooth and fill the cavity evenly, (b) cooling, and hence solidification, can be rapid to shorten cycle time and uniform to reduce warpage, and (c) ejection can be accomplished with as little tooling complexity as possible.

In designing parts to be made by injection molding, die casting, compression molding, and transfer molding, designers must decide--as a part of their design--the direction of mold closure and the location of the parting surface. Though these decisions are tentative, and advice should be sought from a manufacturing expert, it is really impossible to do much DFM in these processes until they are made.

An easy-to-manufacture part must be easily ejected from the die, and dies will be less expensive if they do not require special moving parts (such as moving side cores) that must be activated in order to allow parts to be ejected. Because undercuts require side cores, part configurations without undercuts are less costly to mold and cast. With knowledge of the mold closure direction and parting surface, designers can make tentative decisions about location(s) of features (holes, projections, etc.) in order to avoid undercuts wherever possible.

Because of the need for resin or metal to flow through the die cavity, part configurations that allow for relatively smooth and easy internal flow paths with low flow resistance are desirable. For example, sharp corners and sudden changes or large differences in wall thickness should be avoided because they create flow problems. Such features also make uniform cooling difficult.

Thick walls or heavy sections will slow the cooling process. This is especially true with plastic-molding processes because plastic is a poor thermal conductor. Thus, part configurations that will not result in thick walls or other thick sections are less costly to produce.

In addition, every effort should be made to design part configurations that will enable walls of uniform, or nearly uniform, thickness to be designed. If there are both thick and thin sections in a part, solidification may proceed unevenly, causing difficult-to-control internal stresses and warping. Remember, too, that solidification time, and hence total cycle time, is largely determined by the thickest section.

Large or complex parts may require two or more gates through which resin or metal will flow into the mold. There will then be fusion lines in the part where the streams meet inside the mold. The line of fusion may be a weak region, and it may also be visible. Therefore, designers who suspect that multiple gates may be needed for a part should discuss these issues with manufacturing experts as early as possible in the design process. With proper design and planning, the location of the fusion lines can usually be controlled as needed for appearance and functionality.

DFM Guidelines for Stamped Parts. Because of the short cycle times per part, tooling and material are generally the dominating cost factors for stampings. For example, at production volumes less than 100,000, the proportion of part cost due to tooling is about 75%, while the proportion of part cost due to processing is less than 2%. Even at production volumes of about 2,000,000, the proportion of part cost due to processing still remains low (less than 5%). At such large production volumes, the greatest proportion of part cost (about 75%) is due to material cost.

For large production volumes, designing part configurations to reduce the amount of scrap can be important. However, in most cases, it is the manufacturing process designer who designs the stamping process (often referred to as developing the "strip layout" for the part) to achieve minimum scrap. Therefore, the discussion below is primarily about the relationship between part design and tooling cost.

The number of distinct features in a stamped part configuration should be kept to a minimum. The reason is that as the number of distinct features increases, the number of die stations increases and both die construction costs and die material costs increase.

The necessity for closely spaced features (holes, slots, ribs, etc.) should be avoided when possible. If features must be spaced closely together (less than three sheet thicknesses), then there may be insufficient clearance for the punches. Even if space permits, however, the die sections become thin, making them susceptible to breakage, and punch breakage can occur due to metal deformation around any closely spaced features during piercing. As a result, two stations are required for each type of closely spaced feature; each station creates alternating features.

Configurations that require the use of narrow cutouts and narrow projections should be avoided. If a narrow projection is present, then to separate the link from the strip at one station requires a blanking punch with a narrow cutout along with a die containing a narrow projection. In this situation, the narrow section of the die would be easily susceptible to damage.

The number of bend stages in a part should be kept to a minimum. A U-shaped part, with both bends in the same direction, will have both bends created at the same time at one die station. An equivalent Z-shaped part, with bends in opposite directions, will require that each bend be separately created at two different die stations. Thus, bends in opposite directions create increased tool construction and die material costs.

Bend angles greater than 90° should be avoided whenever possible. To create a bend angle greater than 90° requires two die stations. At the first station the part is bent through 90°, while at the next station the part is bent past 90°. Clearly, then, parts with a bend angle greater than 90° require more costly tooling. Thus, configurations that require side-action features should also be avoided, if feasible. Features such as holes, whose shape and/or location from a bend line must be accurately located, must be created after bending. This requires that one or more additional die stations be added, thereby increasing tooling cost. Also, because the bends themselves cannot be closely controlled, they make poor reference points for important or close tolerances. In general, to keep side-action features to a minimum, the tolerances of feature dimensions that must be referred to bend lines should be generous.

Design for Manufacturing Guidelines for Forged Parts. The nature of the forging process--solid metal is squeezed and moved within a die set to form a part--leads to the following broad DFM guidelines for consideration at the configuration stage.

Materials should be used that are relatively easy to deform because they will require fewer dies, shorten the processing cycle, and require a smaller hammer or press.

Part shapes that provide smooth and easy external flow paths are desirable. Thus, corners with generous radii are desirable. In addition, tall thin projections should be avoided because such projections require large forces (hence large presses and/or hammers) and more preforming stages (hence more dies), cause rapid die wear, and result in increased processing cycle time.

Ribs, if any, should be able to be widely spaced. Spacing between longitudinal ribs should be greater than the rib height; spacing between radial ribs should be greater than 30 °C. Closely spaced ribs can result in greater die wear and an increase in the number of dies required to produce the part.

Internal undercuts, and external undercuts caused by projections, must be avoided because they are impossible to form by the movement of solid metal. External undercuts that are the result of holes should be avoided because they increase both die costs and processing costs.

Qualitative Reasoning on Design for Manufacturing Aluminum Extrusions. Most DFM considerations for aluminum extrusions evolve from the difficulty of forcing the metal to flow uniformly from a large round billet through small complex die openings. This leads to the following "rules" that can help guide the design of more easily extrudable aluminum parts.

Sections with both thick and thin sections are to be avoided. Metal tends to flow faster where thicker sections occur, giving rise to distortions in the extruded shape. Designs should be used that will function with all the walls as uniform in thickness as possible. Designs requiring slugs of material should be avoided. Long, thin wall sections should also be avoided, because such shapes are difficult to keep straight and flat. If such sections are absolutely necessary, then the addition of ribs to the walls will help distribute the flow evenly.

Hollow sections are quite feasible, though they cost about 10% more per pound produced. The added cost is often compensated for by the added torsional stiffness that the hollow shape provides. It is best if hollow sections can have a longitudinal plane of symmetry.

"Semihollow" features should be avoided. A semihollow feature is one that requires the die to contain a very thin--and hence relatively weak--neck.

Design for Assembly Guidelines for Part Design at the Configuration Stage. Readers are referred to the article "Design for Manufacture and Assembly" in this Volume and to the references included there.

Tolerances

The issues of tolerances are at the intersection between the requirements of functionality and capabilities of manufacturing processes. Proper tolerances are crucial to the proper functioning, reliability, and long life of products. However, at the same time a common cause of excessive manufacturing cost is the specification by designers of too many tolerances and/or tighter-than-necessary tolerances.

Mass-produced parts cannot all be produced to any exact dimensions specified by designers. In a production run, regardless of the process used, there will always be variations in dimensions from nominal. Some of the reasons are: tools and dies wear, processing conditions change slightly during production, and raw materials vary in composition and purity. Modern methods for controlling processes are achieving increasingly consistent and accurate dimensions, but variations of some frequency and magnitude are inevitable.

Designers can, in order to get the functionality required, specify the range of dimensional variations in parts that reach the assembly line. However, the stricter these limitations, and the more dimensions subject to special tolerance limitations, the more expensive the part will be to produce.

Fortunately, the functionality of parts seldom, if ever, requires that all or even most dimensions of parts be controlled beyond that obtained by normal manufacturing practices. To achieve the desired functionality (and other requirements) of a part, generally only a few dimensions and other geometric characteristics (e.g., straightness or flatness) may require especially accurate control, while others can be allowed to vary to a greater degree. Thoughtful configuration design can result in parts and assemblies in which the number of characteristics requiring greater than standard dimensional control is minimal. Also, those dimensions that do require critical control may be of a type or at a location where they are more easily controlled during manufacturing.

Every manufacturing process has standard or commercial tolerances. These are the tolerance levels that can be produced with the normal attention paid to process control and inspection. Though standard tolerance values are not always completely and accurately defined--and available in print for designers--they are generally well known to manufacturing process engineers. See also Fig. 5 in the article "Overview of the Materials Selection Process" in this Volume.

Parts designed so that there are no requirements tighter than standard will be the least expensive to produce. Moreover, and this is an important point for designers, the *number* of tolerances that must be critically controlled, whether standard or tighter, is also crucial to ease and cost of manufacturing. Controlling one or two critical dimensions, unless they are of an especially difficult type or extremely tight, is often relatively easy to do if the other dimensions of the part do not need special control.

At the configuration stage of design for parts, even before exact dimensions are assigned, designers can and should think ahead about the dimensions or other characteristics (e.g., flatness) that will need tight tolerancing to achieve the desired functionality. Configurations should be developed, if possible, that reduce the number of such dimensions or characteristics, and configurations avoided that will make tight tolerances more difficult to control. The following paragraphs provide some guidance for several of the most used manufacturing processes.

Injection Molding and Die Casting. In every manufacturing process, certain features, when present and involved in a tolerance specification, have special influence. For example, in injection molding and die casting, the base angle of an unsupported projection or wall will be difficult to control precisely. Thus tolerances applied to dimensions that relate to the end of such projections will also be difficult to control. The unsupported projection or wall is called a tolerance influence feature. Other tolerance influence features in injection molding and die casting include:

- Undercuts
- Unsupported walls and unsupported significant projections
- Supported walls and supported significant projections
- Primitive connections or intersections
- Parting plane

Some of these features (e.g., undercuts) are clearly identifiable at the configuration stage. The existence of others can be verified only after dimensions are added. However, even in these cases, it is often apparent at the configuration stage, even without exact dimensions, that the potential for adverse influence on tolerancing exists.

Trade associations--for example, the Society of the Plastics Industry (SPI)--also describe the features of parts that affect the ability of processes to hold tolerances easily. The Society of the Plastics Industry considers two types of tolerances: dimensional tolerances such as size and location, and geometric tolerances that refer to orientation.

By listing the above tolerance influence features, it is not implied that the presence of a feature in a part necessarily leads to the tolerancing difficulties or added costs. The variable capability of molders and the quality of equipment make exact prediction impossible. It is implied, however, that the presence of the listed features in a part configuration is a signal that designers should investigate their possible impact on tolerancing. Moreover, the number of such features involved in tolerancing should be kept as small as possible.

Stamped Parts. The tolerance influence features in stamping are:

- Side-action features (undercuts)
- Closely spaced features
- Multiple bends

Tolerances involving multiple bends (e.g., on dimensions across one or more bends) are difficult to control in stamped parts because the bends themselves are difficult to control exactly, in part due to springback of the sheet after bending.

Aluminum Extrusions. Configuration guidelines for ease of tolerance control in aluminum extrusions include:

- Avoid tight straightness tolerances on long, thin wall sections. Add small ribs to help achieve straightness.
- Angles of unsupported wall sections are difficult to control precisely. Hence, tolerances on size dimensions involving long legs are difficult to control. If necessary for tolerance control, support long legs with webs connecting to other parts of the extrusion. (This may create a more costly hollow shape, but if tolerances are critical, it may be necessary.)
- Using uniform wall thickness throughout the cross section makes all dimensions easier to control.
- Rounding inside corners makes angles easier to control than when corners are sharp.
- The dimensions of symmetrical shapes are generally easier to control than nonsymmetrical shapes.

Note how some of the issues here are similar to those in injection molding; the reason is that both are internal flow processes.

Forging. Shrinkage and warpage contribute largely to the difficulties of controlling tolerances in forging. By designing forged parts so that they have simple shapes and common proportions, designers can help minimize these effects. It is also important to provide for well-rounded corners, fillets, and edges. Thin sections, such as webs, should be kept to a minimum in number and should be made as thick as possible.

As in injection-molded and die-cast parts, dimensions that extend across the forging die closure parting plane are more difficult to control than those on one side only of the parting plane.

Design for Tolerances: General Guidelines for Configuration Stage. In addition to the process-specific guidelines outlined above, there are some design guidelines relevant to tolerances that apply to all processes:

- Designers should consider tolerances with not only the function in mind, but also with knowledge of the standard tolerance capabilities of the proposed manufacturing process.
- Designers should minimize the need for and use of tolerances; not every dimension requires a special tolerance. The fewer tolerances that are specified, the easier the part will be to manufacture.
- Where tolerances are required, designers should attempt to avoid the need for tolerances that are tighter than standard for the proposed process.
- If nonstandard tolerances cannot be avoided, then the number of them should be minimized.
- Avoid redundant dimensions and consider stack-up effects in evaluating tolerances.

Conceptual and Configuration Design of Parts

Evaluating Trial Part Configurations

Once the set of the most practical part configurations has been generated using the guidelines presented above, a more formal evaluation should be performed. The evaluation can be done by Pugh's method (Ref 4) or by other methods presented in Ref 1. In any method, the criteria on which the alternative configurations are compared will include the following:

- *Functionality:* Can exact dimensions and tolerances be imposed that will enable the part to perform its function properly and reliably?
- *Use of materials:* When dimensions are imposed, will the configuration provide for efficient use of all the required material?
- *Mechanical failure:* When dimensions are imposed, can the risks of failure from mechanical causes such as fatigue, excessive stress, buckling, and so forth, be made suitably low?

- *Analyzability:* Does the configuration enable analyses to be performed for stresses, vibrations, heat flow, and so forth?
- *Manufacturability:* Can the selected manufacturing process hold the tolerances that will be needed for the configuration to meet the required functionality? Does the configuration allow for ease of handling and insertion for assembly? Are there special issues that will influence the time required for tooling and production?

It should also be noted that the tooling costs for parts can be compared quite well when the configuration has been established. Exact dimensions are not required. (See Ref 1, Chapters 11 and 12.)

Conceptual and Configuration Design of Parts

John R. Dixon, Professor Emeritus, University of Massachusetts Amherst

Looking for Risks

All evaluation methods in some sense balance expected benefits against potential risks. Therefore, the notion of *explicitly* looking for technical and manufacturing risks in a design is useful. The idea is to look for any previously unquestioned assumptions that have been made while generating the configuration and while doing the evaluations--that is, to look for issues that may so far have been overlooked.

Risk cannot be avoided completely. No matter how conservative a configuration design is, there will be some risk, some places where absolutely complete information does not exist. Indeed, good designs will have some reasonable risk or they will be too conservative, too costly, too heavy, and so on. However, designers cannot count on good luck: there are many more ways for a design to fail than there are for it to succeed. Thus, risks must be sought out, faced, and evaluated. Table 3 lists questions intended to reveal risks related to part configurations. Additional information is provided in the article "Risk and Hazard Analysis in Design" in this Volume.

Table 3 Questions for revealing part configuration design risks

Factor	Questions
What are the most likely ways the part might fail in service?	
Excessive stress	Can the part be dimensioned to keep stresses below yield levels? Add ribs? Use stronger material?
Fatigue	If there will be cyclic loads, can the configuration be dimensioned so as to keep the internal stresses below the fatigue limit?
Stress concentrations	Can the part be dimensioned to keep local stress concentrations low?

Buckling	If buckling is a possibility, can the configuration be dimensioned to prevent it?
Unexpected shocks or loads	What unexpected dynamic loads might be encountered in service or in assembly? Can these be handled by the configuration?
What are the most likely ways the part might not meet its expected functionality?	
Tolerances	Is the configuration such that functionality will be especially sensitive to the actual tolerances that can be expected in a production situation? Are too many special (tight) tolerances required to make the part work well?
Creep	If creep is a possibility, will it result in loss of functionality?
Strain and deformation	If functional performance is sensitive to retention of size and shape, can the configuration be dimensioned to preserve the required integrity?
Thermal deformations	Might thermal expansion or contraction cause the configuration to deform so that function will be impaired?
Handling and assembly	Might there be unforeseen difficulties with handling and assembly?
Dimensions	Might the part end up being dimensioned so that assumptions about assembleability become invalid?
Tangling	Might the parts tangle if dimensioned in some way?
Will the available production machines be able to make the part?	
Production runs	Are the desired production runs consistent with the machines and expected costs?
Tooling wear	Is tooling wear or maintenance a possible problem that will impact part cost or performance?
Weld lines[(a)]	If the process is a flow process, can weld lines be located appropriately?
Other design and materials factors	
Geometric compatibility	Is the part geometrically compatible with its adjoining parts? What could go wrong is this regard? If there is a small change in this part, or in an adjoining part, can the configuration accommodate the change without major redesign? What about the effects of tolerances of the *adjoining* parts? Or on the assembly as a whole?
Materials	Is the material selected compatible with the configuration and the manufacturing process? Is surface finish properly accounted for? Will standard raw material supplies be of adequate quality? Has the material been thoroughly investigated for its use in *this* particular application? Are there previous uses in similar applications? Have experts on the properties and processing of the material been consulted? Is the material compatible with the rest of the product?
Designer and design	Has every possible, unfortunate, unlikely, unlucky, even stupid "What if . . . " situation been considered? Are

team knowledge	there aspects of the part design where the designer or design team is working without adequate knowledge? Where is the design based on insufficient knowledge of materials, forces, flows, temperatures, environment, etc.? Where are there guesses, hopes, fears, and assumptions instead of knowledge: Materials? Stresses? Fastening methods? Manufacturing process? Tolerances? Costs? Adjoining parts? Environmental conditions?

(a) A weld line is formed when a material flow must divide--say around a hole--and then rejoin. The weld lines tend to be weaker and more subject to fatigue failures.

Redesign Guided by Evaluations

Whatever method of formal part design evaluation and risk analysis is used, the results should point clearly to those aspects of prospective designs that need redesign, or to the need for generating more alternatives. Thus redesign is guided directly by the evaluations. This is the reason that, to get excellent part designs, careful, complete formal evaluation is essential.

Creative Concept Development

B. Lee Tuttle, GMI Engineering and Management Institute

Introduction

MOST ENGINEERS are effectively skilled in utilizing their critical thinking (analytical thinking) skills in the "solution" of product engineering problems. However, the creative thinking (divergent thinking) skills inherent in every human being are often not implemented by the engineer in solving new product designs. The process of creativity in any domain, product design, or artistic creation, involves an iterative application of both creative thinking skills and critical thinking skills to eventually generate, develop, and refine an option that satisfies a human need in a new manner. Without the application of creativity to product design, engineers will continue to improve and refine current forms of products until they become perfect for manufacture, assembly, service, and usage. If an engineer applied only critical thinking skills to the phonograph (record) player, he would design a great phonograph player. If he employed both the creative thinking

skills and the critical thinking skills to the product problem of storing and playing sound, he might create the tape player or the CD player! The evolution in product design will occur only with the application of creativity to the product design process.

Creative Concept Development

B. Lee Tuttle, GMI Engineering and Management Institute

Definitions of Creativity

Many people persist in perpetuating the myth that creativity is a mysterious human ability that is associated with the blinding discovery of a unique product. Creativity is not an inherited talent unique to special people. Creativity is an operation that occurs in the human mind of all individuals, not just certain so-called "gifted" individuals. Creative engineers, chemists, doctors, and accountants are all normal people who use specific abilities and skills to a greater degree than most people do.

Creativity is a very difficult concept to define in terms that can be understood by all individuals. Some of this confusion arises from the approach that researchers have taken in defining what they mean by creativity. Creativity is an extremely complex phenomenon that encompasses the person, the process, the product, and the place (Ref 1). Many definitions of creativity focus on only one dimension of the multifaceted concept of creativity.

To illustrate the complexity of the creativity, some definitions are given here:

- "Creativity is a process that results in novelty which is accepted as useful, tenable, or satisfying by a significant group of others at some point in time." (Ref 2)
- "Creativity, a word that should be reserved to name a complex, multifaceted phenomenon is misused to name only one part of a phenomenon. The multifaceted conception of creativity should consider four factors: person (personality characteristics or traits of creative people); process (elements of motivation, perception, learning, thinking, and communicating); product (ideas translated into tangible forms); and press (the relationship between human beings and their environment)." (Ref 1)
- "[Creativity] is that mental process by which man combines and recombines his past experience, possibly with some distortion, in such a way that he arrives at new patterns, new configurations, and arrangements that better solve some need of mankind." (Ref 3)
- "Creativity is a process of becoming sensitive to problems, deficiencies, gaps in knowledge, missing elements, disharmonies, and so on; identifying the difficulty; searching for solutions, making guesses, or formulating hypotheses about the deficiencies; testing and retesting these hypotheses and possibly modifying and retesting them; finally communicating the results." (Ref 4)

Despite the lack of a formal approved engineering definition of creativity, there appears to be some common threads to the definitions:

- The processing of information in the human mind
- The critical analysis of the problem (need)
- A finite time for the incubation of the problem
- The generation of unusual combinations of disparate concepts drawn from the manipulation of past knowledge

Although each of these elements may be critical to the creative process, the generation of new ideas is a skill that can be taught or retaught to adults to develop their ability to generate new novel products. This style of divergent thinking that shows ways to accomplish a problem solution is termed creative thinking or lateral thinking (Ref 5).

Creative Thinking

The creativity process is a total problem resolution process that yields a truly novel solution to a problem. In order to effect such a novel solution a person must utilize two thinking styles: analytical thinking (vertical thinking, convergent thinking, judgmental thinking) and creative thinking (lateral thinking, divergent thinking, generative thinking). While individuals are born with both styles of thinking equally imbued, the educational system to which they are subjected to from kindergarten to college forces them to use and develop analytical thinking. Throughout their educational experience, the creative thinking skills are suppressed until many people feel uncomfortable using those skills.

In vertical thinking one moves forward with an analysis of an idea in sequential steps after a positive decision has been made about the idea until a final decision is reached about the concept. Once a negative decision is reached about the idea, the process stops cold in its tracks. The mind must then fast reverse along the analysis trail until the original concept statement is reached. All thinking stops now.

In lateral thinking, one's mind moves in many different directions, combining different bits of information into new patterns until several different solution concepts become apparent. Once an idea is exposed, the mind rockets off to another idea.

The difference between vertical thinking and lateral thinking are summarized in Table 1, which is a compilation of work done by DeBono (Ref 5) and Hajcak (Ref 6). From this summary it is evident that vertical thinking evaluates the suitability of an idea for application to a problem in the context of the criteria at that moment. On the other hand, lateral thinking generates many potential solutions to a problem that may or may not be effective when applied to the problem today.

Table 1 Characteristics of vertical thinking and lateral thinking

Vertical thinking (logical thinking)	Lateral thinking (creative thinking)
1. Only one correct solution (selective)	1. Many possible solutions (generative)
2. analytical (judgmental)	2. Is provocative (nonjudgmental)
3. Movement is made in a sequential, rule based manner	3. Movement is made in a chaotic random pattern
4. If a positive decision cannot be made at a step, thinking stops	4. If a positive decision cannot be made at a step, thinking

cold	jumps
5. Follows only the most likely solution path	5. Follows all paths
6. Only relevant facts are considered	6. All facts are considered
7. Deals only with reality as science knows it today (reality)	7. Can create its own reality (fantasy)
8. Moves only if a clear direction is exposed	8. Moves *specifically* to generate a direction
9. Classifications and labels are sacred	9. Reclassifies objects to generate ideas

Source: Ref 5, 6

Since the development of the lateral thinking abilities of most people has been suppressed, tools must be used to rekindle these thinking skills. These tools, which are called creative thinking tools, concept generators, and idea triggers, will be discussed later.

Creative Problem Solving

If creative thinking is thinking in a creative fashion, then what is creative problem solving and what makes it different from creative thinking? Creative thinking produces many ordinary and new means of potentially resolving a need. However, an idea developed from creative thinking is not ready for the marketplace until it has been refined by the application of critical thinking to refine the idea. Creative problem solving is the systematic combination of both creative thinking and critical thinking in an iterative manner that generates potential solutions, refines some solutions, and eventually implements one novel solution to a human need. Not all problem solving needs to be creative problem solving. When a problem is clearly defined and known analytical tools are available to facilitate a solution, then creative problem solving is not needed or warranted.

An example of a process style for utilizing both creative thinking skills and critical thinking skills in problem solving would be the Creative Problem Solving (CPS) process. (Note that when the words Creative Problem Solving are capitalized, the name refers to a specific process of problem development and solution.) The CPS process refers to a specific problem-solving methodology originally developed by Osborn (Ref 7) and evolved by colleagues, Isaksen, Dorval, and Treffinger at the Center for Studies in Creativity at Buffalo State College through the last 20 years (Ref 8). They describe CPS as a broadly flexible process that provides an organizing framework for specific creative thinking tools and critical thinking tools to help design and develop new and useful outcomes. Through this system, productive thinking tools can be applied to understanding problems and opportunities; generating many, varied, and unusual ideas; and evaluating, developing, and implementing potential solutions. A generalized flow chart of the CPS process is shown in Fig. 1. CPS has three components: understanding the problem, generating ideas, and planning for action. Within each

component there are one to three distinct stages that utilize both creative thinking and convergent thinking. The CPS process employs some specific structured divergent thinking and convergent thinking tools to move the thought process toward a final solution.

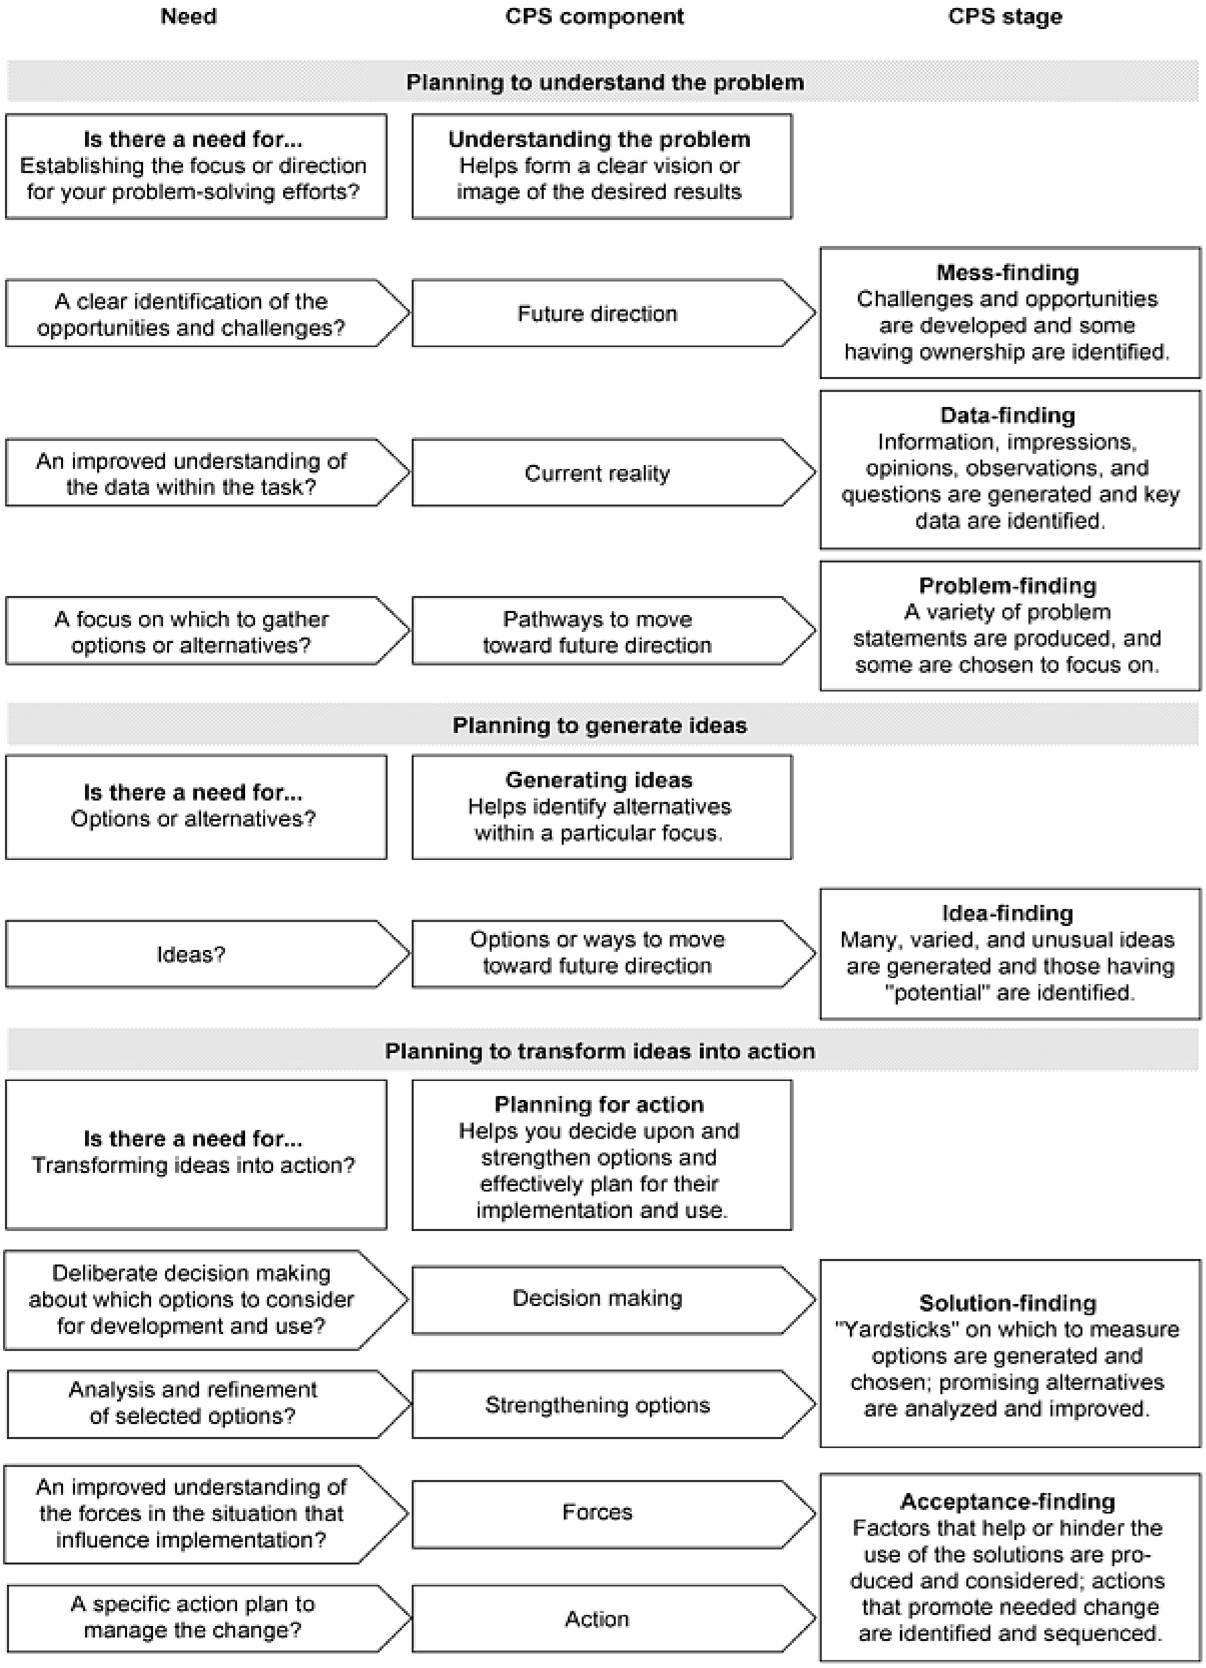

Fig. 1 Generalized flow chart for the Creative Problem Solving process. Source: Ref 9

Creative Problem Solving is a total problem-solving process. The creative thinking tools that are contained in this article are divergent thinking tools that can be used in the idea generation, criteria generation, and acceptance generation phases of the CPS process. Because the focus of this article is on the concept generation tools in product design, the convergent thinking tools that can be used in the idea generation, criteria generation, and acceptance generation stages of the CPS process will not be described.

Design for Manufacture and Assembly

Design for manufacture and assembly (DFMA) is a total problem-solving process applied to the solution of product design problems beginning with the product function specification and ending with the implementation of the product by the customer. As such, the DFMA process utilizes the creative thinking tools in the generation of ideas for the functions of the product, ideas for the processing of individual parts, ideas for the joining of parts, and ideas for the finish of the parts. Like any process of creative problem solving, DFMA utilizes an iterative process of both divergent thinking and convergent thinking to move the concept toward an acceptable solution. Further information about DFMA and the complete product development process is given in the Section "Manufacturing Aspects of Design" in this Volume.

Understanding the Product Problem

Often, an engineer will make a product proposal by specifying the solution to the problem. That is, the engineer will present a sketch of the product, such as the jar opener shown in Fig. 2(a), and say, "Design this jar opener for me." Unknowingly, the engineer has trapped the designer with a visual image of the intended product. In order to facilitate the exploration of the multiple solutions to the product, the physical manifestation of the product must be transformed into something that has no visual image. Sketching is the language of the engineers who traditionally do not express themselves very well verbally. However, it is the verbal explanation of the product function that is needed to move one level backward in abstraction from the physical manifestation of the product, which really represents the solution to the product problem, to the verbal image, which represents the problem statement or need of the customer.

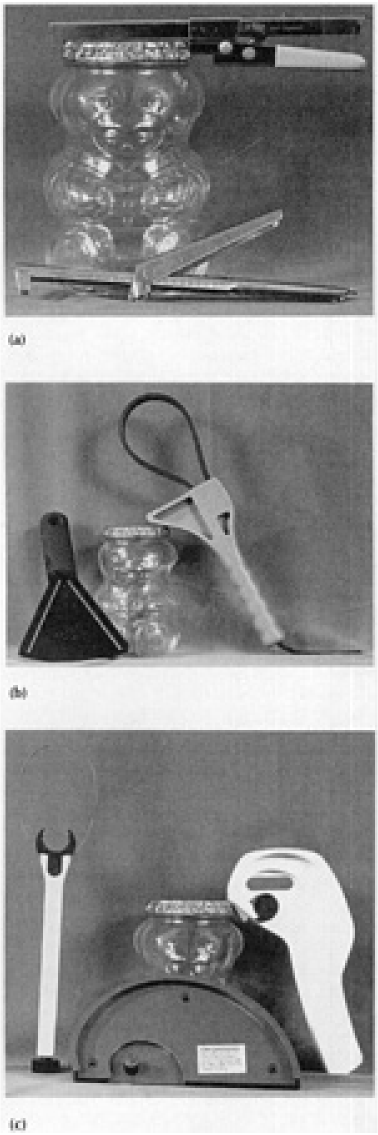

Fig. 2 Jar opener design concepts. (a) Two variants of a jar opener. (b) Alternative mechanisms. (c) Additional concepts

Transforming the Product

The physical manifestation of the product, the mechanical mechanism, represents *how* to accomplish the need of the customer. What we must do is to move the product upward in abstraction and transform it to the verbal side of our brain by specifying *what* the function of the product is. Pahl and Beitz in Germany have been the leaders in the development of this approach to product design (Ref 10). The product functional specification is developed by asking *what* function the product performs and *who* receives the output of the product.

The operation of the product at the product level where it interfaces with the operator and the operatee can be expressed using a simple terminology of two or three words: a verb/noun combination or a verb/noun/noun combination. The verb indicates what is being done by the product, and the noun indicates who is receiving the action. It is critically important at this stage in product specification to clearly distinguish between *what* is being done by the product and *how* it is being done by the specific product variant that is conceived in the initial concept.

The product level functional specification for the product shown in Fig. 2(a) would be "open/jar (lids)." The use of divergent thinking at this stage would reveal that the customer desires the product to be adjustable for different jars and to be portable. This problem would best be broken down into smaller subproblems called subfunctional groups.

Breaking the Product into Subfunctional Groups

In the solution of most product designs, a product function can effectively be broken down into simpler subfunctional groups (SFG) (Ref 11, 12). The SFG is a group of parts that operate together to perform one of the subfunctions of the product. A subfunction of the product is a lower-level function that must be accomplished together with other subfunctions of the product in order to accomplish the total function of the product. Two or more SFGs operate together in series or in parallel to accomplish the overall product function. The definition of the SFG represents the statement of a smaller design problem that within itself still provides the breadth for multiple creative solutions to that problem. The eventual search for solutions to the product problem will normally occur sequentially in each of the SFGs. Depending on the final solutions for each of the SFGs, the SFGs will operate in series or in parallel with each other to eventually accomplish the overall function of the product. At the SFG level, the specification of the function is often accomplished more readily by expressing it in the terminology of a verb/noun/noun. The verb indicates what is being done, the first noun identifies what is doing the action, and the second noun identifies what is receiving the action. The object of the functional specification of the SFG is to specify the interrelationship among several groups of parts that operate to perform the product function. By subdividing the product design into smaller "subproblems," the designer achieves a level of problem abstraction that can be readily understood, but is still abstract enough to permit multiple different solutions to the problem.

At other times it is more appropriate to indicate the function of a product with three terms where there is an interrelationship among three objects. The verb indicates what is being performed, the first noun identifies the object initiating the action, and the second noun indicates the object receiving the action.

The jar opener can be effectively broken down into three subfunctional groups:

1. Adjust/Jaw 1/Jaw 2
2. Grip/Lid (jar)
3. Rotate/Lid/Jar

These three SFGs do not represent the only product decomposition or specification that could be developed. Indeed, one of the critical elements in the design process is to define and then redefine the SFGs until an open-enough definition is achieved to create a wide spectrum of design concepts. The product functional design specification (PFDS) involves first the application of divergent thinking skills to generate different verbal visions of the product function. Second, the convergent thinking skills are employed to refine and reform the verbal functional definition of the product into the proper function terminology of verb/noun to finalize the product functional design specification (PFDS). Third, the various functions are refined into the minimum number of product functions and subfunctional groups that express the operation of the product.

When divergent thinking skills are applied to each subfunctional group to stimulate new, novel methods of performing the function and then these subfunctional concepts are melded together to form complete products, the physical appearance of the products change drastically. Figure 2(b) shows several totally different forms of the jar-opener product. If the designer's mind had been focused on the original physical concept of the product would he have developed the "strap wrench" opener shown in the right corner? Certainly, if he had focused on the physical manifestation of the product, he would not have developed the continuously variable gripping device with no moving parts shown in the left corner. Figure 2(c) illustrates some other versions of a jar opener. The opener shown in the foreground of the jar has transformed the "rotate/jar" function to the operator's hand and the "grip/jar" function to the kitchen cabinet base. The opener on the right has accomplished the "adjust/jaw 1/jaw 2" function to a curvilinear surface that has no parts and accomplished the "adjust/jaw 1/jaw 2" function in one smooth operation with the twist of the hand. On the left side of the picture is a modern strap wrench-style opener in which both ends of the strap are retracted into the handle in a smooth continuous action to accomplish "adjust/jaw 1/jaw 2" and then "grip/lid." If the only tool in the engineer's toolbox was the design for assembly (DFA) tool, then these new, novel product concepts would have never seen the light of discovery. Divergent thinking gives birth to new product methods. Design for assembly refines the concepts into manufacturable and assemblable products.

Creative Concept Development

B. Lee Tuttle, GMI Engineering and Management Institute

Creative Concept Generation Tools

The concept generating tools are often arbitrarily described as individual or group tools. The categories individual and group refer to the context in which the tools were originally developed rather than the specific applications of the tools today.

Individual Tools

Individual tools rely on free association or forced relationships to stimulate the germination of an idea in an individual's mind. Group tools are those that were specifically developed to focus the interaction of the individual persons in the group toward greater concept generation. Because many group techniques rely on the interaction of the minds of diverse persons to stimulate the flow of ideas, those techniques do not lend themselves to idea generation by individuals. However, many individual techniques, particularly forced random stimulation techniques, can be successfully adapted for use inside of a group ideation technique.

Checklists are not, as their name may imply, lists that permit an individual (or a group) to check off novel, creative concepts for a new product. In the process of evolving his brainstorming tool from an advertising conference room tool to a general-usage problem-solving ideation tool, Osborn found that many individuals needed some stimulus to get them started generating ideas. He developed a "checklist" of questions that could be used, or discarded, by an individual desiring to generate ideas (Ref 7). The purpose of a checklist is to give the designer a "check" of the present concept (or already developed concepts) relative to some metrics by addressing some open-ended questions to the problem, such as "What if we . . . to the product?" "Can we . . . the product? "What can we . . . in the product to make it better?" The blank can be filled in with one of the words from the checklist. Some typical checklist words include *enlarge, reduce, add, eliminate, move, rotate, substitute* (to make product more powerful, lighter, quieter, etc.), and *invert.*

Perhaps the simplest form of checklist questions is given by writing instructors for use in developing a composition. Namely, Who?, What?, When?, Where?, How?, and Why?

Because idea-spurring checklists are very general, many individuals find it difficult to modify and adapt the questions to their problem statement. If a product design group will be generating many products that are similar but different, they should generate their own set of product development idea-spurring questions directed toward their brand of product that will be more meaningful to them.

Metaphors. The word "metaphor" comes from the Greek word *metaphora,* derived from the word meta meaning "over," and therein, "to carry" (Ref 13). It refers to a particular style of figurative speech in which the attributes of one object are transferred over to an object that does not normally possess those attributes itself. The objective of figurative speech in language is to create more vivid images of the transferred object in the mind of the reader. The objective of using a metaphorical transformation in creative concept generation is to drive the idea into a new realm. Psychologists who have studied some great inventors discovered that they came up with their discovery by transforming their perspective of the problem through the use of a metaphor (Ref 14).

The use of metaphors is illustrated by the sentence, "Edison forged new products in his New Jersey laboratory from the raw materials of his mind's image." Edison certainly was not a giant metallic forging hammer pounding out ideas from a new material called image. The visual image created by the metaphors in the Edison sentence will only exist if the reader has a previous knowledge of manufacturing processes. The development of the metaphor as an idea trigger should follow some simple guidelines given below:

- The metaphor should make a transference to the problem at hand from a subject area with which the

problem solvers have some familiarity.

- The metaphor should be directed toward the function of the product to be designed.
- Metaphors that develop a unique image using one of the five sensory images (visual, aural, aromatic, tactic, or taste) have been shown to be most effective.
- Once a good metaphor is generated, the engineer should look with this new set of eyes at the original product to imagine new ideas.

The success of the metaphorical transformation of the problem statement lies in the language ability of the user. Many people have difficulty making comparisons between dissimilar objects and thus cannot benefit from analogies. Other people can see all the colors of the rainbow in their mind's eye and are stimulated by metaphors. As with any tool, the generation of metaphors may become a useful idea trigger if the designer practices the generation of metaphors separate from the sessions in which the designer wishes to generate ideas.

Forced random stimulation is an idea-generating technique in which an object is chosen at random, the attributes or functions of that object are force-fit one at a time into the problem statement in an attempt to generate new ideas (Ref 15).

The first step is to select a random object. A very effective method is to select an object, without looking, from a box of miniature objects or tokens of real life objects. The tokens that have been placed in the box are all carefully screened to see that they have positive connotations to most people. Such a box has been called an idea box or an idea factory by various creative practitioners. In the absence of an idea box, the object can be chosen as follows:

- Select one of the primary colors and choose the first object of that color seen in the room.
- Open a catalog at random and select the object printed in the upper (or lower) right (or left) corner of the page.
- Open the dictionary to a page given by the last three digits of a telephone number and select the word from the top whose position is the same as the fifth and seventh numbers of the telephone number.
- Telephone a child and ask the child to describe his/her favorite toy.
- Open a magazine to a page at random and look at the object in the advertisement on that page.

The DFMA team now focuses on the object itself. They play with it. They imagine using it around the home. They envision other people using it. They now write five to ten attributes (descriptors, images, impressions, sounds, or feelings) that come to mind about this object. (Originally when this tool was developed, the team was asked to list the functions of the random object because the tool was being used in the functionally driven design approach. However, the listing of the functions of the random object proved to be too restrictive and not free-flowing. Thus this approach was dropped.) At this time the object is discarded from view and mind, and the attributes are used.

The first attribute is now forced at the problem statement in an effort to generate some new ideas. The problem statement should be approached by stating: What would happen to the problem if we put a (describe the attribute) on (into, near, over, under, in front of, or behind) the problem? Once ideas stop flowing from the first attribute, then the team moves on to the next attribute until all the attributes have been used individually. Then, attributes can be combined together in pairs to force further ideas. The condensed Forced Random Stimulation Worksheet is shown in Fig. 3 (Ref 15).

A team should not be discouraged if the random object does not stimulate any new concepts. When a reasonable effort has been expended on a set of attributes for one random object, then a second random object can be selected and the process repeated. If the technique does not work for a specific team, then other concept-generation techniques should be used.

Product Improvement Checklist. The Product Improvement Checklist, or PICL (pronounced "pickle"), was developed by VanGundy as an unrelated, forced relationship tool for product improvement (Ref 16). It has been successfully applied to real physical products such as toasters, lawn mowers, and electric drills. The PICL tool consists of two series of idea-spurring questions that are displayed on a 22 × 27 in. worksheet or recorded in an electronic file.

Basic PICL uses 91 idea-stimulating questions to prompt new concepts. These questions are organized into categories such as Who?, What?, Where?, When?, and Why? Typical questions are: Who uses the product? Who buys the product? What need does it fulfill? Where is it used?

The questions posed by the Basic PICL chart are employed as follows:

1. Read the product problem statement.
2. Read a question and write down any ideas that come to mind.
3. When ideas stop flowing, move onto another question.
4. When all questions have been answered, evaluate the responses for application to the problem.

PICL Juice is the name given to the 576 idea-stimulating words distributed at random among four categories on the PICL chart. The four major categories of word stimulators are: Try To, Make It, Think Of, and Take Away or Add. A word in each category is selected at random and combined with the title of the category to stimulate ideas. Examples of idea-spurring phrases are:

- *Try to:* do it backwards, separate it, spread it, classify it, roll it, stack it
- *Make it:* porous, hard, flexible, cylindrical, cold, swivel, diverge, opaque
- *Think of:* pogo sticks, scissors, drills, closures, brief cases, plows, Frisbees
- *Take away or add:* rollers, handles, Velcro, sand, movement, springs, music, reflectors

PICL Juice can be applied in the following manner to a product problem:

1. Read the product problem statement.
2. Select a category. Combine the category words one at a time with the random words in that category.
3. Write down any ideas that come to mind. Move on to a new word when ideas stop flowing.

Additional idea-spurring phrases can be generated by selecting at random a word from each category and then applying that phrase of four words to the product statement. For example, you might combine: twist, cylindrical, dental floss, and wheels. Perhaps, the product should have cylindrical wheels made of dental floss or dental floss wrapped around the wheels for traction.

The use of idea stimuli unrelated to the focus of the problem increases the ability of the tool to develop unique ideas. Because there are an infinite number of word combinations, the ability to generate a large number of novel ideas is high. VanGundy states that the major disadvantage of PICL is that many people have trouble using forced relationships when the stimuli are not related to the problem. This type of idea trigger is best utilized by people who have the ability to tolerate ambiguity and see connections between seemingly unrelated objects.

SCAMPER. Eberle developed some techniques to assist children in rekindling their four phases of divergent thinking (fluent thinking, flexible thinking, original thinking, and elaborative thinking) (Ref 17). He recognized that people continually draw from their personal experiences in their mind and adapt, combine, rearrange, and modify these bits of information to form new ideas. Although this process appears to happen randomly in the subconscious mind, he wanted a technique to bring this to the conscious mind and thus increase the probability of novel ideas.

He took some of the idea-spurring questions posed by Osborn in his book *Applied Imagination* (Ref 7) and modified these questions to form an easily remembered list called SCAMPER. The final form of the SCAMPER questions are shown in Table 2.

Table 2 The SCAMPER questions

S	**What can be** SUBSTITUTED? **Who else instead? What else instead? What other material? What other process? What other place?**
C	What can be **COMBINED** with it? What about a blend, an alloy, an assortment, an ensemble? Combine units? Combine purposes? Combine appeals? Combine ideas? Combine concepts?
A	**ADAPT?** What else like this? What other ideas does it suggest? Does the past offer a parallel?
M	**MODIFY?** New twist? Change meaning, color, motion, sound, odor, form, shape? Other changes?
	MAGNIFY? What to add? More time? Greater frequency? Stronger? Higher? Longer? Thicker? Extra value? Duplicate?
	MULTIPLY? Exaggerate?
P	**PUT TO OTHER USES?** New ways to use as is? Other uses if modified? Other places to use? Other people to reach?
E	**ELIMINATE?** Minimize? What to eliminate? What to subtract? Smaller? Condensed? Miniature? Lower? Shorter? Lighter? Split up? Streamline? Understate?
R	**REARRANGE?** Interchange components? Other pattern? Other layout? Other sequence? Transpose cause and effect?

The SCAMPER questions are applied to the problem as follows:

1. Read aloud the first SCAMPER question.
2. Write down ideas or sketch ideas that are spurred by the question.
3. Rephrase the question and apply it to the other features of the product problem.
4. Continue applying the questions until ideas cease to flow.

Because the idea-spurring questions are generalized questions, they sometimes will not apply to a specific product problem. If a question fails to evoke ideas, the thinker should move enthusiastically along toward the next question without feeling uncomfortable. The generalized nature of the questions requires that the concept developer using it be of a mind to make very strange connections between objects.

In new product development the SCAMPER questions may best be applied to the individual subfunctions of the product rather than to the product as a whole.

Creative Concept Development

B. Lee Tuttle, GMI Engineering and Management Institute

Group Tools

Those divergent thinking tools that are classified as group tools usually rely on the interaction between the ideas of diverse people to stimulate the flow of ideas from each individual participant. These tools may use free association, or forced relationship association, to initiate the flow of ideas; however, it is the sparks emitted when the verbal (visual) flint strikes the iron mind that illuminate new ideas in the listener's mind! The effective application of a group tool relies on the ability of a facilitator to keep the ideas flowing from all participants and to prevent a single individual from dominating the ideation process.

Brainstorming is perhaps the best known and yet most poorly understood group creative thinking technique. In today's society the term "brainstorm" has come to mean any effort to think out a problem. In the 1950s, Osborn developed group ideation sessions at his advertising agency that they named "Brainstorm Sessions," literally a tempest in the mind. Osborn had discovered that most people felt meetings were for evaluation of concepts and not the generation of options. To facilitate the rapid-fire exchange of ideas among the participants, Osborn developed the following rules of a brainstorming session (Ref 7):

- *Criticism is ruled out.* Adverse judgment of ideas must be withheld until later.
- *"Free-wheeling" is welcomed.* The wilder the idea, the better. It is easier to tame down than to think up.
- *Quantity is wanted.* The greater the number of ideas, the more the likelihood of useful ideas.
- *Combination and improvement are sought.* In addition to contributing ideas of their own, participants should suggest how ideas of others can be turned into better ideas or how two or more ideas can be joined into still another idea.

Although many people claim to hold "brainstorming" sessions, few group sessions are truly brainstorming sessions. Unless the rules of conduct espoused by Osborn are strictly followed, these sessions are merely meetings. The objective of a brainstorming session is to use the disconnected ideas of individuals to trigger new ideas in each participant. The technique relies heavily on the group interaction to create a rapid-fire exchange of ideas.

Preparing and Conducting a Brainstorming Session. In preparation for a brainstorming session Osborn would select a diverse group of 8 to 12 individuals. The group would include people with a good technical knowledge of the problem and people with little technical knowledge about the problem. Although brainstorming does not require an extensive training process, the procedures and rules of the process would be explained to each member of the group. In preparation for the ideation session, Osborn would send out an expanded problem statement providing group members with a full description of the problem and inviting them to jot down any ideas that occurred before the meeting.

At the beginning of the actual brainstorming session, the facilitator explains the four rules of brainstorming again to the participants. A brief informational discussion is then held to clarify the problem statement. The group is coached by the facilitator in the implementation of the brainstorming process on several warmup exercises on critical problem topics. When the group is ready to begin work on the formal problem, the facilitator writes the problem statement on the flip chart. Ideas are shouted out as rapidly as they come to mind by each participant. They are recorded by a scribe on the flip charts or on a tape recorder for transcription later. After 15 to 30 minutes of intense ideation, most people lose interest. To prevent boredom with the concept of brainstorming, the facilitator leader should close the meeting when he or she sees

that the group's energy is waning. At the end of the session, the facilitator should encourage participants to continue to generate ideas on the problem. Additional ideas can be sent to the facilitator for inclusion in the pool of ideas.

Evolution in Brainstorming Processes. The brainstorming tool has been developed into many variations by different practitioners of creativity through the years. The operation of the traditional brainstorming itself has undergone evolutionary changes through the years since Osborn developed it in the 1950s. During their development of the Creative Problem Solving process, Isaksen, Dorval, and Treffinger have implemented several changes in the brainstorming tool (Ref 8). More recent CPS research has shown that ideas flourish better in a smaller group of five to seven participants rather than the eight to twelve participants suggested by Osborn. The gathering and sharing of ideas can be sped up by having the participants write their ideas on self-adhesive note paper and read them aloud to the group. The notes are then passed to the facilitator for display on the wall. Other concept-generating tools, particularly those employing unrelated stimuli, have been introduced within the framework of the brainstorming session.

A significant development in the original brainstorming process occurred when the group was employed for culling, sorting, screening, and selecting among the ideas that were generated in the ideation session. Isaksen, Dorval, and Treffinger have shown the value of using critical thinking tools to bring some degree of closure to each brainstorming session in order to move the problem-solving process forward.

The traditional brainstorming tool can be applied to many types of problems. For example, it can be used to generate methods to accomplish the functions of a new product, develop criteria for the final selection of the product concepts, and evolve multiple methods of packaging the product for shipment to the customer.

Attribute Listing. Crawford discovered in his study of the creative process in new product development that the creation of a new product consisted generally of shifting an attribute from an unrelated product to the product to be created (Ref 18). The attributes which Crawford referred to could be the physical features of the product, the operational functions of the product, and the aesthetic visions of the product. If a product has been defined in a functional specification that utilizes subfunctional groups, then the attributes should be the functions of the subfunctional group. For those people who are visual thinkers, then the physical features of the product that achieve these functions might be the attributes. Once the attributes are listed, then each attribute is explored for ideas separately from the other attributes.

A prescription for the implementation of this technique might be:

1. Define the product in terms of its functional attribute or physical features.
2. List each function on a piece of paper. Generate as many alternate means of creating the function (feature) as possible.
3. Move on to each successive function (feature) when the ideas for each one stop flowing.
4. Combine different new methods of achieving each attribute to generate a totally new product.

One of the problems that is often encountered in this method is that the ideas do not flow for a specific attribute. If this is encountered, then the combination of an idea-spurring tool such as SCAMPER is appropriate to get the ideas to flow.

A student examined a new design for a flour sifter using the product functional specification that divided the product into four subfunctional groups: contain (release)/flour, break/lumps, sift/flour, and grip/hand. The various alternative means for accomplishing the function "break lumps" are shown in Fig. 4 expressed both in the verbal thinking style and in the visual thinking style. The actual idea implemented by the student employed a combination of the nut chopper and the pill crusher.

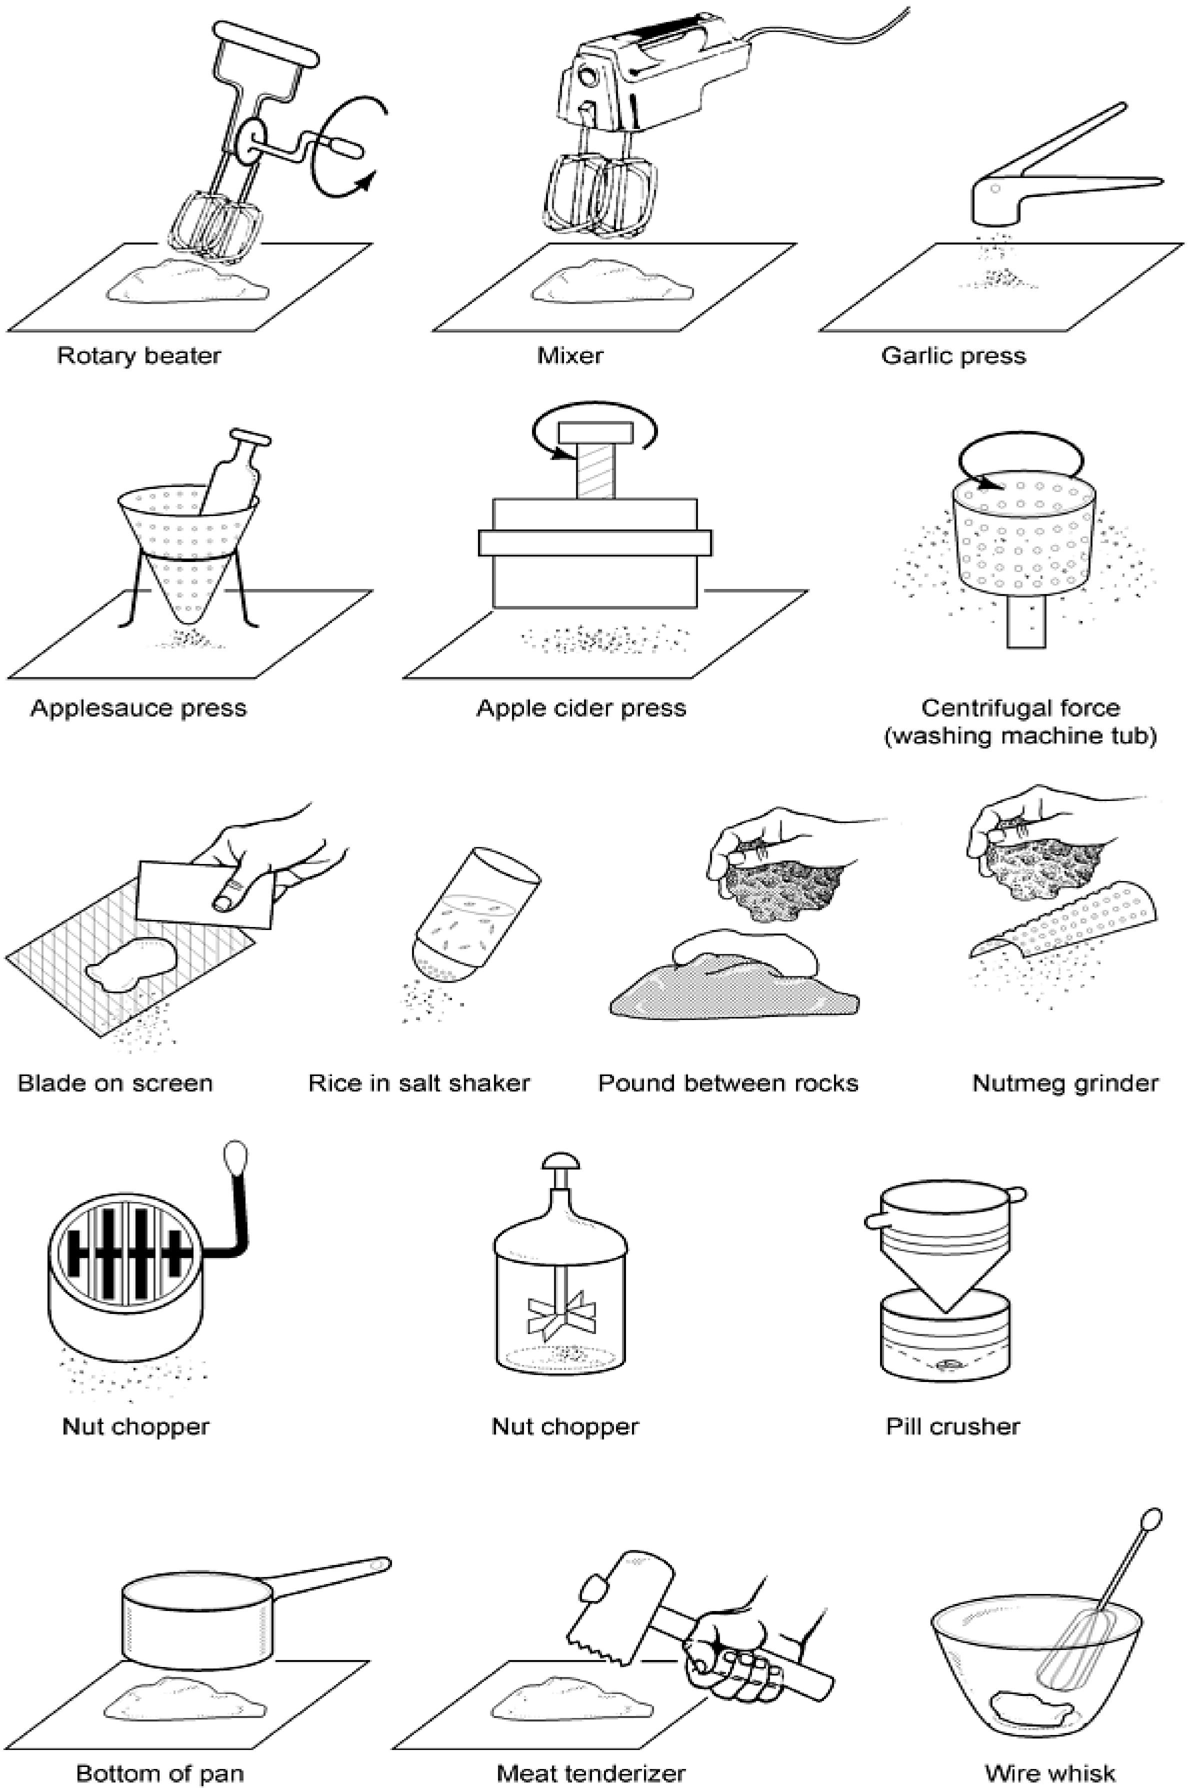

Fig. 4 Concepts generated for the attribute "break lumps." Courtesy of Christina Earnhardt, GMI Engineering and Management Institute

The attribute listing technique is best applied to product design when the functional or physical features of the product are defined first. The search for alternate means of achieving each attribute is best made using an idea-spurring tool in addition to the usually employed free association.

Morphological analysis (matrix analysis) was developed by Zwicky as a structured tool to force comparisons among the various attributes (parameters, functions) of a problem (Ref 19). The tool raises the problem solver one level above the basic attribute listing approach by rigorously forcing the problem solver to consider all potential solution combinations no matter how unlikely.

In applying the tool, the following steps should be followed:

1. The problem should be stated in a few (three to six) attributes. In product development these would represent functions or physical features.
2. Arrange the major attributes as the sides of a matrix (two-dimensional comparison) or the sides of a cube (three-dimensional comparison).
3. Using free-association divergent thinking, generate a list of methods of accomplishing the first attribute. Repeat the free-association divergent thinking process for each attribute until multiple concepts are available for each attribute.
4. Review the lists for each attribute. Discard any that are inappropriate for the problem until the lists have the same number.
5. Write one method of achieving the function in each row (column) of the matrix.
6. Systematically combine one solution concept from each attribute to identify a new product.
7. Record the identity of all the methods of achieving the functions of the product for later evaluation.

An excellent example of this technique applied to a product development problem is the personal transportation system described by Parnes and Haring in Crawford's book, *The Techniques of Creative Thinking* (Ref 18). The three parameters of the transportation system to be investigated are: provide power, support passenger, support carriage. Figure 5 shows a matrix on which are listed some of the alternate methods for achieving each subfunction of the total product. The product configurations are developed by combining the various methods for each subfunctional group represented by each of the cells of the cube. (That is 320 product ideas in all.)

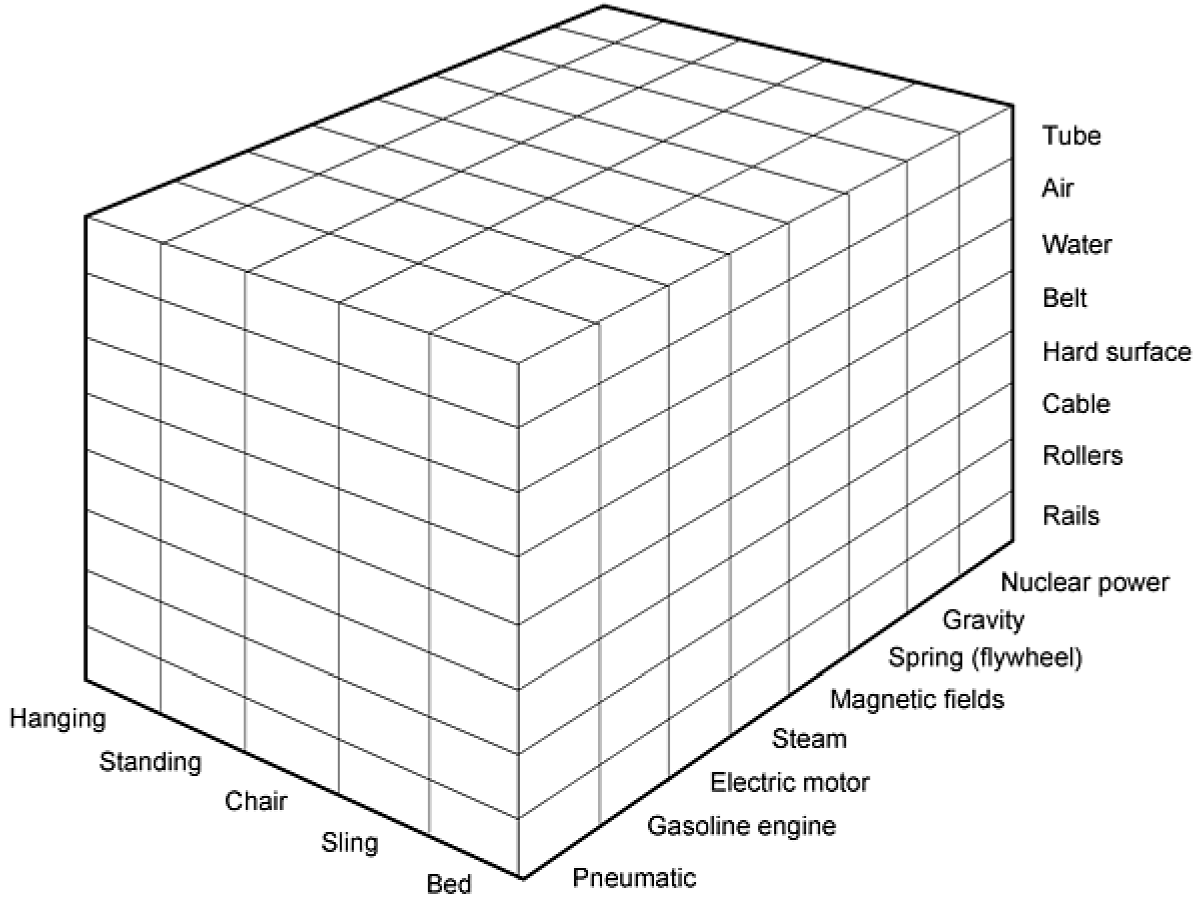

Fig. 5 Morphological analysis for a personal transportation problem. Source: Ref 18

A few of the ideas can be considered to demonstrate the direction of the tool. One product concept might involve: electric motor, chair, and rails. That defines a very old electric trolley car. Another product concept might be: electric motor, standing, and cable. That might define a cable car in San Francisco. In the Alps, that might define a cable car. Another product variation might be: gasoline engine, belt, and lying. What might this transporter be?

Morphological Matrix. The morphological analysis tool as developed by Zwicky (Ref 19) had the major disadvantage that when all possible combinations are considered a very large number of ideas had to be either hard or soft selected to achieve convergence. The underlying concept of the tool was modified by Parnes and later further refined by Treffinger, Isaksen, and Dorval to a morphological matrix format (Ref 8, 9).

The morphological matrix can be employed as follows:

1. Construct a matrix with the 4 to 6 functions of the product at the head of each column. Each column should have about ten rows beneath it.
2. Beginning with the first function, generate ten methods of performing that function. Record each method, one per line, down the column.
3. Continue generating and recording methods of accomplishing each of the functions until all the functions have been developed.
4. Randomly select one method of performing each function from each column to develop a new product level concept. The random selection can be facilitated by the use of a four- to six-digit random number to sequence the selection of the functional methods from each column. When the individual or group feels that they have enough new combined ideas to consider, they should end the random combination of ideas.

The morphological analysis (matrix) tool is an analytical idea generation tool that appeals to the adaptive style of many engineers. It generates a new product level concept by combining existing methods of accomplishing each of the subfunctional groups (parameters) of the product in new, novel ways. Because the ideas in each attribute (function) category are achieved by free association, they are not as wild as might be achieved by a forced-relationship tool. However, the act of combining subfunctional group concepts in a random manner yields some unusual if not improbable products.

Syntectics. William J.J. Gordon and George M. Prince worked in the Invention Design Group of the Arthur D. Little Company in the early 1950s. Rather than inventing the new product themselves, they helped the engineers at the client company develop the product concepts themselves. Gordon and Prince became more interested in the process of generating ideas for new products than in actually inventing new products. Their interest in creative concept generation led them to form their own company, Synectics, Inc. (Cambridge, MA). Their name for the creative concept development process that they developed was Synectics, a Greek word meaning the joining together of seemingly unrelated and different concepts to create a solution (Ref 20). Gordon and Prince continued to develop their process of concept generation by conducting continuing studies of how the idea-generation teams thought during the product invention sessions. Eventually the Synectics process developed from a concept generation technique into a full creative problem-solving process similarly to the manner in which brainstorming developed into the Creative Problem Solving process. The emphasis here is on the original Synectics tool for concept generation.

The essence of the Synectics process has been described as follows:

1. Make the strange familiar.
2. Make the familiar strange.
3. Transform the strange into familiar again.

The original Synectics research identified three characteristics of good creative concept generators:

- Creative efficiency in people can be increased if they understand the psychological process by which their mind operates.
- In the creative process, the emotional component is more important than the intellectual, the irrational more important than the rational.
- It is the emotional, irrational elements that can and must be understood in order to increase the probability of success in creative concept generation (Ref 20).

In any concept generation situation the first step is to formulate the problem statement or the product functional specification. One of the early discoveries of the Synectics research was that too many engineers took the problem statement at face value. The first step requires that the team develop alternative product specifications and select the one that eventually describes the product as it really is. Gordon and Prince found that when engineers reformulated the problem statement into terms that were familiar to them they were better able to find solutions to the problem.

The second step was one of the startling discoveries of the Synectics research. Namely that efficient generative problem solvers were those who purposely distorted the image of the problem statement in their mind until it became far removed from the original frame of reference. These engineers focused their energy on solving this distorted problem without the constraints of the original frame of reference for the problem. Freed from the constraints of normal places, they generated numerous ideas for the distorted problem.

The last step was to take the solutions to the distorted problem and force fit them back into the original problem situation. Synectics research has shown that many of the problem solutions generated by the distant formulated problem could be force fit to the original problem (Ref 21, 22).

The heart of the original Synectics research and the tool itself was the study and development of the ways in which people distorted the original problem. The work of Gordon and Prince showed that the product designers transformed their original problem into a new problem through the use of four basic types of analogies: personal analogy, direct analogy, symbolic analogy, and fantasy analogy.

Personal Analogy. In this type of analogy, the individual places himself/herself in the position of the machine and performs the function of the product. A student design team was once observed in the design studio to be pivoting in a circle, raising up their mouths open at one point in the rotation and falling back to the ground with their mouth closed at another point in the rotation. They reported that once they had assumed the identity of the parts of the toy fishing game, they had a different perspective of how the product was operating and what it was doing.

Direct analogy is the one that engineers used most often in the original Synectics research because it involves a comparison between different technologies or looking for a solution in a totally different scientific field. Many inventions have been created by drawing an analogy between the mechanical device and a phenomenon in the field of botany, biology, or anatomy. George de Mestral was working on a special button for pompier's coats that would permit them to fasten and unfasten them rapidly with gloved hands. When he returned to his home one evening after a stroll though the woods, he noticed some cockleburs clinging to his pants. As he removed these from the pants, he observed the strong fastening that they made with the pants. He pressed them back to the pants and observed that they again clung to the pants. He went to his workshop and studied the cockleburs and the fabric of his pants under the microscope. Eventually he developed the Velcro-type fastener in which one side has the stiff, barbed hooks like those on the burrs and the other side has soft loops like the fabric of his pants.

Symbolic analogy actually tries to transform the problem statement from a verbal image to a visual image using a generalized image to represent a particular function of the product. The objective is to indicate a functional relationship among the various parts of a problem without defining the physical embodiment of the interfaces between each element in the product design. A mechanical engineer developing a hydraulic system for a die casting machine would represent the hydraulic system by a block (function) diagram without physically specifying the details of each function block. Typically, several physical mechanisms could perform the function in each element block of the block diagram. Pahl and Beitz encourage engineers to develop a function structure diagram of the product functions using symbols or "pictures" representing the characteristic operation performed by that portion of the product (Ref 10, 11).

Fantasy Analogy. The least-used analogy (at least in the view of Gordon and Prince) was the fantasy analogy. The fantasy analogy moves the mind into the realm of time and space where physical laws as they are known do not exist. The creators of science fiction novels exist in this realm all the time. Individuals who are successful in employing this analogy will develop the most novel ideas for a product.

Analogy Development. The development of the analogies employed in the Synectics method is guided by a trained facilitator. Because the key element to the idea-generating system is the analogical relationship between the original problem and the distorted problem, the abilities of the facilitator to generate meaningful analogies for the team members is critical for success.

Applying Creative Concept Generation in New Product Design

Most product design engineers would say that the "creative" portion of the product development process occurs during the early concept discovery of the process. Indeed, this may be the norm for some engineers. However, engineers must realize that the purpose of their analysis (critical thinking) is to identify opportunities for improvement in the product form, manufacturing process, assembly process, and product function. Once these opportunities for improvement have been identified by a specific engineering analysis tool, only the creative thinking skills can generate potential methods to accomplish these opportunities. The improvement of a product can only be accomplished with the balanced application of the analytical skills and the creative skills of the engineer.

Creative Thinking in Design for Assembly

Once the functionality of the new product concept has been evaluated, the embodiment of the product concept needs to be refined for ease of assembly and manufacture. The engineering team should perform a design for assembly analysis concentrating at the subassembly level to identify which parts must be separate physical parts in the given mechanism and which parts can be physically fused together into new mega parts. (Further details about DFA methodology are provided in the article "Design for Manufacture and Assembly" in this Volume.)

Once the critical thinking questions are answered for the Theoretical Minimum Part count, then the engineering team needs to use their divergent thinking skills to develop different ways to combine the nonseparate parts into the separate parts. Figure 6 illustrates a simple pneumatic piston actuator from a copy machine that has been often used to illustrate the methodology of the DFA analysis technique. Figure 7 illustrates a DFA linear redesign concept matrix for that product. The original product contained seven individual parts. The theoretical minimum part count for the product indicated the product could be made from as few as two or three parts. Each of the design concept columns indicates various combinations of the original parts that could be achieved for products with 4, 3, or 2 parts. Concept 3 would fuse the physical features of the cover and the screws into one piece (C); the piston, the piston stop, and the spring into a second piece (B), and the main block into a third piece (A). The combination of the zeros and ones in the theoretical minimum part count column may or may not involve divergent thinking skills. However, generating a physical shape for the newly merged parts in this product will call upon the divergent thinking skills of any engineer.

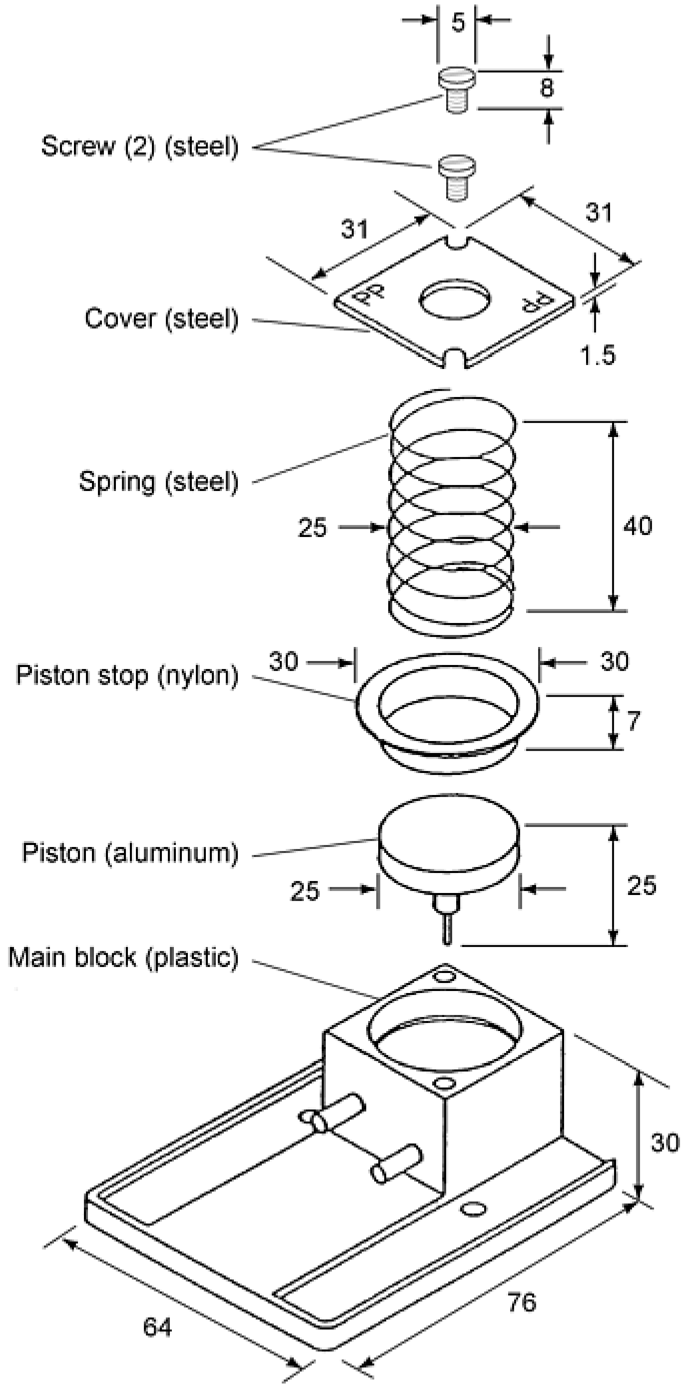

Fig. 6 Pneumatic piston subassembly. Dimensions given in millimeters. Source: Ref 23

Theoretical minimum part count	Name of assembly: pneumatic piston		Design concepts				
	Part name		1	2	3	4	5
1	Main block		A	A	A	A	
1	Piston		B	B	B	B	
0	Piston stop		D	C	B	B	
1/0	Spring		C	C	B	B	
0	Cover		D	C	C	B	
0	Screws		D	C	C	B	
		Part count	4	3	3	2	

Fig. 7 Design for assembly redesign concept matrix for the part shown in Fig. 6

Divergent Thinking in Manufacturing

Many practitioners equate the design for manufacture (DFM) analysis with only the manufacturing process for individual parts. The DFM analysis is concerned with the primary manufacturing process, the secondary manufacturing processes, the finishing processes, and the assembly process for the parts within each subassembly. After the DFA analysis is performed and number of parts in the product concept is minimized, the engineering team is faced with developing a manufacturing processing system that can physically produce that shape. Without the divergent thinking skills of the manufacturing engineer, many of the products on the market today could not be made from the concepts developed by the DFA engineers.

Conclusions

The process of innovation and evolution in product design involves the integrated application of both convergent thinking (critical thinking) and divergent thinking (generative thinking) in an iterative continuous process flowing both from customer and process back to the customer and processor. Some tools to stimulate divergent thinking are described in this article. Other tools and methods of creative thinking are contained in the books described in the list of References. Each product design team should seek those divergent thinking tools that are functional for them and apply those tools at appropriate junctures in the product development process.

Cross-Functional Design Teams

Preston G. Smith, New Product Dynamics, Portland, Oregon

Introduction

THE TERM *TEAMS* is used heavily in industry today, often with little more than a hope behind it. However, as companies strive for greater productivity and responsiveness to market changes, effective teams often play a central role in initiating organizational change. Such real teams may occur in any part of the business, but this article focuses on the particular issues arising in using teams in the product design process.

The most effective design teams generally involve a clearly delineated group of individuals who work full time on the specified project from its beginning until market introduction. The team comprises not only research and development professionals but also manufacturing and marketing members, and often members from quality, finance, or field service. These teams cut across traditional organizational boundaries, thus changing traditional reporting and decision-making relationships. Team members often report to the team leader for the duration of the project and are physically located together (co-located). Although these characteristics can increase productivity and responsiveness greatly, each also represents a major challenge in organizational change for most companies.

Specifically, such team characteristics encourage the use of generalists as team members, thus creating challenges in incorporating specialists, such as materials engineers or scientists. This article provides special coverage on alternative roles for such specialists whose expertise is essential to the success of the project but whose involvement with the team may violate some of the above characteristics.

Cross-Functional Design Teams

Preston G. Smith, New Product Dynamics, Portland, Oregon

Background: The Changing Role of Product Design and Development in Industry

Most manufacturing companies today are under heavy pressure to succeed, even to survive. Service industries have taken a dominant role in commerce, much manufacturing has moved offshore, and many manufactured goods, especially materials, have become commodities. In addition, environmental and product liability issues complicate manufacturing operations. All of this is occurring with a rising tempo, as evidenced by market shifts and other external demands that occur ever more frequently.

The Growing Importance of New Products. Senior managers often see new products as the key to coping with this chaotic environment. New products promise higher profit margins, opportunities to avoid commodity product status by creating market niches and added value, and an avenue for revitalizing the corporate image. New products are no longer just something done in research and development but have become central to the plans of the corporation. Many business leaders go beyond this by deciding to use new product development as the keystone in a broader plan of fundamental improvements in how their companies operate.

An Emphasis on Productivity and Responsiveness. Two thrusts come from these management desires:

- A requirement for consistently successful new products in a less predictable environment
- A requirement to obtain these products ever more quickly while using fewer financial and human resources

Design, or more broadly, development, teams have an effect on the product success requirement, but increasingly they are being considered essential to achieving productivity and time-to-market goals. This optimism regarding teams is well founded: many stories have appeared in trade and business magazines and research journals describing how cross-functional teams have brought new products to market far more quickly and inexpensively than more traditional organizational approaches to product development.

As discussed in a later section, a team is not the answer to every development project, but teams have demonstrated their power to improve development effectiveness dramatically. This article covers the characteristics of such teams, how to staff and organize them, and the critical role of specialists, such as materials specialists, in working with such teams.

Cross-Functional Design Teams

Preston G. Smith, New Product Dynamics, Portland, Oregon

Types of Teams

Team is a heavily used and abused term in the workplace today. Any identifiable group of workers is generally labeled a team, and teams form in the sales, accounting, and research departments and from the factory floor to the executive suite. Seldom does calling a group a team change the way in which work gets done.

Effective teams can exist anywhere in the organization, but teams that deliver superior performance exhibit certain characteristics (Ref 1):

- A small (fewer than ten), well-defined group with complementary skills
- A meaningful purpose, specific goals, and agreement on concrete operating principles for reaching the goals
- Mutual accountability for results and joint ownership of work products

Teams and Meetings. Katzenbach and Smith (Ref 1) distinguish teams that make or do things from those that recommend things or ones that run or manage things. Product development teams are of the type that do things, and it is essential to recognize that the doing gets done mostly between team meetings. Development team meetings are to assess what got done, solve problems, and set plans for doing the next work. Although meetings are an essential tool of teams, if the team equates itself with meetings and depends on meetings to get work done, progress will be slow. In effective teams, meetings tend to be highly spontaneous and largely transparent. These teams demand far more of their members than just participating in scheduled meetings.

Special Characteristics of Cross-Functional Development Teams. Three traits of product development make development teams particularly challenging ones to set up and manage: (a) most of those involved are professional knowledge workers; (b) a broad range of professional skills is needed, including engineering, science, marketing, manufacturing, and finance; and (c) innovation is an uncertain activity. Although some exceptions exist (Ref 1, 2), most of the team literature treats simpler situations, such as assembly plant operations or mortgage application processing. Consequently, the literature is of limited use here; this article relies more on tools that the author and his colleagues have seen work well in other product development settings.

One insight from this experience in helping clients set up development teams is that the organizations doing best at it are those that have already tried other kinds of teams. They simply have a greater appreciation for the difficulties involved and the training required.

Staffing a Development Team

Much like a cooking recipe, this "recipe" first lists the ingredients (the staffing issues) and then moves on to directions for combining them (the organizational issues).

The Team Leader. Choosing a team leader is the most important decision management will make in setting up a development team. Two criteria should guide the choice. One is that, because product development amounts to an obstacle course, the leader must be strong enough to figure out how to overcome the obstacles and work the existing system. The second is that the leader must operate from a business perspective, not a particular functional perspective, such as engineering or marketing.

If the team leader cannot deal effectively with the obstacles, then management must step in, which destroys the team's value and morale. Similarly, if the leader operates from a particular functional perspective, other functional managers will step in to ensure the participation of their function, again undermining the team's integrity. Neither of these situations provides the high-quality problem-solving and decision-making infrastructure desired.

In addition, a leader should have a strong, customer-centered vision of the product and sense of project direction. This is crucial in providing the leader with a touchstone for making the countless daily decisions that can deflect the team from its course. Leadership, then, is the ability to transform this vision into action.

Clearly, another essential requirement is a leader with excellent people skills, including communication (listening and providing ongoing performance feedback), conflict management, and the ability to influence others throughout the organization. A key part of people skills is giving credit and exposure to team members, rather than the leader accepting it.

From Which Department? For highly technical products, it is natural to choose a technical person as team leader. It seems that only a technical person will understand the design adequately. Others, with a longer view, might argue that only a marketer could provide the customer-focused guidance needed for marketplace success. Similarly, manufacturing might make a case for a manufacturing person as leader because a manufacturable product is essential.

Unfortunately, all of this discussion misses the point. No company has enough candidates for the demanding team leader job, so no company can afford to restrict its search to one function. Besides, the qualified person is someone who thinks and operates as a general manager, not a functional specialist.

Team Members. While much has been written about leaders and leadership, little guidance is available on selecting team members. Kelley (Ref 3) makes the point that the criteria for selecting team members are remarkably similar to those for team leaders. In particular, a development team needs self-starters able to work without supervision and individuals who will present their thoughts independently. Groupthink is dangerous on a development team, and the best defense is team members with the strength of conviction to present contrary views.

Another key criterion is a willingness to share information and credit. A member who tries to build his or her own self-worth by withholding information or credit is disastrous on a development team.

Generalists Versus Specialists. In the development of sophisticated products, the tendency is to think of using highly specialized people who can contribute that something extra that will yield a competitive success in the marketplace. Usually, the recognition, compensation, and promotion systems of a company reinforces this bias toward specialists.

Unfortunately, specialists create several difficulties on a team, including scheduling problems, lack of commitment to the project, and lack of a solid understanding of project objectives and customer desires. Therefore, the bias in selecting team members should swing toward generalists who have a firm grasp of the job to be done and can be engaged for the duration of the project. The ideal member is the so-called T-shaped individual, one who has depth in a crucial area but is

also able and willing to handle many other jobs, often under the direction of others, when their specialty is not needed (see Fig. 1).

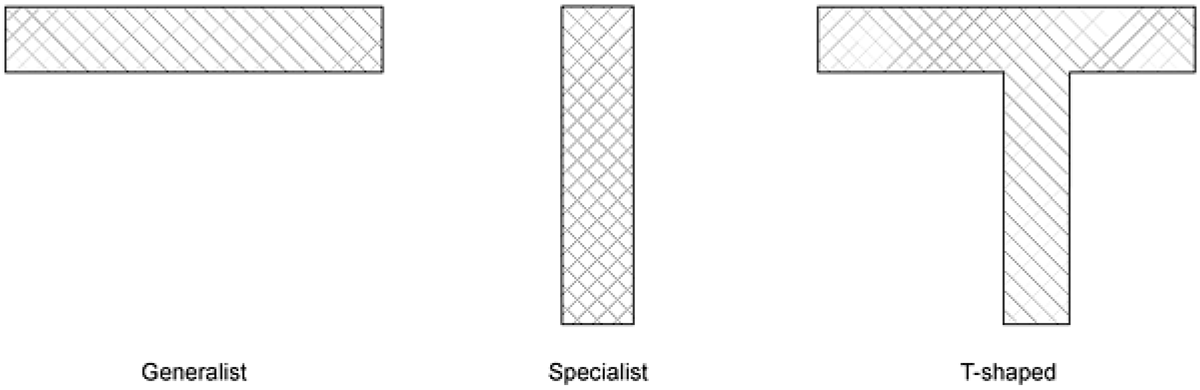

Fig. 1 T-shaped individual. The horizontal direction portrays breadth of experience, and vertical indicates depth of specialization.

Figure 2 is a staffing chart for a simple product developed by a company preferring specialists. Each bar represents one individual on the team, and the height of the bar indicates this individual's degree of dedication to the project, that is, the number of hours he or she spent on it compared against the total number of hours possible for the duration of the project. Specifically, five people on the tail end of the chart are purchasing specialists, each permitted to purchase only a specific commodity.

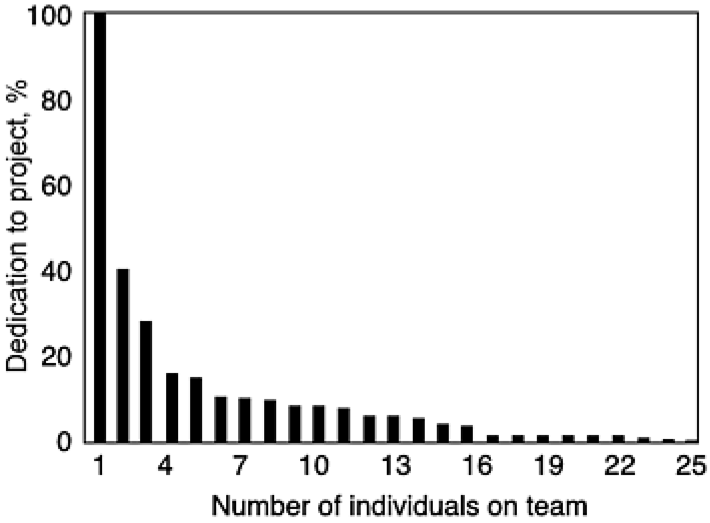

Fig. 2 Staffing diagram for a project that depended on many specialists, most of whom contributed less than 10 percent of their time to the project. Source: Ref 4

The company represented in Fig. 2 has moved toward generalists. It uses fewer members on a team, but each is involved at a high level of dedication. Communication, coordination, and commitment have improved accordingly.

Clearly, the specialist-generalist issue applies to a materials specialist whose expertise may be needed for a small portion of the project.

Team Selection Process. To enhance commitment to the project, team members should have a say in whether or not they want to be on a team; in essence, they should volunteer (Ref 4, p 127-128).

Normally, the team leader recruits team members after management recruits the leader. Recruiting team members is a negotiating process between the team leader and management because management will be unable to release certain members requested by the leader.

Suppliers on the Team. To leverage their resources, manufacturers are turning increasingly to suppliers to provide larger portions of their products. Also, there is a trend toward forming strong alliances with a few key suppliers rather than working with many at arms length to avoid being held hostage by a single supplier.

Product development is not as far along as production in making these transitions, but the changes are definitely occurring in product development as well. What this means for product development is that supplier personnel are joining their customers' development teams just as if they were employees of the customer. This practice has become routine for automobile manufacturers where suppliers are involved at many different levels (Ref 5).

Suppliers should be considered as team members when they have essential technical expertise to contribute, when their parts are critical to the cost or schedule of the product, or when the customer's design of a part will affect the supplier's ability to produce it reliably.

Clearly, many different levels of supplier involvement are possible. It is important to be flexible in molding each circumstance to fit the requirements. When supplier involvement is planned, the previously covered concerns about specialists should be kept in mind. A few key suppliers involved heavily are better than many involved superficially.

Cross-Functional Design Teams

Preston G. Smith, New Product Dynamics, Portland, Oregon

Organizing a Development Team

Every organization has its formal organization depicted on the organization chart. Each also has an informal organization, the linkages by which things actually get done, decisions get made, and information flows. These systems have evolved over time to serve the primary needs of the firm. Due to need and tradition, most of these organizational structures are vertically (functionally) oriented. Although this vertical structure may be best for many corporate activities, it does not work well for developing innovative new products, which require heavy horizontal information flow.

Fortunately, corporate organizational structures are becoming more horizontal as firms delayer, decentralize, empower workers, and move toward team-based activity. The increasing emphasis on new products encourages this shift. However, the growing need for new products is outpacing changes in inertia-bound organizational structures. Usually, this suggests a bias toward structures for product development that are more horizontal and team based than the familiar ones. The change will require some organizational inventing and pioneering. Such organizational innovation is far more likely to take root if it is planned and set up before initiating a project.

Products of today are often complex, which means a development team must incorporate several types of technical expertise. Consider something as commonplace as a telephone set. Developing a new one requires electrical, mechanical, and software engineers, acoustics and materials experts, industrial design and ergonomics, and manufacturing process expertise. In addition, marketing, purchasing, and finance will be key participants. Thousands of decisions lie ahead, and thousands of problems await solutions. For the set to be a commercial success, the developers must reach delicate cross-functional balances repeatedly.

The present task is to provide an environment, that is, a team, to address such cross-functional problems and decisions quickly and effectively. Without such a team, the more vertical communication infrastructure in a company is likely to degrade the quality of the new product, add to its cost, and delay it.

Candidate Organizational Forms. It is helpful to think of the possible organizational forms as spanning a spectrum, from the functional one (strongly vertical) in Fig. 3, through the balanced matrix (Fig. 4), to the separate project shown in Fig. 5. The critical parameter that varies in these charts is the degree of control and influence the team leader has over individuals on the team compared with that held by the functional managers. In Fig. 3, there is no team leader, so all decisions flow through functional managers. In the balanced matrix, the team leader and functional managers hold equal power over team members. In Fig. 5, the team leader has unquestioned authority over those assigned to the project.

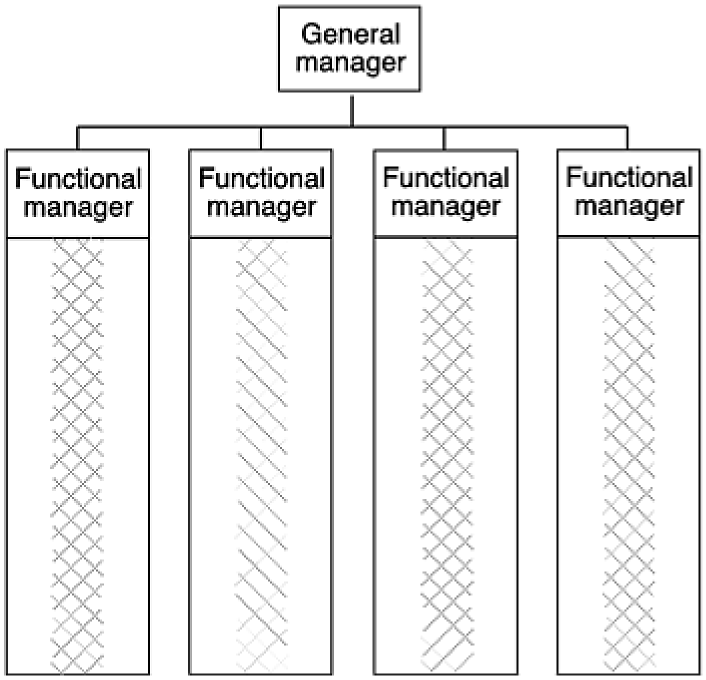

Fig. 3 A functional organization, in which authority rests with the functional managers. Source: Ref 4

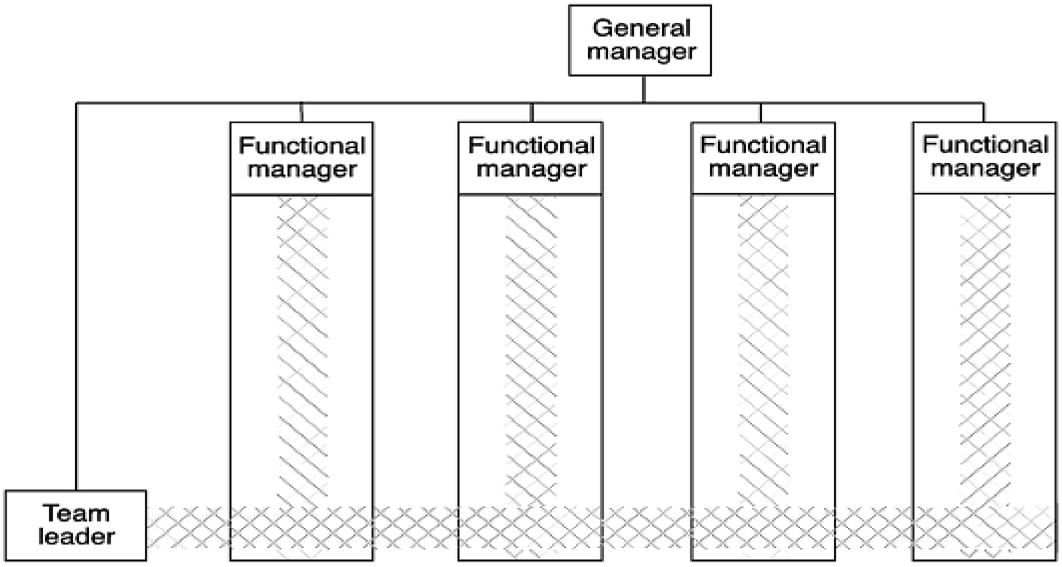

Fig. 4 A balanced matrix, where the team leader and functional managers have equal authority over team members. Source: Ref 4

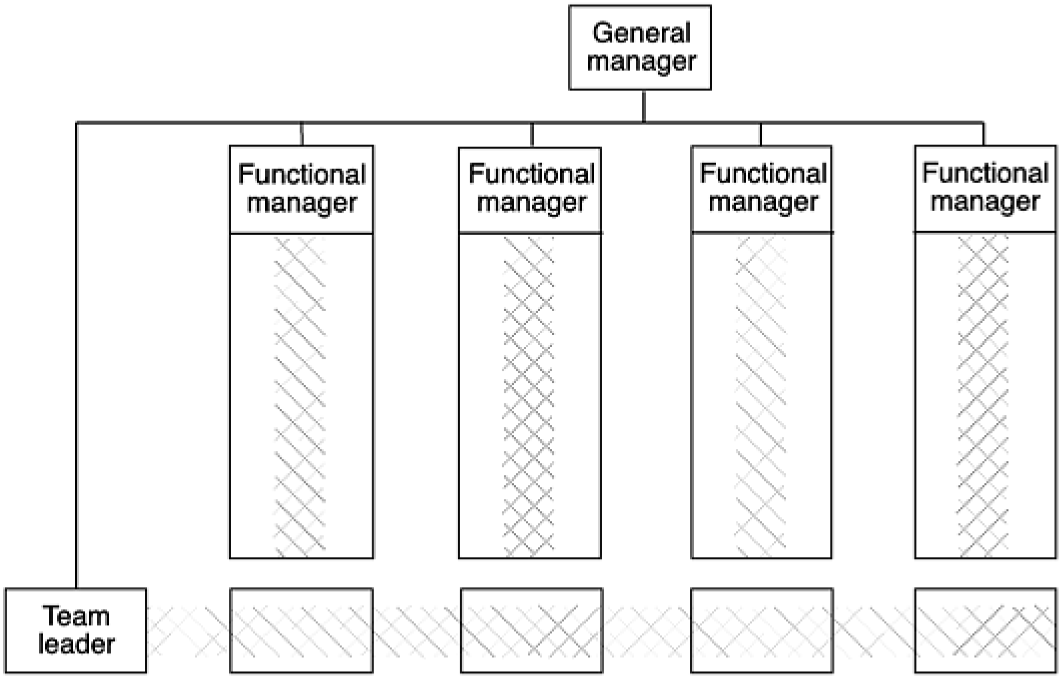

Fig. 5 A separate project organization, in which members report solely to the team leader. Source: Ref 4

Important points on this spectrum occur between the illustrated ones. For example, between the charts displayed in Fig. 3 and 4 is a so-called lightweight team leader form, in which a team leader exists but has less clout than the functional managers. This is a popular and often dangerous form because organizations have moved to it from the functional form, thinking they have arrived at teams but not realizing that they really need to take more steps. Lightweight teams are often impotent, as the label suggests, and the leader often becomes frustrated. Between Fig. 4 and 5 is the heavyweight team leader form, a powerful one used by Honda, among others.

Figures 4 and 5 illustrate another key point. The team leader reports to a general manager, not to a functional manager, such as the vice president of engineering. Recall the earlier discussion about the team leader functioning as a general manager so that he or she would integrate the viewpoints of all functional managers. If the team leader reports to a functional manager, the project will take on the orientation of that function. The other functional managers will get involved to inject their opinions, bringing back the shortcomings of the functional form.

Selecting the Best Form for a Project. Every organizational form has its pros and cons. For example, the functional form is superior for maintaining consistency between products in a company's product line. But it is poor at facilitating communication across the functions involved in developing an innovative new product. Conversely, the separate project form excels at such cross-functional communication but is weak in cross-project coordination. The balanced matrix provides some of both but introduces potential conflicts because individuals on the team essentially have two equal bosses tugging at them.

The solution to this dilemma is to choose the form with strengths that most closely match the primary objectives of a particular project, then recognize the shortcomings of the chosen form, and put compensating mechanisms in place to handle them. For example, many firms introduce cross-functional project communication into the functional form by having weekly team meetings. (The earlier warning about trying to run a team through meetings should be noted.)

A consequence of this approach to organizational design is that each project will have its own structural form based on the specific objectives of that project. This makes the organization chart more complex but enables each project to use the most effective organizational tools available.

In general, a form closer to the separate project should be used for innovative, new-to-the-world products, and more functionally oriented forms should be used for more routine product upgrades (Ref 6).

There is nothing magical about the terminology used here, for instance the *heavyweight team leader* form. Other jargon is used, such as *core teams.* What really matters is how members are involved day-to-day, which is the next topic.

Full-Time, End-to-End Involvement. Another important characteristic of effective development teams is that, to the greatest extent possible, each member serves from the beginning of the project to its end and is involved full time for that period. Handoffs from person to person or from department to department mean breaks in the continuity of vital information. Engineers, according to a stereotype that is partially true, often want to redesign whatever they receive from someone else.

Full-time involvement (also called dedication) translates into higher commitment and accountability and into greater focus on key objectives of the project, such as the desires of key customers. By using full-time people, fewer people can handle the project, with the benefit that communication becomes far simpler. If a full-time member cannot be justified, their role should be defined carefully (Ref 4, p 142).

Full-time, end-to-end involvement is much easier to accomplish with generalists. This is one benefit of using generalists on a team, as discussed earlier.

The first person to be dedicated full time for the duration of the project should be the team leader. Part-time involvement in this key position is particularly ineffective.

The Power and Difficulties of Co-Location. Once a leader is selected, team members are recruited, an organizational form is chosen, and the degree of dedication expected from each member is established, then the last decision to be made is where to locate this crew. The basic choices are to leave members in the place where they were before the team formed or to physically locate them close together; this latter choice is called co-location.

The argument for co-location is that product development, especially for highly innovative products, requires a great deal of cross-functional communicating, problem solving, and decision making. Placing the participants close together simplifies these activities greatly. Project focus and easy access to project-related materials, such as products of the competitors, are additional advantages.

Figure 6 illustrates the basic case for co-location. These data from several research and development sites show how likely individuals are to communicate about technical matters, depending on their separation. Note that the "knee" of the curve is at about 10 m (30 ft), which suggests that there is great value in having team members close enough to overhear conversations of one another.

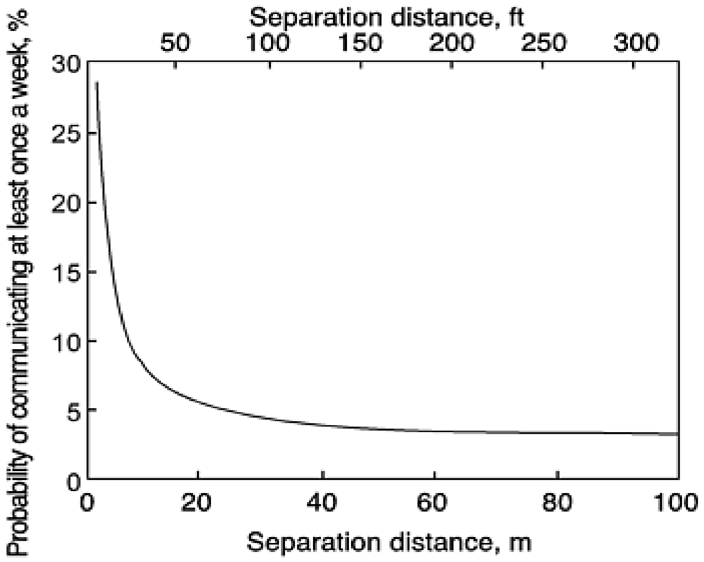

Fig. 6 Effect of separation distance on communication between team members. Communication is much more likely to occur if team members are located within about 10 m (30 ft) of one another. Source: Ref 7

Thus, true co-location means that team members are within conversational distance, not just in the same building or on the same floor. As discussed earlier, this team includes members from marketing and manufacturing, not just the research and development portion of the team. In the author's experience in working with over a hundred product development teams, this type of co-location is a powerful tool to shorten development cycle time dramatically.

Although the benefits of co-location are great, the resistance can be equally great in many organizations. Those who have tried it appreciate its benefits and would always use it again if effective project communication were critical. Many who have not tried it are skeptical, often due to personal reasons, such as lack of privacy; see Ref 4 (p 145-150, 271-272).

Co-Location Versus Electronic Team Linkages. The data in Fig. 6 are from Ref 7, which is over 20 years old. Many engineers in high-tech industries discount Fig. 6, asserting that modern electronic means of communication, for instance, faxes, e-mail, and videoconferencing, have superseded the need for physical co-location. Figure 6 suggests that the threshold (10 m, 30 ft) is so low that people are not willing to work very hard to communicate. If they have to take the effort to dial the phone, compose a message on their computer, or arrange a videoconference, they will instead just make this mini decision themselves. After a while, poor mini decisions pile up.

Electronic communications have two other shortcomings. One is that they are not very fast; the inherent delays in phone tag and its e-mail equivalent are commonplace. The more fundamental weakness is a lack of communication quality. The words themselves account for less than half of what a message communicates, most of the communication being attributed to intonation, body language, and timing. To various extents, all of the electronic media filter out this vital information. Even the current resolution of videoconferencing fails to pick up many clues.

Electronic media certainly have their value, but their limitations diminish their ability to facilitate rapid, effective team progress. Being aware of the limitations will help the team to compensate for them.

The Role of Rewards and Other Motivators. Many researchers and authors have addressed the effectiveness of motivators, such as compensation, recognition, and promotion in improving corporate productivity. This is a difficult subject about which to be definitive, and much of the available material is contradictory. However, two general observations apply to cross-functional development teams.

One is that these systems ultimately have to come into alignment with the behavior desired of the team, or the team will revert to traditional ways of operating. For example, if the culture punishes mistakes, then the behavior change sought, learning from mistakes and getting beyond mistakes quickly, will not occur. The new products developed by the team will not likely be very innovative in such a risk-averse environment. Similarly, if team cooperation is the desired outcome, individuals should not be rewarded.

Second, substantial dependence on rewards to achieve results is likely to backfire. In the author's experience, clients who focus on rewards usually have other, more fundamental difficulties, such as overbearing top management, and superficial fixes with rewards will not overcome the fundamental issue. In the end, team members must be motivated intrinsically by an interest in the work itself, and extrinsic motivators will have limited effect. For a sobering view of this subject, see Ref 8.

The Specialist's Role on a Development Team

An assumption underlying this article is that the reader is probably a materials specialist or manager who is reading it concerning their involvement on a cross-functional development team. Thus, the specialist's role needs specific attention here.

Balancing Team Needs with the Specialist's Needs. The dilemma of the specialist was covered earlier: the specialist's expertise is often needed to provide the technical product innovativeness essential to marketplace success, but the specialist introduces several complications in managing a high-performance development team. Thus, the specialist's role is one of those organizational design factors that should be resolved by first satisfying the major project objectives, then identifying known weaknesses in the specialist's role, and compensating for these. This means that the best solution is likely to differ every time.

The Specialist on a Weak Team. A weak team, for example, a functional organization or a lightweight team leader form, is really just a variety of specialists being guided by functional managers. Consequently, technical specialists fit into these forms quite naturally, but they also contribute to all of the shortcomings of these forms.

Whatever the organizational form, a chronic weakness of highly specialized technical people on development projects is that they often have little contact with the customer for which they are designing. They need to get into the field rather than rely on filtered information from others. For example, a plastics specialist working on a new type of plastic body panel resin for automobiles should spend time in body shops, car wash establishments, and shopping mall parking lots to see firsthand just how cars get used and abused.

The Specialist on a Strong Team. The specialist's role dilemma is most evident in the stronger team forms. Fortunately, there are options for how the specialist can contribute to the team.

Joining the Team Option. If the specialist's expertise constitutes a major contribution to the project, this person should be a regular, dedicated, co-located member of the team for at least most of the development and testing. The specialist should be a T-shaped individual, as discussed earlier, to justify end-to-end, full-time involvement. Limited involvement would mean that this person will be gone when problems associated with his or her design choices begin to appear later.

Expert Contributor Option. This is a popular middle ground, but it must be treated with care to get a quality, responsive contribution from the specialist. This individual is not a member of the team (trying to include such associates to help them feel more involved will simply dilute the significance of the team).

Therefore, a regular member of the team acts as a liaison to the specialist, and clear objectives, deliverables, and due dates are established for each task. The liaison should monitor progress closely, watching for slippage due to the specialist's other activities or lack of understanding of project goals. The specialist must spend enough time with the team that he or she can experience firsthand what the team is about. Team meetings may not be the place for specialists to get this direct exposure.

The expert contributor option simply provides a contracted deliverable, much like a supplier's, and should be managed accordingly.

Expert Advisor Option. An expert advisor acts as a consultant to the project and is expected to deliver competent professional advice, based on one's field of expertise. It is the team's responsibility, not the specialist's, to be sure this advice fits with team objectives and to identify contextual shortcomings in it. For example, if an automotive plastics specialist suggests a certain resin, it is the team's responsibility to ascertain that this resin is suitable for Siberia and Saudi Arabia, where they may intend to sell their cars.

If the specialist's advice is critical to the success or schedule of the project, then the specialist's participation should be arranged in advance.

Preston G. Smith, New Product Dynamics, Portland, Oregon

Conclusions

Unlike much of the other material covered in the *ASM Handbook,* this article covers subjects without a strong scientific basis. There are few firm rules, and the best solution will depend greatly on the specific circumstances involved. Much of the supporting evidence is anecdotal, as in the case of co-location, for example.

However, this does not mean that there are no preferred solutions. Some solutions are far more powerful and effective than others, so it is definitely worth struggling with the issues to find the solution that works best in a specific situation. Individuals forming a design team should form their objectives, analyze the existing data to select an approach, and then *do something.* In making progress, action is preferable to inaction.

Initial team "experiments" should be operated on a manageable scale where the risk is reasonable, and they should involve the most enthusiastic people to initiate change. See Ref 4, Ch 15, for further information on making such changes. Results should be monitored, and adjustments should be made on an ongoing basis. See Ref 9.

For more detailed coverage of the material in this article, see Ref 4, especially Ch 7 and 8.

Concurrent Engineering

Don Clausing, Massachusetts Institute of Technology

Introduction

CONCURRENT ENGINEERING is product development that is done by concurrently utilizing all of the relevant information in making each decision. It replaces an approach to product development in which one type of information was predominant in making each sequential decision.

Sequential engineering, the product development style that was dominant in the United States during the 1960s and 1970s, emphasizes expertise. Decisions are taken by specialists. Each decision-making activity considers primarily only one specialty. Then each decision is passed on to another group of specialists for further decisions. This style does provide much expertise in the decisions. However, the integrated result leaves much to be desired. It has become caricatured as work that is thrown over the wall from one group of specialists to the next group.

Concurrent engineering came into practice in many companies in the United States during the 1980s. By 1990 it was widely recognized as the desired form of product development in most industries. Concurrent engineering emphasizes holistic decision making, with each decision taking into account the knowledge of all of the relevant specialties. The viewpoints of all of the specialties are integrated by being made responsive to the voice of the customer. By focusing expert knowledge on the needs of the customers, concurrent engineering avoids suboptimization and introspective specialized objectives that are irrelevant to the customers. Thus concurrent engineering provides products that customers want and will purchase.

Concurrent Engineering

Don Clausing, Massachusetts Institute of Technology

Concurrent Process

The concurrent process utilizes all relevant expertise in making each decision.

Holistic Decisions. All product development decisions must take into account the following three aspects:

- *Product functionality:* the ability of the product to perform
- *Production capability:* the ability to produce the new product
- *Field-support capability:* the ability to support the product after it is shipped

If a product functions well but is difficult to produce or difficult to support in the field, it is a weak product. In the concurrent process, all three viewpoints are taken into account in making each decision. This is suggested in Fig. 1. The three functional activities are shown occurring concurrently. In the older style they occurred sequentially.

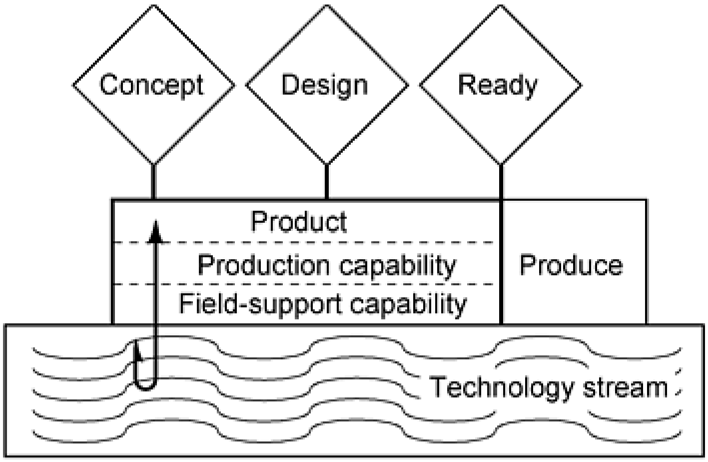

Fig. 1 Concurrent engineering process

In addition to the specializations that are displayed in Fig. 1, many other specializations separate development people. Examples are mechanical engineers, electrical engineers, and computer scientists. Concurrent engineering is intended to integrate all forms of specialization.

Of course, all of the several aspects of product development cannot be kept in mind at the same time. Concurrent decision making is a matter of degree or of the time scale of iteration. In sequential engineering, the tendency is to make all of the functional decisions first. Then it is thrown over the wall for production decisions. Subsequently this is repeated for field-support decisions. This leads to massive iteration loops, with a time scale of months or years.

Concurrent engineering still requires iteration. However, the time scale for the iteration is typically minutes or hours, not months. Also, all of the relevant people are involved throughout. Therefore, the knowledge from other specialties does not come as a surprise after thinking has become solidified around a viewpoint based on personal expertise. This closing of minds tends to happen in sequential engineering. The interleaving of knowledge to form a holistic fabric is the key feature of concurrent engineering.

For example, a team of three people are working together to make the critical decisions about a key part for a machine. It is essentially a beam to support small mechanisms. First they consider the deflection of the beam and the need to keep its deflection less than 0.05 mm--the functional viewpoint. After half an hour they have an initial design for a stiffening rib. Then they work for 45 min on the production capability. Should the beam be an aluminum die casting or fiber-reinforced polymer? They decide on an aluminum die casting and adjust the processing to minimize distortion due to residual stresses. The details of the rib geometry are refined for aluminum die casting. Then for half an hour the team of three considers the field-support need to be able to readily remove the part in the field for servicing. Thus one could say that they are working sequentially. However, the time scale of each sequence is very small. Also, all three people are involved in all decisions so that they develop commitment to the decisions. This is the concurrent process.

Example 1: Problems Encountered in Sequential Engineering of a Materials Innovation.

In the 1960s, dual-hardness armor was developed at the United States Steel Research Center in Monroeville, Pennsylvania. This was a marvelous accomplishment. However, in the sequential style that was dominant in that era, the functionality of the armor plate was emphasized for a long period of time before production capability was seriously addressed.

Traditional armor plate has two conflicting requirements: It must be very hard, to shatter the projectile, but also tough, so that the armor plate is not shattered. Traditional armor tries to satisfy both requirements with one parameter, the composition/microstructure of the armor. However, one parameter is insufficient to satisfy two requirements.

At the United States Steel Research Center, an invention was made that introduced two parameters to satisfy the two requirements: dual-hardness armor. This combined a hard front plate with a tougher rear plate. The two were diffusion bonded together to form one solid plate.

The functional development was done with plates that were 1 ft in diameter --easy to make in laboratory equipment. The first production trials with 4 ft by 6 ft plates revealed a spherical bow (curvature) that was five times the specified limit.

The source of the bow was obvious. During the heat treatment, the dual-hardness plate behaved in a way similar to a bimetallic strip. The problem had not attracted serious attention during the functional development because the deviation from flatness varies as the square of the span of the plate. In 1 ft spans, the deviation did not look bad. However, the larger plates had 25 times as much deviation from flatness, an unacceptable bow.

After much time had been spent concentrating on the functional development, the production capability became the prime focus. The first attempt was to build a curved quenching die. This bent the hot plate in the opposite direction from the quenching curvature. The intent was that the two curvatures would cancel each other. This worked in the 1 ft plates. However in the larger plates, another problem arose.

After they were quenched, the larger plates appeared to attempt to reach a flat condition. However, they were elastically unstable. They snapped through the flat position. There were two stable positions, one on each side of flat. This was the familiar oil-can phenomenon.

A review of the applied mechanics literature revealed a paper that provided the needed analysis. Spherically curved plates with a sufficiently large ratio of span to thickness are unstable. They snap through the flat position. However during this analytical work, it was recognized that the differential strains that caused the objectionable bow were very small, less than 0.1%. This led to another invention.

The invention was simply to compress the softer, concave side of the plate. This expanded it laterally until it was the same dimension as the hard side, which eliminated the bow. A rolling-mill roll was prepared with bumps on it, something like a sheepsfoot roller. When the bumps pressed against the concave side of the dual-hardness plate, they made very slight impressions (Brinelling), which were sufficient to flatten the plates. The localized deformation provided the needed flattening without requiring high values of rolling force. This was very satisfactory on the laboratory plates. As no potential instability was involved, this process would undoubtedly have worked on production plates also.

However, another difficulty intervened. When the two inventors (the dual-hardness-armor inventor and the flattening-process inventor) went to a production rolling mill (factory) to plan production trials, they were rebuffed. "Run armor plate through our rolling mill--no way!" The mill operators were of course accustomed to rolling soft steel. Armor plate seemed out of bounds to them. The production-operations people had been involved too late to build up confidence in the approach.

This is the way sequential development work is done. It usually has problems of the type that are revealed in this example. Concurrent engineering does much better. If this project were done with concurrent engineering, a multifunctional team would be formed early in the project. The team would consist of:

- Metallurgist, the inventor of the functional capability (dual-hardness armor)
- Materials scientist/applied mechanician, the inventor of the flattening process
- Production mill engineer

In concurrent engineering, the same work would be done, but it would be done concurrently. This would address the technical and production aspects of the bowing problem much sooner. It would also gain the confidence and commitment of all three members of the team.

Note that the production process for flattening the bowed plates was eventually addressed in two stages:

- Analytical, which revealed the fundamental nature of the problem and led to a solution
- Production operations

Often future production problems can be addressed analytically at very early stages of development. This is an important practice in concurrent engineering. To make it fully effective, the production-operations people should be included on the team during the analysis so that their concerns can be adequately addressed and their commitment developed.

Concurrent Engineering

Don Clausing, Massachusetts Institute of Technology

Multifunctional Teams

The concurrent process is carried out by a multifunctional team that integrates the specialties (functions). There are five types of organizational configuration for product development:

- Functional structure
- Lightweight product manager
- Heavyweight product manager
- Project execution team
- The independent product development team

The first two organizational types emphasize functional expertise and are of less interest in today's complex competitive world. The last three of these configurations are all referred to as multifunctional teams although they differ substantially from one another.

The heavyweight product manager form of organization still has the players in functional homes. The multifunctional team aspect is achieved by the heavyweight product manager, who has enough power in decision making to focus the people on the product and its customers.

In the project execution team, many of the members have functional homes, but are seconded into the team organization for the duration, or at least a significant fraction of the duration, of a product development program. This achieves even more focus on the product and its customers than the heavyweight product manager form of organization. It also enables development people to return periodically to functional homes to maintain their functional competence.

In the independent product development team (PDT), the product development people do not have functional homes. Their complete organizational role is as a member of a PDT. This generates even greater focus on the product and its customers than the project execution team (although it tends to cause some career development problems for the team members).

In reality the different forms of organization lie on a continuum that relates the relative strength of the functions and the PDTs (Fig. 2). In the functional structure organizational configuration, the functions have the power, as suggested in Fig. 2(a). Progressing through the five types of organizational configuration, the functions (rows) become weaker, and the PDTs (columns) become stronger until in the independent PDT configuration the PDTs have all of the power (Fig. 2b). In the heavyweight product manager configuration--the first one that is typically referred to as a multifunctional team--the PDTs and the functions usually have roughly equal power.

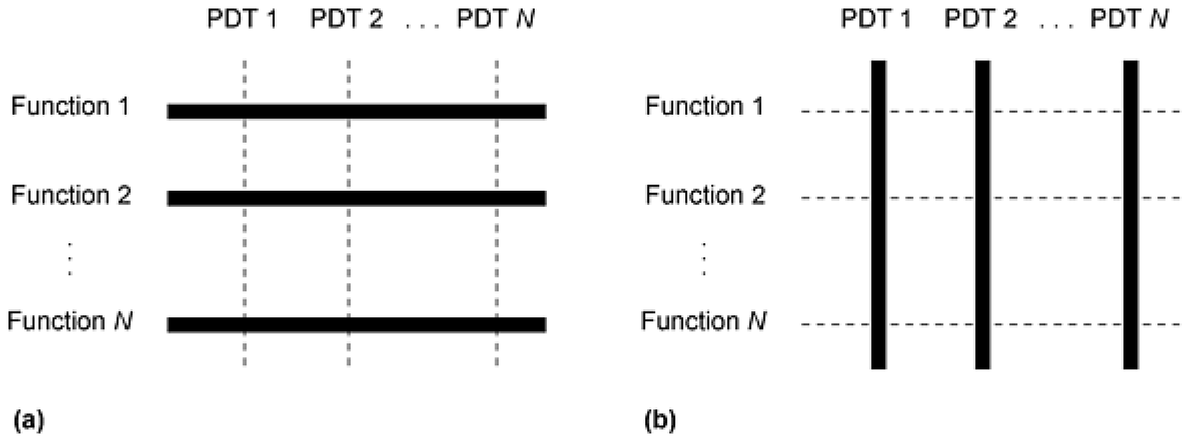

Fig. 2 Product design teams versus functional roles. (a) Organizational configuration with strong functional roles. (b) Organizational configuration with strong product design teams

If the products are fairly simple, the market is changing only slowly, and technical expertise is very important, then the functional organization works well. However, for complex products in a rapidly changing market with only normal technical-expertise requirements, the functional organization has proven unsatisfactory; it is too slow and weak in coping with complexity.

The independent PDT configuration has the great advantage of strong focus on each product and its customers. It has three potential dangers:

- Functional obsolescence
- Weak learning across the PDTs
- Weak technology development

One approach to overcoming these three problems is to have a technology development organization that is responsible for avoiding the three dangers. These three dangers must be guarded against even when the concept of the independent PDT is working very well.

The trend since 1980 has been toward the project execution team and the independent PDT configurations. They provide the needed focus on the product and its customers.

Subsystem Teams. For relatively simple products, the multifunctional team is sufficient. However, for more complex products, the organizational configuration will have a team for each subsystem, as shown in Fig. 3(a). For still more complex products, the organization can have added features, for example, another layer, modules, can lie between the Chief Engineer and the subsystem teams.

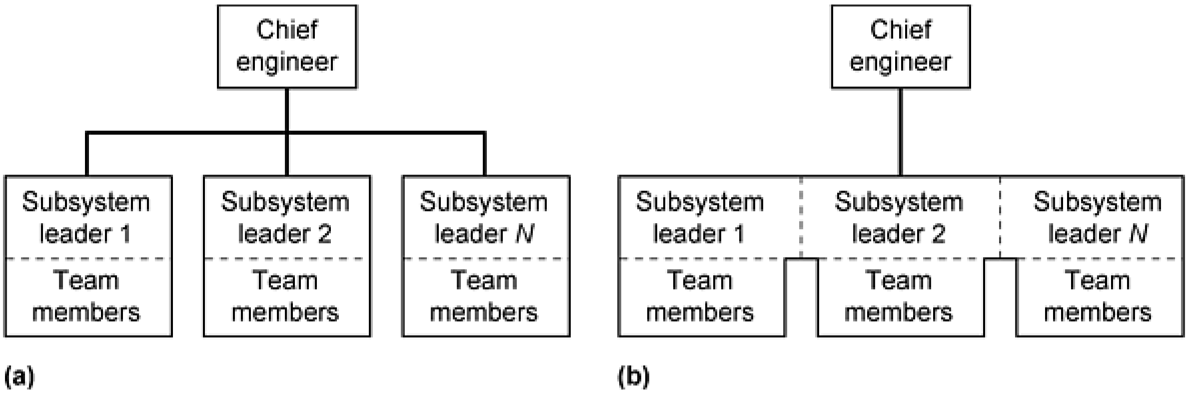

Fig. 3 Product design team configurations. (a) Subsystem teams. (b) Team of subsystem leaders

Higher Level Teams. An extension of the subsystem teams is indicated in Fig. 3(b). In this organizational configuration, the subsystem leaders also work as a team to make decisions. For example, resources are shifted from one subsystem to another as required. The practice of this higher level of multifunctional teamwork is still lagging behind the success of the multifunctional subsystem teams.

It is now increasingly important to extend the multifunctional team along the complete value chain. The early form of this has been called supplier involvement or something similar. However, the trend is to more equal partnerships, that is, the extension of multifunctional teamwork along the value chain. A critical decision is the design of the value-chain enterprise. Enterprise here usually means more than one corporation. This is a further challenge to the concept of the multifunctional team. Additional information about team-based activities is provided in the article "Cross-Functional Design Teams" in this Volume.

In summary, the central concept of concurrent engineering is the multifunctional team that concurrently brings all of their specialized knowledge to bear in making each decision. Next the decision-making style of the multifunctional team is considered. As they carry out the concurrent process, their decision-making style is critical to success.

Don Clausing, Massachusetts Institute of Technology

Requirements, Concepts, and Improvement

The multifunctional product development teams make many types of decisions. All of them follow a three-step decision-making process: requirements, concepts, and improvement.

1. *Requirements:* What the product needs to be and do is assessed.
2. *Concepts:* The concept with the best potential to satisfy the requirements is determined.
3. *Improvement:* The details of the concept are rapidly improved to approach its full potential.

This three-step decision process is applied repeatedly, starting with a very broad scope and converging to the most detailed decisions. Early in the total development process, the decisions will be about product families and platforms. Near the end of the development, the decisions will be very detailed, for example, how a hole should be drilled in a part. The earlier decisions become requirements for the later, more detailed decisions. For example, after the team has decided that a part will be made of aluminum, the decision about the hole must be for an aluminum part. The fact that it is faster to make a hole in a polymer is then no longer relevant. Aluminum has become a requirement. The concept of the hole (cast, drilled, reamed, broached, etc.) must be responsive to the requirement of aluminum. (Of course, the machinability of the

material was taken into account in the earlier decision to select aluminum.) The style that teams use to make the decisions about requirements, concepts, and improvement can range from ad hoc to structured decision making.

Structured Decision Making

Simply having a multifunctional team improves decision making in three ways:

- All relevant information is brought to bear.
- Iteration loops are short.
- The commitment of all parties makes success possible.

However, experience has shown that problems still exist with decision making by multifunctional teams.

The default decision-making style of teams is slightly caricatured as follows. Everyone sits around a table, talks, and waves their hands. At the end of the meeting, they write down on a flip chart some words that point to the decisions that were made. This ad hoc style of decision making leads to non-vigilant information processing.

Teams in their decision making need to achieve common understanding, consensus, and commitment. When teams engage in the ad hoc decision-making process that they tend to fall into by default, they seldom do well in achieving common understanding, consensus, and commitment. This is especially true for complex systems.

By definition, multifunctional teams lack common understanding as they start their work. The diversity of knowledge is what makes a multifunctional team necessary. Only after they develop a reasonable set of common understandings are they able to engage together in sound decision making.

Consensus and commitment are needed for the decisions to be applied in the future. A great weakness of the ad hoc approach to decision making is that the words on the flip chart at the end of the day are often ignored in subsequent decision making.

Experience and research have shown that structured decision making leads to vigilant information processing, which achieves common understanding, consensus, and commitment. There is still some concern that structured methods will inhibit creativity or have other negative effects. As Aristotle pointed out, the golden mean is usually desirable. It is possible to go too far with structured methods. However, in the opposite direction lies non-vigilant information processing and chaos and confusion, especially in the face of complexity. The judicious application of structured methods enables sound decisions and makes it possible to reduce complexity to workable tasks.

The structured decision-making processes described below enable the multifunctional team to make high-quality decisions in a reasonably short time. These high-quality decisions save much time by avoiding the later rework that plagues the projects that try to make do with ad hoc decisions.

Requirements Development

There are two types of requirements development by multifunctional teams. One, quality function deployment (QFD), is market driven. The second, functional analysis, is an engineering analysis that is driven internally.

Quality Function Deployment (QFD). QFD starts with the needs of the customers as expressed in the voice of the customer. The PDT then deploys these requirements from the voice of the customer to the factory floor. This deployment is done in small logical steps that are feasible to do.

QFD uses large visible displays to help the team in its decision making. These large visible displays are matrices (input/output tables) that are usually on large sheets of paper, approximately two meters square, that are fastened to a wall. This becomes the focus of the team decision making. It enables the team to refresh their memory about the relevant information, see the relationships among the information, and to record the decisions as they are made.

The first matrix in the deployment chain is for product planning and is called the "house of quality." Its input is the voice of the customer, and its output is the quantified specifications for the new product.

The product planning matrix is referred to as a house simply because it has the shape of a house (Fig. 4). Then each field within the matrix is called a room. Room 1 is the voice of the customer, the input. Rooms 2 and 8 contain the output. Room 2 contains the names of the specifications for the new product. Room 8 contains the quantified goals for the new product. For example, for a car, one column would specify the horsepower, while another column would specify the required life.

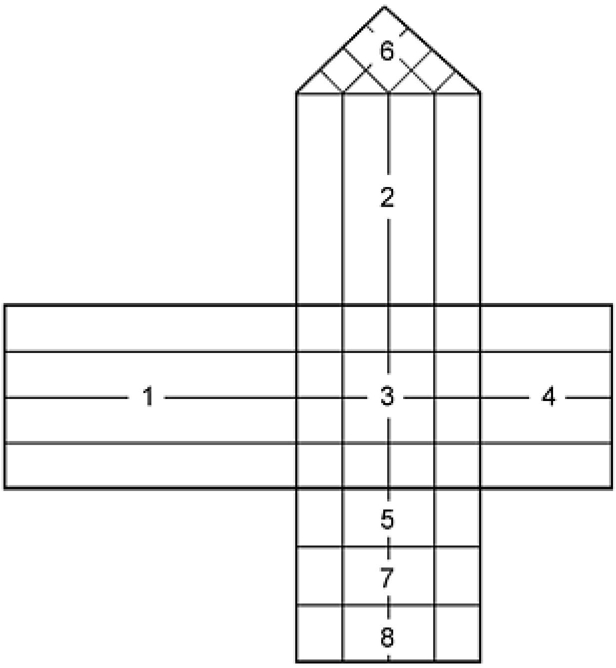

Fig. 4 Organization of a quality function deployment (QFD) "house of quality" product planning table. 1, voice of customer input; 2, specifications for new product; 3, translation between voice of customer and product specifications; 4, market research information; 5, technical benchmarking; 6, intersection of specifications (to examine conflicts or synergy); 7, weighting of importance of each characteristics; 8, quantitative goals for new product

The other rooms in the house of quality are to help the PDT to make the decisions that deploy the objectives from room 1 to rooms 2 and 8. Room 3 is used to understand, model, and verify the translation from the voice of the customer (room 1) to the corporate requirements (room 2).

Rooms 4 and 5 are market research and benchmarking results, which serve as the basis for deciding the quantitative goals in room 8. Room 4 is benchmarking by customers (market research), as well as strategic goal setting. Room 5 is benchmarking by technical tests. Then the quantitative goals in room 8 are selected to be sufficient improvements over the benchmarks.

Rooms 6 and 7 are used to help plan the development project. Each cell in room 6 is the intersection of two columns, and the question becomes whether the requirements conflict or are synergistic. For example, hardness and toughness conflict. By recognizing all conflicts early, the PDT can plan the development project to apply the resources to achieve success in both characteristics, not simply settling for the existing trade-off. Room 7 contains an estimate of the importance of each characteristic and an estimate of the difficulty in achieving the quantified specification. Other project-management information can be included in room 7. The combination of rooms 6 and 7 helps the PDT to plan the development project, that is, which objectives should have the most resources. Thus the project is made responsive to the needs.

Once the product has been planned, the PDT has a clear statement of what the product must be and do. Furthermore, the PDT is committed to the goals because they worked together to develop them.

Next the goals are deployed to the next stage of decision making. The exact path that is followed depends on the complexity of the product. Also, it is necessary to select the product concept before the requirements can be completely deployed into more detail.

Before the deployment path is considered, the other form of requirements development is described. Additional information about QFD is provided in the article "Conceptual and Configuration Design of Products and Assemblies" in this Volume.

Functional analysis is a traditional engineering practice, often used in the past in value engineering. It is even more useful when it is used from the beginning of the development project in conjunction with QFD.

The basic approach is the construction of a functional tree; an example is shown in Fig. 5. The top of the functional tree contains the primary function to be performed by the whole product. The requirement for a copier is to make copy. Then the PDT members ask the question *how*? This leads to the next level of functions. Feed sheet is one of the "hows" to make copy. Each function is stated as a verb and a noun. Sometimes adjectives are added to clarify the meaning of the noun. By simply answering how, the PDT deploys the functional requirements into more detail. (The complete functional tree for a copier has several hundred boxes. Although this might seem to imply thousands of requirements in the accompanying QFD matrices, in actual practice the requirements in each QFD matrix are prioritized so that a typical matrix has roughly 30 requirements.)

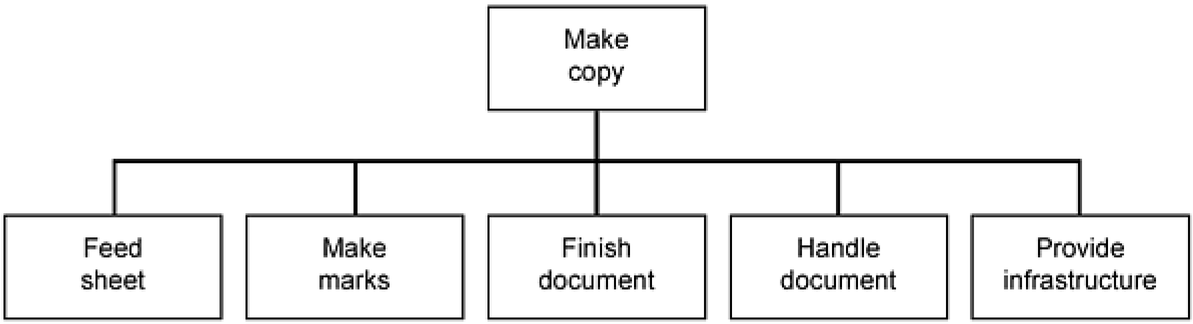

Fig. 5 Example of a functional tree for a photocopier

As with QFD, it is not possible to develop the complete set of requirements until some concept selection has been completed. For example, the requirements at the next more detailed level will depend on the selection of xerography or ink jet as the marking concept.

Integration of QFD and Functional Analysis. Functional analysis is a sparse, engineering statement of requirements. QFD is much more detailed and starts with the voice of the customer. The basic concept of integrating the two is simple. The statement that the requirement for a copier is to make copy includes many other caveats. It should cost less than a penny per copy. The copier should not take too much space. It should be easy to use, etc. These amplifications of the functional requirement are captured in the columns of the QFD matrix. The amplifications that are most important to the development project are captured in the QFD matrix. Other amplifications of the functional requirement are more mundane and fall into the category of knowledge-based engineering or standards. (Knowledge-based engineering emphasizes engineering practices, art, and solutions that have a record of success. These techniques often are implemented with the help of computers.) This relationship is indicated in Fig. 6.

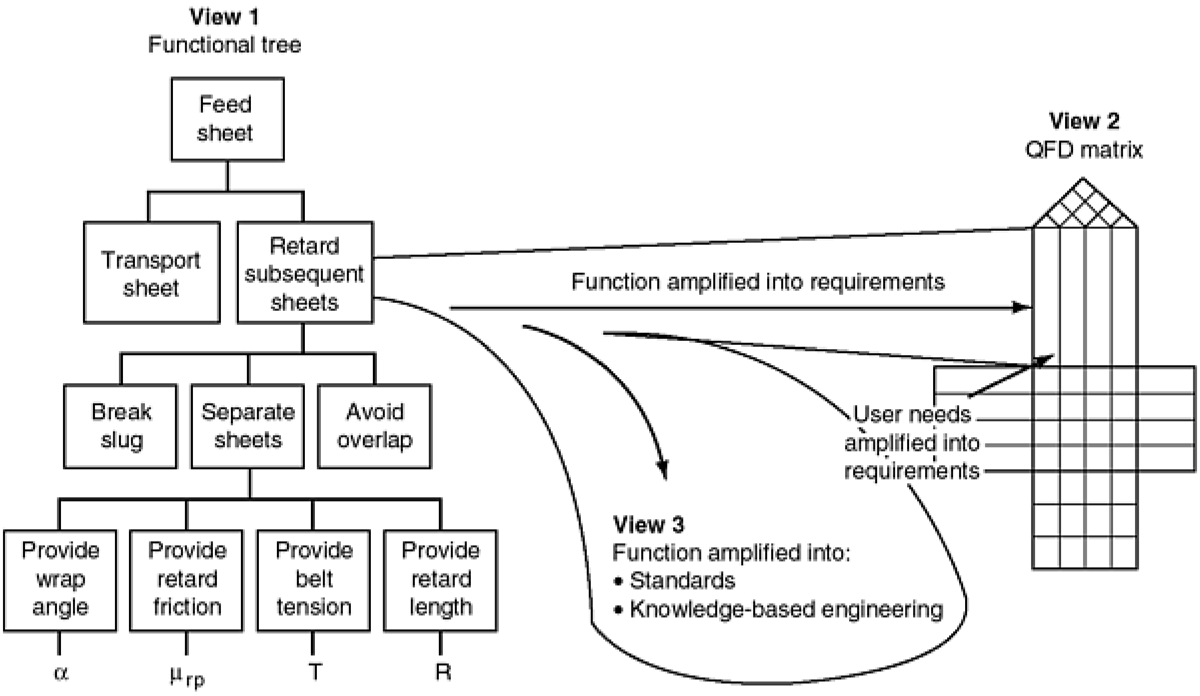

Fig. 6 Three views of product requirements

As indicated in Fig. 6, the column headings in the QFD matrix can be thought of as having two sources:

- The rows of the matrix
- The associated functional requirement

There is not at this time a detailed methodology for executing this integrated view of requirements. Usually it is sufficient for the PDT to prepare the QFD matrices and the functional trees, and have the relevant knowledge-based engineering and standards available. Then the PDT considers all three types of requirements:

- Functional tree
- QFD matrix
- Knowledge-based engineering and standards

The relationships among the three are suggested by Fig. 6. The important operational step is for the team to come to a consensus on a consistent message while considering all three types of requirements.

The requirements lead to the generation and selection of the concept.

Concept Development and Selection

The PDT selects the concept in response to the requirements. First, concepts must be found or generated. Then starting with the initial set of concepts, the PDT progressively develops and selects concepts until they converge on the dominant concept.

The generation of new concepts, invention, has long been said to be the one area to which structured methods cannot be applied. The best approach has been to immerse the creative people in the definition of the requirements. (Necessity is the mother of invention.) In response to the emerging statement of the requirements, the creative people will spontaneously generate new concepts. This is still a good approach. However, in the mid-1990s, a structured approach is also starting to

be used in the United States. Additional information is provided in the article "Creative Concept Development" in this Volume.

TRIZ. A structured method for invention that was developed in the former USSR is starting to be used in the United States and western Europe. It is called theory of inventive problem solving (TIPS), or TRIZ (the Russian equivalent of TIPS), or related names. Although the experience with this approach is brief, it appears to be very promising and is attracting many early applications.

TRIZ was developed by Genrikh Altshuller in the USSR, who studied a huge number of patents and observed patterns in invention. Some of his key observations are:

- Conflicts are the mother of invention.
- Standard solutions occur in diverse fields.
- Evolution of technological systems follow certain patterns.
- Systematic application of scientific effects aids invention.

An example will help to communicate the basic approach of TRIZ. In Fig. 7(a) shot is flowing through a pipe. A basic contradiction is displayed. The TRIZ solution is shown in Fig. 7(b). The use of one of the interfacing materials to form the interface is one of the standard approaches that has emerged from the study of the huge number of patents. Mastery of TRIZ involves learning these standard approaches and the other patterns that have emerged from the long study of invention.

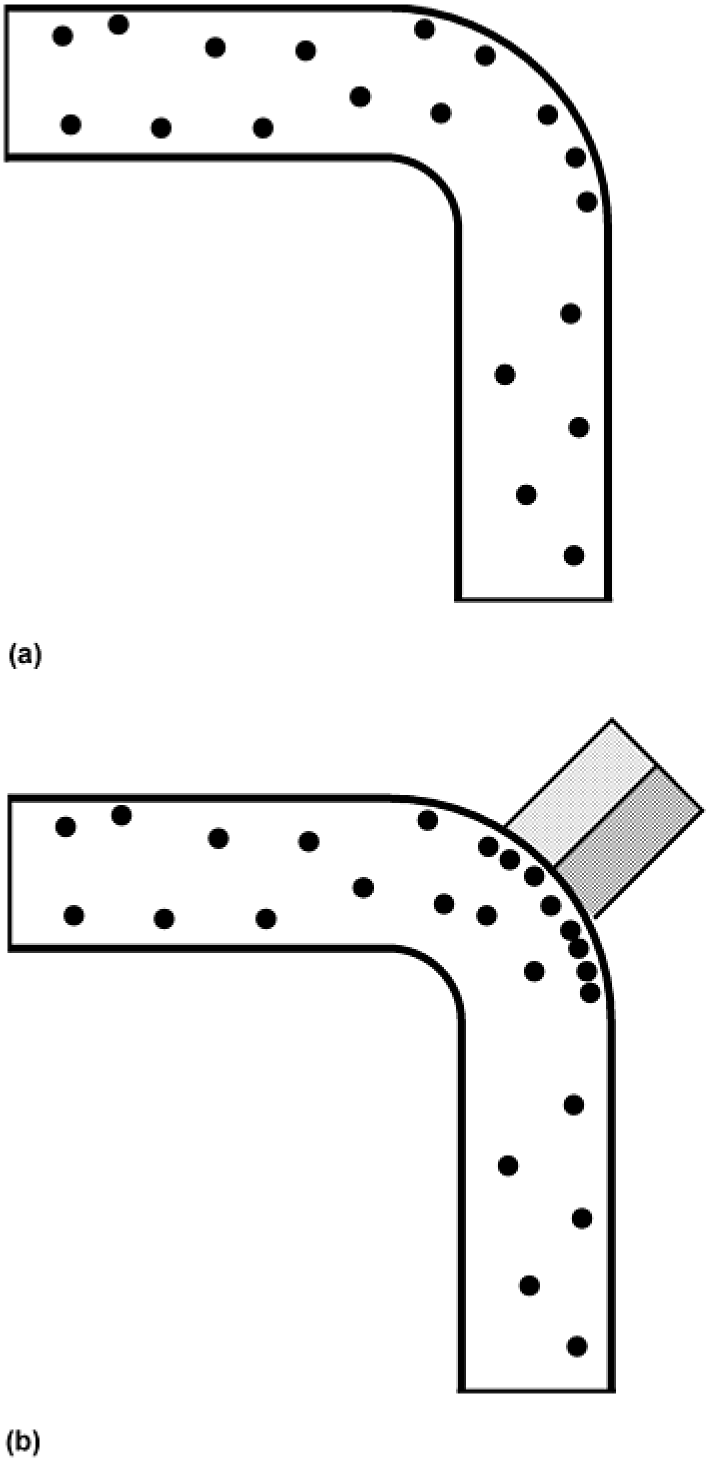

Fig. 7 Design problem and solution. (a) Problem: Shot wears pipe at turn. The contradiction is that a coating appears to be needed, but is not a good solution because of added cost and short life. (b) Solution: Magnets are used to form a continuously replenishable protective layer of shot.

However the concepts are formed, it is important to build a set of competing concepts that are each responsive to the requirements. These are used as the starting concepts in the Pugh concept selection process.

Pugh Concept Selection. The Pugh concept selection process starts with the initial set of concepts and the requirements, and helps the PDT to develop and select the best concept. Although it is called selection, the concept that is selected is seldom exactly one of the initial concepts. "Evolution" describes the successful practice better than does "selection." The team further develops the concepts as the result of the insights that this process helps them to recognize.

The Pugh concept selection process is carried out with a large matrix, Fig. 8. The rows are the criteria, and the columns are the concepts. The criteria are based on the QFD matrix and the functional tree. The PDT typically develops 15 to 20 criteria to be used in the Pugh matrix.

Responsiveness	Datum	+	+	+
Braking	Datum	–	–	–
Ease of manufacturing	Datum	S	–	–
Safety	Datum	+	+	–
Risk	Datum	–	–	–
Complexity	Datum	S	–	–
Total		+2	+2	+1
		S 2	S 0	S 0
		–2	–4	–5

Fig. 8 Example of a Pugh concept selection matrix. +, better than; S, same as; and -, inferior to the datum

One concept is selected as the datum (reference concept), and the other concepts are evaluated with respect to the datum. This is done one row at a time. This pair-wise comparison is essential to the success of this process. Pair-wise comparison is much superior to abstract evaluation. Each concept is simply judged to be better than (+), the same as (S), or inferior to (-) the datum concept.

Although the scores are shown added up in Fig. 8, the main value of the Pugh concept selection process is that it helps the team to develop insight into both the criteria (row headings) and the concepts. These insights lead to clarification of the criteria and to improved concepts. The new concepts that are generated during this process are often hybrids of the initial concepts.

This is an iterative process. Typically the matrix is run one or two times during a session. The datum is changed between runs. There are explicit efforts to eliminate negatives and reinforce positives. After another week or two of work, the team comes together again to run the matrix. The process is complete when the team converges on the dominant concept in which they have confidence and to which they are committed.

The Pugh concept selection process leads to the selection of good concepts without the application of excessive resources. The good concept and the confidence of the team are essential to the successful development of the new product. An example of the Pugh method applied to materials selection is provided in the article "Decision Matrices in Materials Selection" in this Volume.

Integration of Requirements Development and Concept Development and Selection

Figure 9(a) displays the integration of requirements and concept. In the spirit of concurrent engineering, the requirements for the product and the requirements for the production process are considered together in selecting the concept. The concept includes both the product itself and the production capability to produce the product. (Field-support capability is also included, but for simplicity it is omitted from this description.)

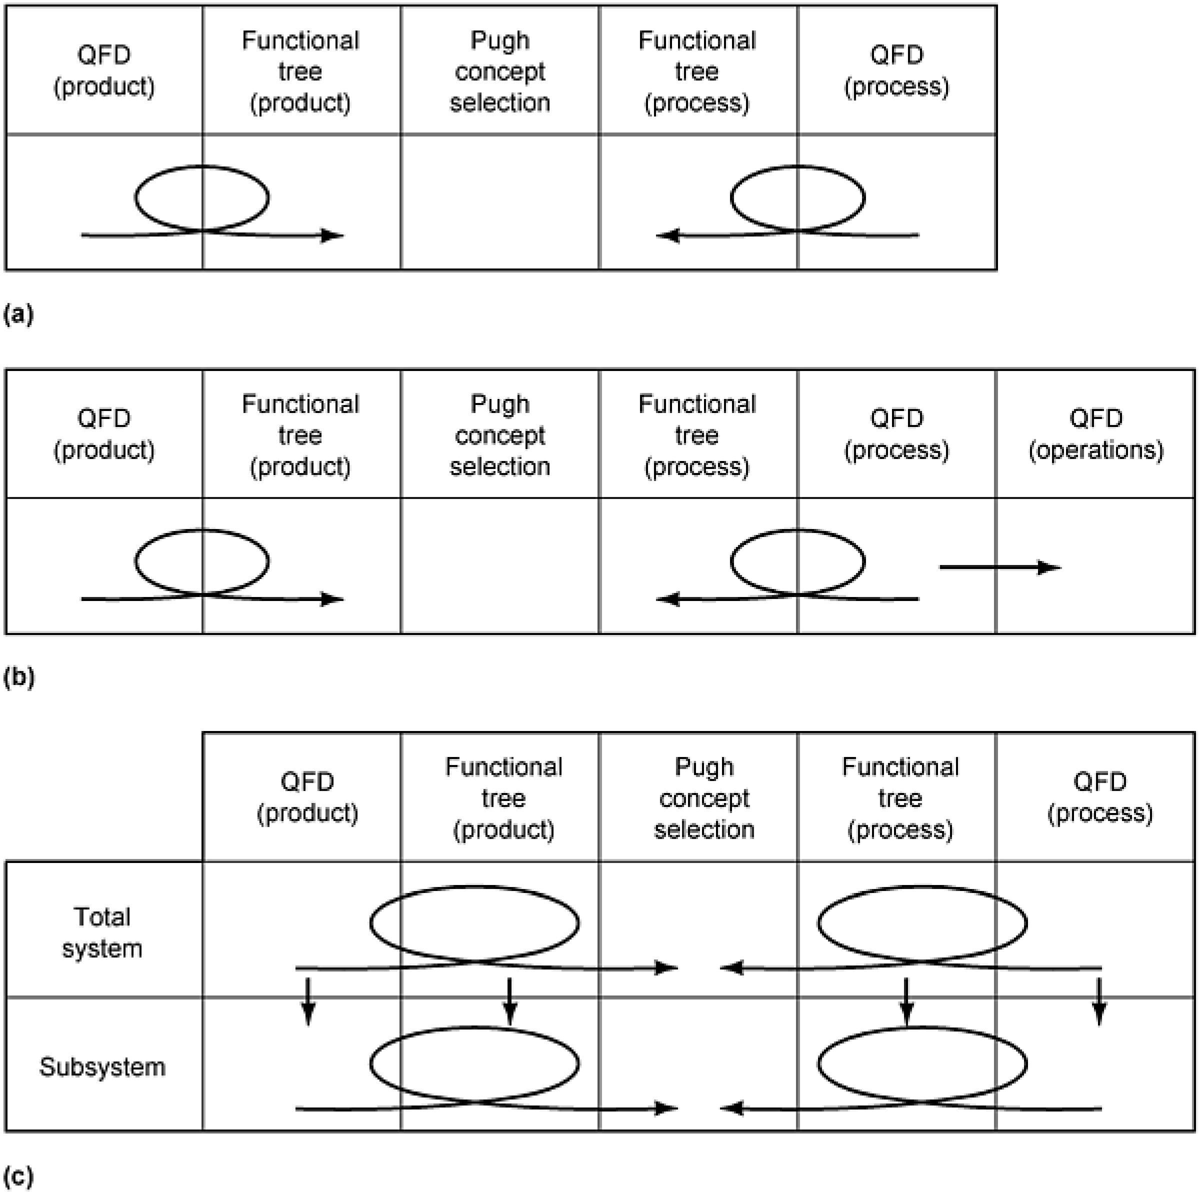

Fig. 9 Integration of product requirements and concept development. (a) Idealized representation of steps for developing product requirements, concept, and production capability. (b) Steps including deployment to the factory floor (operations QFD). (c) Deployment through the levels of the system

The arrows with loops in Fig. 9(a) indicate that the QFD form of the requirements and the functional tree form of the requirements are developed together and made to be consistent. This is done for both the product and for the production capability. The production process capability QFD matrix has for its input (rows) the product requirements (columns) of the product QFD matrix. This integrates the product and its production capability, and makes both responsive to the customers.

In reality, Fig. 9(a) is highly idealized with respect to actual practice. The typical concurrent practice goes through the steps of Fig. 9(a) iteratively. Usually the product requirements and concept are done first; then the production capability is considered. If the production appears to be straightforward, it is often not considered until later. Functional trees are often postponed until later. Each multifunctional team needs to find a path through Fig. 9(a) that is effective for them. However, the best practice is to integrate the elements of Fig. 9(a) as much as possible; that is to do all of the steps with iteration loops that are very short in duration.

After the steps of Fig. 9(a) are completed, the production decisions are deployed to the factory floor in the QFD operations matrix, as implied in Fig. 9(b). The process QFD is process engineering, while the operations QFD generates the nitty-gritty information that is needed for factory operation.

For a simple product (e.g., a knife with one or two parts), Fig. 9(b) is all that is needed. However for complex products, the requirements and concepts must be developed in several levels, such as total system, subsystem, and piece part or component. The decisions at each level must be relatively complete before proceeding very far at the next level. For example, the total system architecture (TSA) must be selected before the requirements are deployed from the total system level to the subsystem level.

The basic concept is displayed in Fig. 9(c). First the requirements are developed, and the concept is selected at one level. Then in the context of the selected concept, the requirements are deployed down to the next level, and the process is repeated. This is done for as many levels as is necessary, which will depend on the complexity of the system that is being developed. A typical set of levels for one complex system is: total system, module, subsystem, subassembly, piece part, and piece-part feature. This hierarchy also extends upward to include platforms and families of products.

Concepts that are responsive to the requirements are selected for each system level by the process that is displayed in Fig. 9(c). These concepts have high potential. However, some of them will be innovative but embryonic. They need improvement to let their full potential bloom. The improvement is needed rapidly to satisfy the ever shortening time-to-market requirements.

Improvement of Concepts

After a concept is selected, it must be improved to achieve something close to the full potential of the concept. Of course, if the concept was already improved close to its potential limit for a previous product, then it does not have to be improved again. This is a big advantage of reusability. Nevertheless, some elements of a product are usually new concepts that have not previously been systematically improved.

Improvement to achieve high quality and reliability has two aspects:

- Improving performance to make it close to ideal
- Minimizing mistakes

Very different approaches are needed for these two aspects.

Robust Design. Robustness means that the performance of the system is always acceptably close to the ideal function of the system. Even the best of concepts does not do this in its initial configuration and trials. Systematic optimization rapidly improves the performance from the initial promising but inadequate state to a level that captures most of the potential of the concept.

Metallurgists have long practiced a simple form of this systematic improvement. The concept of a new alloy is developed on the basis of prior knowledge until the composition and heat treatment are approximately as desired. Then designed experiments are used to improve the alloy to its final design. The initial composition can be thought of as the concept. Then rapid improvement is done. The emphasis has been on the design of the experiments. The improvement of an alloy is relatively simple.

The rapid improvement of a complex system is much more difficult than fine tuning an alloy. First of all, the emphasis must shift. The design of the experiments is challenging, but is relatively the simpler part of the entire process. The greater challenge is to define the objective in a way that will be effective. A second challenge is to conduct the improvement activity in a way that is time efficient. People with experience in the simple improvement of alloys usually have had some difficulty in making the switch to the improvement of complex systems. It is a big mistake to think of robust design as just a small extension of the design of experiments (DOE).

Although there were pockets of robust design activity in the United States before 1980, it became a well-recognized industrial practice when Dr. G. Taguchi came to the United States and introduced his comprehensive and well-developed approach. Taguchi developed his approach as a practicing engineer in industry. It is uniquely well suited to competitive product development.

Taguchi's quality engineering has two major elements:

- *Parameter design:* optimization of the nominal values of the critical parameters of the system to make the performance robust
- *Tolerance design:* the selection of the best precision levels around the nominal values

It is critically important to do parameter design first. Tolerance design selects the best precision levels around the optimized target values of the critical parameters. Tolerance design alone, no matter how well done, is never a substitute for parameter design.

Parameter Design. A critical parameter is simply a parameter that strongly affects the performance of the system and for which the PDT can select the nominal value. In Taguchi's nomenclature, these are control parameters because the PDT has control of the nominal value. For a steel alloy, the amount of nickel is a critical control parameter. Fault trees (the negative of functional trees) have been found to be very useful in helping PDTs to identify the critical parameters.

Complex systems typically have hundreds of critical parameters: dimensions, forces, friction coefficients, electrical characteristics, etc. One big designed experiment with hundreds of parameters is not feasible. Therefore, most of the optimization of robustness is done at the subsystem or subassembly level. The number of control parameters in one designed experiment is commonly in the range of 4 to 15.

Time-efficient improvement is achieved by an appropriate tradeoff between time and certainty. One could run many repetitions of the same system setup in order to be more certain (higher confidence level) of the result. However, this is a poor tradeoff, which will take too much time. Usually there is a fixed amount of time to complete the improvement of the robustness of the system, typically a few months. The available time can be used to optimize a few parameters with great certainty. Alternatively, many more parameters can be optimized with somewhat less certainty. The latter is the best approach. Therefore, unless repetitions are very easy and quick to do, they are not used. Putting it in another way, between any two trials of the system the values of the critical control parameters are systematically changed. (The changes are defined by an orthogonal array, a table of designed experiments.) This provides much more information than repetitions.

In addition to the parameters that the PDT can control, there is another type of parameter that affects the performance of the system. For a product that operates out of doors, the ambient temperature is an example. The PDT cannot control such a parameter during operation by customers. Still they must be taken into account during the optimization. Taguchi calls such parameters noise parameters. There are three types of noise parameters:

- *Environmental:* Ambient temperature is an example.
- *Manufacturing:* No two units of production are exactly alike.
- *Deterioration:* This will cause further changes in the parts of the system.

Note that the last two types of noises, manufacturing and deterioration, are essentially the same, that is, deviations of the values of the critical control parameters away from the nominal value. The manufacturing type includes the initial deviations within the product as it is shipped. The deterioration type includes further changes as the result of use and time.

It is very important to introduce noises when doing the optimization of robustness. One of the primary objectives is to make the system robust against the noises. Thus the noises are intentionally introduced into the optimization. This is problem prevention, not waiting for the problem to appear much later. In the absence of an explicit approach to robustness, the noises are usually ignored until late in the development project; that is, the system is initially pampered. When noises are introduced during production-readiness testing, the bad effects are observed when it is too late to effectively cope with them. Parameter design introduces the noises very early so that the optimization can mitigate the effects of the noises. This avoids many problems and much rework later in the development project.

The introduction of noises often requires some ingenuity and development. A paper feeder is an example. One failure mode is the feeding of two sheets of paper. Many good types of papers have little tendency to have this failure mode. Testing with such papers has little value for the improvement of the robustness of the performance. Eventually it was recognized that alternating sheets from two different types of paper created a special paper stack with a useful amount of noise; that is, it challenged the feeder with a tendency to multifeed. Developing such noise conditions is often essential to the efficient optimization of robustness.

The most important element in the successful practice of robust design is the characterization of the performance. As an example, consider an electrical resistor. Its performance is usually characterized by the resistance, *R*. However, the value of *R* is not important to quality and reliability. Any nominal value of *R* that is desired is easily achieved. The characterization *R* already assumes a linear relationship between voltage and current, with *R* being the slope of the assumed straight-line relationship between voltage and current. The specific value of *R* is not of primary interest in optimizing the robustness of the resistor. Rather the quality of the straight-line relationship between voltage and current is important. Therefore, voltage is plotted versus current with two noise conditions: noise values that cause small current and noise values that cause large current. The most robust resistor is the one that has the least deviation from a straight line, which is the ideal performance of the resistor. The smallest value of the ratio of the deviation from the straight line divided by the slope of the straight line is needed. After further analysis, the square of the ratio is taken. Therefore, the ratio of the average of the square of the deviations (averaged over all data points) is divided by the square of the slope of the best-fit straight line through the data. This is the measure of robustness. Taguchi developed a set of such metrics to which he gave the name signal-to-noise (SN) ratios. Larger values of any SN ratio represent more robustness.

The most important steps in robust design are:

1. Define the ideal performance - often not simple to do
2. Select the best SN definition to characterize the deviations from ideal performance
3. Develop the sets of noises that will cause the performance to deviate from the ideal

After some experience, the use of the design of experiments to rapidly increase the SN value is relatively straightforward.

As an example, a subsystem is considered for which the PDT has identified the 13 most critical control parameters. Initial judgments are made of the best nominal values for each of the 13 control factors. Seeking improvement, a larger value and a smaller value are selected as representing feasible but significant changes to the initial design. This gives three candidate values for each of the 13 critical control factors. The total number of candidate sets of values is 3^{13}, which is 1,594,323. Even a relatively simple subsystem gives a large number of candidates from which the PDT must select the best one, or better yet, quickly pick one of the best candidates. This requires systematic trials, that is, designed experiments. A standard orthogonal array is found that has 13 columns and 27 rows. The 13 critical control factors are assigned to the 13 columns. Each row defines one candidate for the critical values of the 13 parameters. The 27 rows define a balanced set of 27 candidates from the total of 1,594,323 candidates. For each of the selected 27 candidates, the appropriate sets of noises are applied and the performance is determined, either analytically or experimentally. The SN ratio (robustness) of each of the 27 candidates is calculated. A simple interpolation among the 27 values of the SN ratio predicts the candidate from the total of 1,594,323 that is probably the best. Typically the PDT iterates two or three times. The control factors that had little effect are dropped, and some others are introduced. The ranges of the values for the control factors are reduced to fine tune the optimization. Then a confirmation trial is conducted to verify the magnitude of the improvement. It is very important to do this parameter design early and quickly.

The results of the parameter design are best captured in a critical parameter drawing. This drawing shows the system (usually a subsystem) with only as much detail as is needed to make the critical parameters clear, and it shows the values of the critical functional parameters that have been optimized. These then become specifications for the detailed design. By constraining the detailed design to the optimized values of the critical functional parameters, the robust performance is ensured.

Tolerance Design. The optimization of robustness (SN value) often brings very large improvements. After the nominal values of the critical control factors are optimized, tolerance design is done. Of course, most of tolerance design is guided by standards and knowledge-based engineering. However, some decisions require more in-depth analysis. The primary step in tolerance design is to select the production process (or the precision of a purchased component) that provides the best tradeoff between initial manufacturing cost and quality loss in the field. Taguchi developed methods for this analysis. After the production process is selected, tolerances are calculated to be put on the drawings and other specifications. However, selecting the production process is the most important step in tolerance design, as it controls the inherent precision.

The timing of robust design is critical for success. The optimization of robustness must be done early to achieve the benefits of problem prevention. As shown in Fig. 10, most of the optimization of robustness (parameter design) should be done to new technologies before they are pulled out of the stream of new technologies and integrated into any specific product. Any remaining product parameter design (SPD) is done early in the product program, before detailed design has

progressed very far. The final verification of the robustness is done in the system verification test (SVT). The SVT is usually performed on the first total-system prototypes, which are made after the detailed design has been completed. (In the concept phase, the decisions of the first row of Fig. 9(c), total system decisions, are made. In the design phase, the decisions of the second row of Fig. 9(c), subsystem decisions, and the decisions at the other more detailed levels are made. In the readiness phase, the decisions are deployed to the factory floor, as indicated at the right of Fig. 9(b). Also in the readiness phase, mistakes are eliminated.)

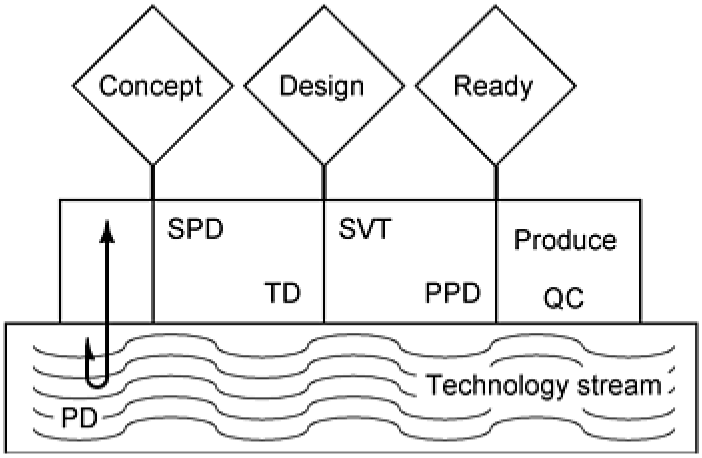

Fig. 10 Timing of Taguchi robust design steps. PD, parameter design (new product and process technologies); SPD, system (product) parameter design; TD, tolerance design; SVT, system verification test; PPD, process parameter design; QC, on line quality control (factory floor)

Robust design is very important. Robust systems provide customer satisfaction, because they work well in the hands of the customer. They have lower costs because they are less sensitive to variations. Robust subsystems and components can be readily integrated into new systems because they are robust against the noises that are introduced by new interfaces. Most important of all, the early optimization of robustness reduces time to market by eliminating much of the rework that has traditionally plagued the latter stages of product development. This section is a brief introduction to the subject that has emphasized the primary features. Additional information is provided in the article "Robust Design" in this Volume.

Mistake minimization is completely different from the optimization of robustness. Robustness optimization is done for concepts that are new, for which the best values of the critical functional parameters are unknown. Mistake minimization applies to system elements for which there is experience and a satisfactory design approach is known, but was not applied. Examples range from a simple dimensional error to a gear that is mounted on a cantilever shaft that is too long. The excessive deflection of the shaft causes too much gear noise and wear. The design of gears and shafts is well understood, so one that has a problem is a mistake. The mistake could be a simple numerical error. It could be that the person (or computer program) with the necessary knowledge was not readily available.

The first approach is to avoid making mistakes by using a combination of:

- Knowledge-based engineering (and standards)
- Concurrent engineering (multifunctional teams)
- Reusability

Knowledge-based engineering helps to design standard elements, such as gears and shafts, using design rules and computers to implement proven approaches. Multifunctional teams help to avoid mistakes by having the needed expertise available. (A common source of mistakes is that the knowledgeable person was not involved in the design.) Reuse of proven subsystems, which have demonstrated that they are not plagued with mistakes, will also reduce mistakes.

Despite all of the best efforts to avoid the occurrence of mistakes, some mistakes will still occur. Then they must be rooted out of prototypes of the system by the problem solving process. This process is basically:

- Identify problems.
- Determine the root causes of the problems.
- Eliminate the root causes while ensuring that no new problems are being introduced.

Failure-modes-and-effects analysis (FMEA) is very useful in doing this (see the article "Risk and Hazard Analysis in Design" in this Volume).

The combination of robust design and mistake minimization will achieve excellent system quality and reliability. It is important to recognize that reliability is not a separate subject above and beyond robust design and mistake minimization. The traditional field that is called reliability is primarily devoted to keeping score of reliability and projecting it into the future based on certain assumptions. Robust design and mistake minimization achieve early and rapid improvement of reliability. This will rapidly develop new concepts to capture their full potential.

Conclusions

The fundamental core of concurrent engineering is the multifunctional team that carries out the concurrent process to make holistic decisions. These decisions integrate the many diverse specialties to develop a product that provides customer satisfaction.

Simply having a multifunctional team improves the decision making by bringing all of the relevant information to bear on each decision. The concurrent process also gains the commitment of all of the participants to the decisions, which leads to effective implementation. However, multifunctional teams can improve their decision making relative to the ad hoc approach into which it is all too natural to fall. The judicious application of structured methods described in this article and elsewhere in this Volume enables sound decisions and makes it possible to reduce complexity to workable tasks.

A multifunctional team that makes holistic decisions by using the best structured decision-making processes while concentrating on both customer satisfaction and business goals provides the greatest leverage for the abilities of the product development people. The products that they develop will:

- Be quick to market
- Satisfy customers
- Have constrained costs
- Be flexible in responding to changes in the marketplace

The ultimate purpose of concurrent engineering is to provide products that customers want and will purchase.

Designing to Codes and Standards

Thomas A. Hunter, Forensic Engineering Consultants Inc.

Introduction

REGARDLESS OF THE MATERIAL to be used, most design projects are exercises in creative problem solving. If the project is a very advanced one, pushing the boundaries of available technical knowledge, there are few guidelines available for the designer. In such instances, basic science, intuition, and discussions with peers are common approaches that combine to produce an approach to solving the problem. With the application of skill, daring, a little bit of luck, money, and patience, a workable solution usually emerges.

However, most design projects just are not that challenging or different from what has been done in the past. In mechanical and structural design, for example, a tremendous amount of solid experience has been accumulated into what has been called *good practices.* Historically, such information was carefully guarded and was often kept secret. With the passage of time, however, these privately developed methods of solving design problems became common knowledge, ever more firmly established. Eventually they evolved into published standards of practice. Some government entities, acting under their general duty to preserve general welfare and to protect life and property from harm, added the standards to their legal bases. This gave the added weight of authority to the standards development movement.

In some cases, use of a standard may be optional to the designer. In others, adherence to standard requirements may be mandatory, with the full backing of the legal system to enforce it. In any case, as soon as the problem has been defined, a competent designer should make a survey of any existing standards that may apply to the given problem. There are two obvious advantages to this effort. First, the standards may give valuable guidance to the problem solution. Second, conformance to standards can avoid later legal complications with product liability lawyers.

Designing to Codes and Standards

Thomas A. Hunter, Forensic Engineering Consultants Inc.

Historical Background

Anyone who has taken a course in elementary physics has been taught about the "fundamental" quantities of mass, length, and time. When the metric system of measurements was established in 1790, a standard was set for the unit of length: one ten-millionth of the distance from one of the earth's poles to the equator. It was, by definition, the meter. However, there were a couple of problems with it. Because there was no way to make such an actual measurement at that time, there was a certain degree of error, and the standard suffered from a lack of portability. Some improvement was made in 1889, when an international convention on weights and measures agreed that the standard meter would be defined by the distance between two marks on a metal bar. This improved both accuracy and portability, and this standard was used until 1960. Then the standard changed to the wavelength of an orange-red line in the spectrum of Krypton 86. In 1983 the standard of length changed again, this time to a measurement based on the speed of light in a vacuum. The point here is that even the most basic standard units are subject to change as methods of measurement become more and more refined.

While basic standards change only infrequently, technical standards and codes are all subject to more frequent modification. The thousands of published standards and codes are reviewed and updated periodically, many of them on an annual basis. Therefore, when making the recommended survey of applicable standards, the designer should check to make certain they are the most current ones. In addition, because of the periodic review process, it is advisable to query the publisher of the standard to find out if a revised version is being worked on, and if it may be released before the design is scheduled for completion. Obviously, to avoid instant obsolescence, any oncoming changes should be factored into the decisions made by the designer.

Designing to Codes and Standards

Thomas A. Hunter, Forensic Engineering Consultants Inc.

The Need for Codes and Standards

The information contained in codes and standards is of major importance to designers in all disciplines. As soon as a design problem has been defined, a key component in the formulation of a solution to the problem should be the collection of available reference materials; codes and standards are an indispensable part of that effort. Use of codes and standards can provide guidance to the designer as to what constitutes good practice in that field and ensure that the product conforms to applicable legal requirements.

The fundamental need for codes and standards in design is based on two concepts, interchangeability and compatibility. When manufactured articles were made by artisans working individually, each item was unique and the craftsman made the parts to fit each other. When a replacement part was required, it had to be made specially to fit. However, as the economy grew and large numbers of an item were required, the handcrafted method was grossly inefficient. Economies of scale dictated that parts should be as nearly identical as possible, and that a usable replacement part would be available in case it was needed. The key consideration was that the replacement part had to be interchangeable with the original one.

Large-scale production was not possible until Eli Whitney invented the jig. Although he is best remembered for his invention in 1793 of a machine for combing the seeds out of cotton, the gin (which any good mechanic could copy it and many did), Whitney made his most valuable contribution with the jig. Its use enabled workers to replicate parts to the same dimensions over and over, thus ensuring that the parts produced were interchangeable.

Before the Civil War, the Union Army issued a purchase order for 100 rifles, but included a unique requirement that all the rifles had to be assembled, fired, taken apart, the parts commingled, and then reassembled into 100 working rifles. Interchangeability was the key problem. Whitney saw that the jig was the solution. By using jigs, Whitney was the only bidder able to meet the requirement. With that, the industrial age of large-scale production was on its way.

Standardization of parts within a particular manufacturing company to ensure interchangeability is only one part of the industrial production problem. The other part is compatibility. What happens when parts from one company, working to their standards, have to be combined with parts from another company, working to *their* standards? Will parts from company A fit with parts from company B? Yes, but only if the parts are compatible. In other words, the standards of the two companies must be the same.

Examples of problems resulting from lack of compatibility are common. For years, railroads each had their own way of determining local times. A particular method may have been useful for the one railroad that used it, but wrecks and confusion demanded that standard times be developed. There used to be several different threads used on fire hose couplings and hydrants. All of them worked, but emergency equipment from one town could not be used to assist an adjoining town in case of need. So a national standard was agreed upon.

Any international traveler knows that the frequency and voltage of electric power supplies vary from one country to another. Some are 110 V, others 220. Some are 50 Hz, others 60. In addition, all the connecting plugs are different. Even the side of a road on which one drives presents compatibility problems. Approximately 50 countries, notably the United Kingdom and Japan, use the left side; other countries use the right lane. With the global market for automobiles, manufacturers must produce two different versions to meet the incompatible local market requirements. Perhaps someday there will be a global standard, but the costs of any changeover will be enormous. This situation points out the near-

irreversibility of somewhat arbitrary standardization decisions. Because of the relative permanence of their decisions, standards writers bear a

Purposes and Objectives of Codes and Standards

The protection of general welfare is one of the common reasons for the establishment of a government agency. The purpose of codes is to assist that government agency in meeting its obligation to protect the general welfare of the population it serves. The objectives of codes are to prevent damage to property and injury to or loss of life by persons. These objectives are accomplished by applying accumulated knowledge to the avoidance, reduction, or elimination of definable hazards.

Before going any further, the reader needs to understand the differences between "codes" and "standards." Which items are codes and which are standards? One of the several dictionary definitions for "code" is "any set of standards set forth and enforced by a local government for the protection of public safety, health, etc., as in the structural safety of buildings (building code), health requirements for plumbing, ventilation, etc. (sanitary or health code), and the specifications for fire escapes or exits (fire code)." "Standard" is defined as "something considered by an authority or by general consent as a basis of comparison; an approved model."

As a practical matter, codes tell the user *what* to do and *when* and under what circumstances to do it. Codes are often legal requirements that are adopted by local jurisdictions that then enforce their provisions. Standards tell the user *how* to do it and are usually regarded only as recommendations that do not have the force of law. As noted in the definition for code, standards are frequently collected as reference information when codes are being prepared. It is common for sections of a local code to refer to nationally recognized standards. In many instances, entire sections of the standards are adopted into the code by reference, and then become legally enforceable. A list of such standards is usually given in an appendix to the code.

How Standards Develop

Whenever a new field of economic activity emerges, inventors and entrepreneurs scramble to get into the market, using a wide variety of approaches. After a while the chaos decreases, and a consensus begins to form as to what constitutes "good practice" for that economic activity.

By that time, the various companies in the field have worked out their own methods of design and production and have prepared "in-house" standards that are used by engineering, purchasing, and manufacturing to ensure uniformity and quality of their product. In time, members of the industry may form an association to work together to expand the scope of their proprietary standards to cover the entire industry. A "trade" or "industry" standard may be prepared, one of its purposes being to promote compatibility among various components. This is usually done on a consensus basis. However, this must be done very carefully because compatibility within an industry may be regarded as collusion by the justice department, resulting in an antitrust action being filed. A major example of this entire process is the recent growth of the Internet, where compatibility plays a primary function in the formulation of networks, but so far regulators have used a light hand.

As an industry matures, more and more companies get involved as suppliers, subcontractors, assemblers, and so forth. Establishing national trade practices is the next step in the standards development process. This is usually done through the American National Standards Institute (ANSI), which provides the necessary forum. A sponsoring trade association will request that ANSI review its standard. A review group is then formed that includes members of many groups other than the industry, itself. This expands the area of consensus and is an essential feature of the ANSI process.

ANSI circulates copies of the proposed standard to all interested parties, seeking comments. A time frame is set up for receipt of comments, after which a Board of Standards Review considers the comments and makes what it considers necessary changes. After more reviews, the standard is finally issued and published by ANSI, listed in their catalog, and available to anyone who wishes to purchase a copy. A similar process is used by the International Standards Organization (ISO), which began to prepare an extensive set of worldwide standards in 1996.

One of the key features of the ANSI system is the unrestricted availability of its standards. Company, trade, or other proprietary standards may not be available to anyone outside that company or trade, but ANSI standards are available to everyone. With the wide consensus format and easy accessibility, there is no reason for designers to avoid the step of searching for and collecting any and all standards applicable to their particular projects.

Designing to Codes and Standards

Thomas A. Hunter, Forensic Engineering Consultants Inc.

Types of Codes

There are two broad types of codes: performance codes and specification or prescriptive codes. Performance codes state their regulations in the form of what the specific requirement is supposed to achieve, not what method is to be used to achieve it. The emphasis is on the result, not on how the result is obtained. Specification or prescriptive codes state their requirements in terms of specific details and leave no discretion to the designer. There are many of each type in use.

Trade codes relate to several public welfare concerns. For example, the plumbing, ventilation, and sanitation codes relate to health. The electrical codes relate to property damage and personal injury. Building codes treat structural requirements that ensure adequate resistance to applied loads. Mechanical codes are involved with both proper component strength and avoidance of personal injury hazards. All of these codes, and several others, provide detailed guidance to designers of buildings and equipment that will be constructed, installed, operated, or maintained by persons skilled in those particular trades.

Safety codes, on the other hand, treat only the safety aspects of a particular entity. The Life Safety Code, published by the National Fire Protection Association (NFPA) as their Standard No. 101, sets forth detailed requirements for safety as it relates to buildings. Architects and anyone else concerned with the design of buildings and structures must be familiar with the many No. 101 requirements. In addition to the Life Safety Code, NFPA publishes hundreds of other standards, which are collected in a 12-volume set of paperbound volumes known as the National Fire Codes. These are revised annually, and a set of loose-leaf binders are available under a subscription service that provides replacement pages for obsolete material. Three additional loose-leaf binders are available for recommended practices, manuals, and guides to good engineering practice.

The National Safety Council publishes many codes that contain recommended practices for reducing the frequency and severity of industrial accidents. Underwriters' Laboratories (UL) prepares hundreds of detailed product safety standards and testing procedures that are used to certify that the product meets their requirements. In contrast to the ANSI standards, UL standards are written in-house and are not based on consensus. However, UL standards are available to anyone who orders them, but some are very expensive.

Professional society codes have been developed, and several have wide acceptance. The American Society of Mechanical Engineers (ASME) publishes the Boiler and Pressure Vessel Code, which has been used as a design standard for many decades. The Institute of Electrical and Electronic Engineers (IEEE) publishes a series of books that codify recommended good practices in various areas of their discipline. The Society of Automotive Engineers (SAE) publishes hundreds of standards relating to the design and safety requirements for vehicles and their appurtenances. The American

Society for Testing and Materials (ASTM) publishes thousands of standards relating to materials and the methods of testing to ensure compliance with the requirements of the standards.

Statutory codes are those prepared and adopted by some governmental agency, either local, state, or federal. They have the force of law and contain enforcement provisions, complete with license requirements and penalties for violations. There are literally thousands of these, each applicable within its geographical area of jurisdiction.

Fortunately for designers, most of the statutory codes are very similar in their requirements, but there can be substantial local or state variations. For example, California has far more severe restrictions on automotive engine emissions than other states. Local building codes often have detailed requirements for wind or snow loads. Awareness of these local peculiarities by designers is mandatory.

Regulations. Laws passed by legislatures are written in general and often vague language. To implement the collective wisdom of the lawmakers, the agency staff then comes in to write the regulations that spell out the details. A prime example of this process is the Occupational Safety and Health Act (OSHA), which was passed by the U.S. Congress, then sent to the Department of Labor for administration. The regulations were prepared under title 29 of the U.S. Code, published for review and comment in the Federal Register, and issued as legal minimum requirements for design of any products intended for use in any U.S. workplace. Several states have their own departments of labor and issue supplements or amendments to the federal regulations that augment and sometimes exceed the minimums set by OSHA. Again, recognition of the local regulatory design requirements is a must for all design professionals in that field.

Designing to Codes and Standards

Thomas A. Hunter, Forensic Engineering Consultants Inc.

Types of Standards

Proprietary (in-house) standards are prepared by individual companies for their own use. They usually establish tolerances for various physical factors such as dimensions, fits, forms, and finishes for in-house production. When outsourcing is used, the purchasing department will usually use the in-house standards in the terms and conditions of the order. Quality assurance provisions are often in-house standards, but currently many are being based on the requirements of ISO 9000. Operating procedures for material review boards are commonly based on in-house standards. It is assumed that designers, as a function of their jobs, are intimately familiar with their own employer's standards.

Industry consensus standards, such as those prepared by ANSI and the many organizations that work with ANSI, have already been discussed. A slightly abridged list of ANSI-sponsoring industry groups and their areas of concern will be given under the following section on Codes and Standards Preparation Organizations.

Government specification standards for federal, state, and local entities involve literally thousands of documents. Because government purchases involve such a huge portion of the national economy, it is important that designers become familiar with standards applicable to this enormous market segment. To make certain that the purchasing agency gets precisely the product it wants, the specifications are drawn up in elaborate detail. Failure to comply with the specifications is cause for rejection of the seller's offer, and there are often stringent inspection, certification, and documentation requirements included.

It is important for designers to note that government specifications, particularly Federal specifications, contain a section that sets forth other documents that are incorporated by reference into the body of the primary document. These other documents are usually federal specifications, federal and military standards (which are different from specifications), and applicable industrial or commercial standards. They are all part of the package, and a competent designer must be familiar with all branches of what is called the specification tree. The MIL standards and Handbooks for a particular product line should be a basic part of the library of any designers working in the government supply area. General Services Administration (GSA) procurement specifications have a format similar to the military specifications and cover all nonmilitary items.

Product definition standards are published by the National Institute of Standards and Technology under procedures of the Department of Commerce. An example of a widely used Product Standard (PS) is the American Softwood Lumber

Standard, PS 20. It establishes the grading rules, names of specific varieties of soft wood, and sets the uniform lumber sizes for this very commonly used material. The Voluntary Standards Program uses a consensus format similar to that used by ANSI. The resulting standard is a public document. Because it is a voluntary standard, compliance with its provisions is optional unless the Product Standard document is made a part of some legal agreement.

Commercial standards (denoted by the letters CS) are published by the Commerce Department for articles considered to be commodities. Commingling of such items is commonplace, and products of several suppliers may be mixed together by vendors. The result can be substantial variations in quality. To provide a uniform basis for fair competition, the Commercial Standards set forth test methods, ratings, certifications, and labeling requirements. When the designer intends to use commodity items as raw materials in the proposed product, a familiarity with the CS documents is mandatory.

Testing and certification standards are developed for use by designers, quality assurance agencies, industries, and testing laboratories. The leading domestic publisher of such standards is the American Society for Testing and Materials (ASTM). Its standards number several thousand and are published in a set of 70 volumes divided into 15 separate sections. The standards are developed on a consensus basis with several steps in the review process. Initial publication of a standard is on a tentative basis; such standards are marked with a T until finally accepted. Periodic reviews keep the requirements and methods current. Because designers frequently call out ASTM testing requirements in their materials specifications, the designer should routinely check ASTM listings to make certain the applicable version is being called for.

International standards have been proliferating rapidly for the past decade. This has been in response to the demands of an increasingly global economy for uniformity, compatibility, and interchangeability--demands for which standards are ideally suited. Beginning in 1987, the International Standards Organization (ISO) attacked one of the most serious international standardization problems, that of quality assurance and control. These efforts resulted in the publication of the ISO 9000 Standard for Quality Management. This has been followed by ISO 14000 for Environmental Management Standards, which is directed at international environmental problems. The ISO has several Technical Committees (TC) that publish handbooks and standards in their particular fields. Examples are the ISO Standards Handbooks on Mechanical Vibration and Shock, Statistical Methods for Quality Control, and Acoustics. All of these provide valuable information for designers of products intended for the international market.

Design standards are available for many fields of activity, some esoteric, many broad based. Take marinas for example. Because it has so many recreational boaters, the state of California has prepared comprehensive and detailed design standards for marinas. These standards have been widely adopted by other states. Playgrounds and their equipment have several design standards that relate to the safety of their users. Of course one of the biggest applications of design standards is to the layout, marking, and signage of public highways. Any serious design practitioner in those and many other fields must be cognizant of the prevailing design standards.

Physical reference standards, such as those for mass, length, time, temperature, and so forth, are of importance to designers of instruments and precision equipment of all sorts. Testing, calibration, and certification of such products often call for reference to national standards that are maintained by the National Institute for Standards and Technology (NIST) in Gaithersburg, MD, or to local standards that have had their accuracy certified by NIST. Designers of high precision products should be aware of the procedures to be followed to ensure traceability of local physical standards back to the NIST.

Designing to Codes and Standards

Thomas A. Hunter, Forensic Engineering Consultants Inc.

Codes and Standards Preparation Organizations

U.S. Government Documents. For Federal government procurement items, other than for the Department of Defense, the Office of Federal Supply Services of the General Services Administration issues the Index of Federal Specifications, Standards and Commercial Item Descriptions every April. It is available from the Superintendent of Documents, U.S. Government Printing Office. Washington, D.C. 20402.

General Services Administration item specifications are available from GSA Specifications Unit (WFSIS), 7th and D Streets SW, Washington, D.C. 20407.

Specifications and standards of the Department of Defense are obtainable from the Naval Publications and Forms Center, 5801 Tabor Avenue, Philadelphia, PA 19120.

To order documents issued by the National Institute of Standards and Technology it is first necessary to obtain the ordering number of the desired document. You get this from NIST Publication and Program Inquiries, E128 Administration Bldg., NIST, Gaithersburg, MD 20899. With the ordering number, the documents are available from the Government Printing Office, Washington, D.C. 20402, or the National Technical Information Service, Springfield, VA 22161.

Underwriters' Laboratories documents can be obtained from Underwriters' Laboratories, Inc., Publications Stock, 333 Pfingsten Road, Northbrook, IL 60062.

ASTM Standards. Publications of the American Society for Testing and Materials can be ordered from ASTM, 100 Barr Harbor Drive, West Conshohocken, PA 19428.

National Fire Codes and other NFPA publications can be ordered from the National Fire Protection Association, 1 Batterymarch Park, Quincy, MA 02269-9101.

Building codes are issued by three organizations. The southern states use the Standard Building Code published by the Southern Building Code Congress International, Inc. (SBCCI), 900 Montclair Road, Birmingham, AL 35213-1206. The western states use the Uniform Building Code published by the International Conference of Building Officials (ICBO), 5360 Workman Mill Road, Whittier CA 90601-2298. The central and eastern states use the BOCA National Building Code obtainable from Building Officials and Code Administrators International, Inc. (BOCA), 4051 West Flossmoor Road, Country Club Hills, IL 60478-5795. A separate building code, applicable only to one and two family dwellings, is published by the Council of American Building Officials (CABO), 5203 Leesburg Pike, Falls Church, VA 22041, as a joint effort of SBCCI, BOCA, and ICBO and is obtainable from any of them.

The International Mechanical Code is published by the International Code Council, Inc., as a joint effort of the BOCA membership. It is intended to be compatible with the requirements of the Standard, Uniform, and National Building Codes and can be obtained from any CABO organization.

The International Plumbing Code is also published by the International Code Council as a CABO joint effort and is obtainable from any member organization.

The Model Energy Code is published under the auspices of CABO as a joint effort of BOCA, SBCCI, and ICBO with heavy input from the American Society of Heating, Refrigerating, and Air Conditioning Engineers, Inc. (ASHRAE) and the Illuminating Engineering Society of North America (IESNA). Copies are obtainable from any CABO member.

ANSI Documents. The American National Standards Institute (ANSI), 11 West 42nd Street, New York, NY 10036, publishes and supplies all American National Standards. The American National Standards Institute also publishes a catalog of all their publications and distributes catalogs of standards published by 38 other ISO member organizations. They also distribute ASTM and ISO standards and English language editions of Japanese Standards, Handbooks, and Materials Data Books. ANSI does not handle publications of the British Standards Institute or the standards organizations in Germany and France.

As mentioned previously, there are many organizations that act as sponsors for the standards that ANSI prepares under their consensus format. The sponsors are good sources for information on forthcoming changes in standards and should be consulted by designers wishing to avoid last-minute surprises. Listings in the ANSI catalog will have the acronym for the sponsor given after the ANSI/ symbol. For example, the standard for Letter Designations for Radar Frequency Bands, sponsored by the IEEE as their standard 521, issued in 1984, and revised in 1990, is listed as ANSI/IEEE 521-1984(R1990). All of one sponsor's listings are grouped under one heading in alphabetical order by organization. The field of interest of each sponsor is usually obvious from the name of the organization. Table 1 is slightly abridged from the full acronym tabulation in the ANSI catalog. Addresses and phone numbers have been obtained from listings in association directories. ANSI does not give that data.

Table 1 Sponsoring organizations for standards published by the American National Standards Institute

Acronym	Organization
AAMA	American Apparel Manufacturers Association. 2500 Wilson Blvd., Arlington, VA 22201 (703) 524-1864
AAMA	American Architectural Manufacturers Association. 1540 E. Dundee Rd., Palatine, IL 60067 (708) 202-1350
AAMI	Association for the Advancement of Medical Instrumentation. 3330 Washington Blvd., Arlington, VA 22201 (703) 525-4890
AASHTO	American Association of State Highway and Transportation Officials. 444 N. Capitol St., N.W., Washington, D.C. 20001 (202) 624-5800
AATCC	American Association of Textile Chemists and Colorists. P.O. Box 12215, Research Triangle Park, NC 22709-2215 (919) 549-8141
ABMA	American Bearing Manufacturers Association and Anti-Friction Bearing Manufacturers Association (AFBMA). 1900 Arch St., Philadelphia, PA 19103 (215) 564-3484
. . .	American Boat and Yacht Council. 3069 Solomon's Island Rd., Edgewater, MD 21037-1416 (410) 956-1050
ACI	American Concrete Institute. P.O. Box 19150, Detroit, MI 48219 (313) 532-2600
ADA	American Dental Association. 211 E. Chicago Ave., Chicago, IL 60611 (312) 440-2500
AGA	American Gas Association. 1515 Wilson Blvd., Arlington, VA 22209 (703) 841-8400
AGMA	American Gear Manufacturers Association. 1500 King St., Alexandria, VA 22314 (703) 684-0211
AHAM	Association of Home Appliance Manufacturers. 20 W. Wacker Dr., Chicago, IL 60606 (312) 984-5800

AIA	Automated Imaging Association. 900 Victor's Way, Ann Arbor, MI 48106 (313) 994-6088
AIAA	American Institute of Aeronautics and Astronautics. 370 L'Enfant Promenade, S.W., Washington, D.C. 20024 (202) 646-7400
AIIM	Association for Information and Image Management. 1100 Wayne Ave., Silver Spring, MD 20910 (301) 587-8202
AISC	American Institute of Steel Construction, Inc. 1 E. Wacker Dr., Chicago, IL 60601-2001 (312) 670-2400
ANS	American Nuclear Society. 555 N. Kensington Ave., La Grange Park, IL 60525 (708) 352-6611
API	American Petroleum Institute. 1220 L St., N.W., Washington, D.C. 20005 (202) 682-8000
ARI	Air-Conditioning and Refrigeration Institute. 4301 N. Fairfax Dr., Arlington, VA 22203 (703) 524-8800
ASAE	American Society of Agricultural Engineers. 2950 Niles Rd., St. Joseph, MI 49085-9659 (616) 429-0300
ASCE	American Society of Civil Engineers. 1015 15th St., N.W., Washington, D.C. 20005 (202) 789-2200
ASHRAE	American Society of Heating, Refrigerating and Air-Conditioning Engineers. 1791 Tullie Circle, N.E., Atlanta, GA 30329 (404) 636-8400
ASME	American Society of Mechanical Engineers. 345 E. 47th St., New York, NY 10017 (212) 705-7722
ASQC	American Society for Quality Control. 611 E. Wisconsin Ave., Milwaukee, WI 53201 (414) 272-8575
ASSE	American Society of Sanitary Engineering. P.O. Box 40362, Bay Village, OH 44140 (216) 835-3040

AWS	American Welding Society. 550 LeJeune Rd., N.W., Miami, FL 33126 (305) 443-9353
AWWA	American Water Works Association. 6666 W. Quincy Ave., Denver, CO 80235 (303) 794-7711
BHMA	Builders Hardware Manufacturers Association. 355 Lexington Ave., New York, NY 10017 (212) 661-4261
CEMA	Conveyor Equipment Manufacturers Association. 9384-D Forestwood Ln., Manassas, VA 22110 (703) 330-7079
CGA	Compressed Gas Association. 1725 Jefferson Davis Highway, Arlington, VA 22202-4100 (703) 412-0900
CRSI	Concrete Reinforcing Steel Institute. 933 Plum Grove Rd., Schaumburg, IL 60173 (708) 517-1200
DHI	Door and Hardware Institute. 14170 Newbrook Dr., Chantilly, VA 22021-2223 (703) 222-2010
EIA	Electronic Industries Association. 2500 Wilson Blvd., Arlington, VA 22201 (703) 907-7550
FCI	Fluid Controls Institute. P.O. Box 9036, Morristown, NJ 07960 (201) 829-0990
HI	Hydraulic Institute. 9 Sylvan Way, Parsippany, NJ 07054-3802 (201) 267-9700

Standards Information Services. Copies of standards and information about documents published by the more than 350 code- and standard-generating organizations in the United States and several other countries can be obtained from resellers such as Global Engineering Documents, Englewood, CO. They provide information on CD-ROM, magnetic tape, microfilm, or microfiche formats. Similar services exist in many countries throughout the world.

Designing to Codes and Standards

Thomas A. Hunter, Forensic Engineering Consultants Inc.

Designer's Responsibility

As soon as a designer has been able to establish a solid definition of the problem at hand, and to formulate a promising solution to it, the next logical step is to begin the collection of available reference materials such as codes and standards. This is a key part of the background phase of the design effort. Awareness of the existence and applicability of codes and standards is a major responsibility of the designer.

A primary component of the reference materials collection will be the codes and standards of which the designer is aware and that are known to be applicable to the design problem. As pointed out previously, there are several readily accessible sources for the myriad reference documents that the designer may review and examine to decide which ones are applicable.

One of the designer's responsibilities in the background phase is to make certain that the collection of reference codes and standards is both complete and comprehensive. Considering the enormous amount of information available, and the ease of access to it, this can be a formidable task. However, a designer's failure to acquire a complete and comprehensive collection of applicable standards is ill-advised in today's litigious environment. In addition, failure of the designer to meet the requirements set forth in the standards can be considered professional mal-practice.

If the designer's product goes into production and enters the marketplace, the maker of the product hopes that it will be accepted by purchasers and will be an economic success. The purchasers, on the other hand, hope that the product will meet their expectations. Among their expectations are: first, that the product will perform its intended function and, second, that it will do no harm to them personally or to their property. In other words, the purchaser expects the product to be safe to use in its ordinarily intended manner of use. This expectation of safety extends even to some uses never intended or even conceived of by the designer (misuse) and to instances of deliberate overloading of the product (abuse). Thus, one of the designer's responsibilities is to eliminate the possibility that the product will do harm. If any of these customer expectations of the product are violated and harm occurs the result may be a legal action based on the laws of torts.

Torts, in the legal sense, are simply acts of wrongdoing. The failure of a product to perform as intended is not a tort, just a bad product. However, if the product does harm to any person or property, that may be considered a wrongful act. Recovery for damages caused by the wrongful act can be obtained through the courts by filing a lawsuit.

If the suit results in a finding that the product was defective in some way, and that the defect was related to the causation of the personal injury or property damage, then monetary damages may be assessed against the maker of that product. That is, the maker is liable for the resulting harm caused by that product. This is the part of the tort arena treated by the product liability laws. Further discussion of this subject is given in the article "Products Liability and Design" in this Volume.

One of the most commonly used allegations of product defect, and one of the easiest ones to prove, is that the designer failed to recognize and observe requirements set forth in applicable standards. Such a situation is extremely hard to defend and frequently results in the court making what is called a summary judgment for the plaintiff.

How does a designer avoid such situations? The best method is through frequent and thorough design reviews. Part of being thorough is being aware of applicable codes and standards and taking their requirements into consideration at the first design review session. Of course, design reviews should cover several areas: material selection, the processing of the material during the manufacturing cycle, quality assurance, costs, and several other factors must all be considered and trade-offs made to secure the optimal solution to the design problem. A tedious and often contentious process to be sure, but design reviews help to define the problems very clearly.

The designer's responsibility to avoid doing harm requires that during the review process a special effort is made to discover and define all potential sources of harm inherent in the proposed design. That is the hazard recognition phase of the design effort. Some hazards may be open and obvious. The challenge is to ferret out the hidden or unusual hazards that can cause problems later.

Once the designer has recognized the hazards, the next, best, and most obvious step is to design the hazards out of the product. Sometimes that is not entirely possible, so the second-best approach must be used. This is to figure out some way of mitigating the hazard by adding a guard to protect the user from the recognized hazard. If a suitable guard cannot be designed, then the third and least effective approach to hazard mitigation is used: placing warnings on the product. There are even standards for doing that. They are given in ANSI Z535.4-1991, "Product Safety Signs and Labels."

Related information is provided in the articles "Safety in Design" and "Products Liability and Design" in this Volume.

Statistical Aspects of Design

Richard C. Rice, Battelle Columbus

Introduction

FOR MANY YEARS engineers have designed components and structures using best available estimates of material properties, operating loads, and other design parameters. Once established, most of these estimated values have commonly been treated as fixed quantities or constants. This approach is called deterministic, in that each set of input parameters allows the determination of one or more output parameters, where those output parameters might include a prediction of factors such as operating stress, strain, deflection, deformation, wear rate, fatigue strength, creep strength, or service life. In reality, virtually all material properties and design parameters exhibit some statistical variability and uncertainty that influence the adequacy of a design.

It is common practice that almost all engineered components or structures are designed with the expectation that only a small percentage of the units that are produced will fail within the warranty period. In the case of structures that are sold with warranty provisions, warranty costs are directly tied to failure rates within that period. Invariably, greater-than-anticipated failure rates lead to extraordinary warranty costs. In addition, high recall rates, even on noncritical structural components, often lead to buyer perceptions that the product, as a whole, is unreliable and perhaps unsafe.

Assume, for example, that the average service life of structure A is 20% greater than that of structure B (the good news). However, assume also that the variability in service lives for structure A is twice that of structure B (the bad news). For simplicity, consider that this variability has been shown to conform to a normal distribution. In spite of the inferiority of structure B in average performance, the first failures out of a sample (or fleet) of 1000 units for structure A would be expected to occur at service lives approximately 17% less often than for structure B, making structure B more desirable in terms of predicted service life to initial "fleet" failures. This simple case will be illustrated in detail later in this article.

The example just described requires that a significant data base exist, one that allows accurate estimates of average properties and realistic estimates of the variability in those properties. In a typical design scenario, the data base available to define material, design, and operating parameters is limited. Handbook data on similar materials and operating loads

collected on a similar design may be all that is available in some instances. In such cases, lower- or upper-bound parameter estimates (whichever are seen as most critical) are often used in combination to produce what are believed to be conservative performance estimates. With regard to safe operating loads or stresses, industry standard design factors or "safety factors" can also be applied. With limited data, the actual conservatism of individual parameter estimates can vary widely, and the ultimate degree of conservatism in the performance estimates is unknown. This situation can lead to either an unconservative design with unacceptably high failure rates, or a very conservative design that provides the required performance with unnecessarily high product costs.

Fundamentally, designing to prevent service failures is a statistical problem. In simplistic terms, an engineered component fails when the resistance to failure is less than the imposed service condition. Depending on the structure and its performance requirements, the definition of failure varies; it could be buckling, permanent deformation, tensile failure, fatigue cracking, loss of cross section due to wear, corrosion, or erosion, or fracture due to unstable crack growth. In any of these cases, the failure resistance of a large number of components of a particular design is a random variable, and the nature of this random variable often changes with time. The imposed service condition for these components is also a random variable; it too can change with time. The intersection of these two random variables at any point in time represents the expected failure percentage and provides a measure of component reliability, as shown in Fig. 1.

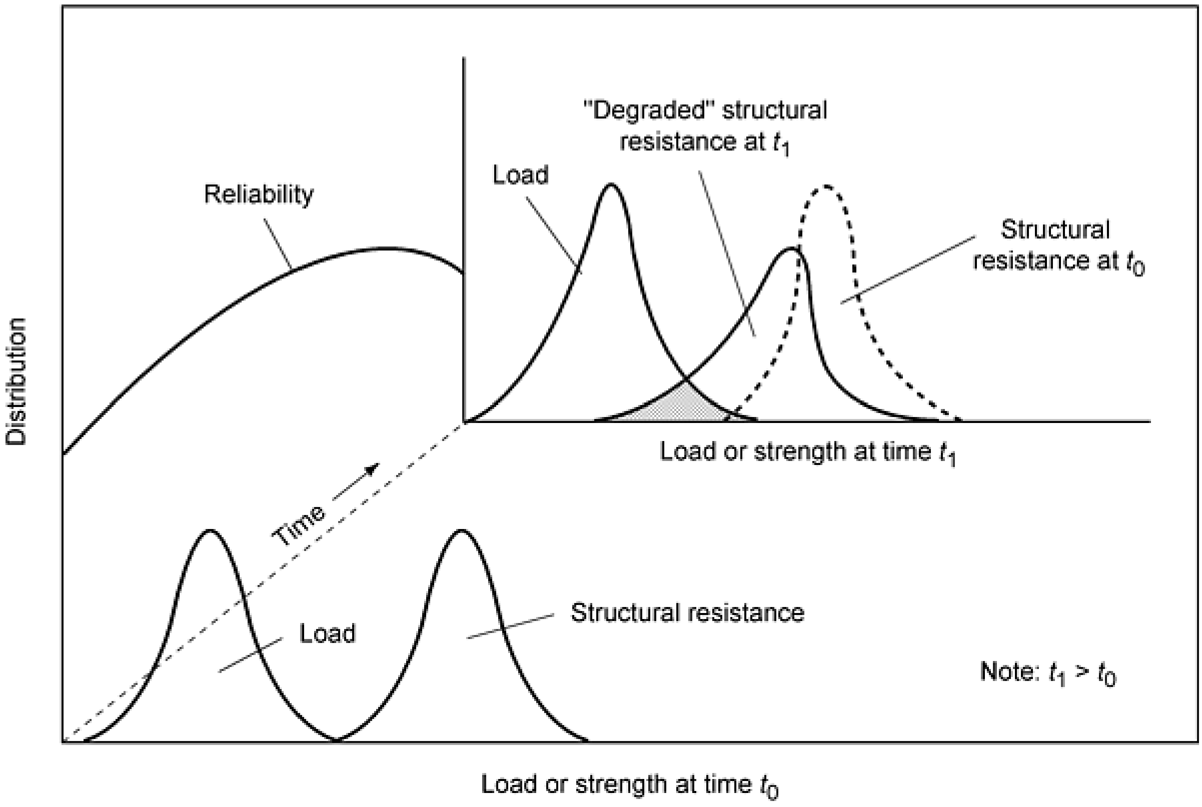

Fig. 1 Reliability as it relates to statistical distributions of structural integrity and applied loads

There are numerous texts on statistics, as well as many references on engineering design. A number of sources have combined these two disciplines in addressing the statistical aspects of design; some of these sources are cited in the Selected References at the end of this article.

This article presents some of the statistical aspects of design from an engineer's perspective. Some statistical terms are clarified first because many engineers have not worked in the field of statistics enough to put these terms into day-to-day engineering practice. Commonly used statistical distributions are reviewed next in the section "Statistical Distributions Applied to Design," with the primary goal of providing some guidance on practical engineering applications for these distributions. The section that follows, "Statistical Procedures," describes some basic statistical procedures that can be used to address questions of variability and uncertainty in an engineering analysis; some example problems are included. The final section, "Related ASTM Engineering Statistics Standards," is provided as an easy reference guide; it has a table listing relevant statistics standards published by the American Society of Testing and Materials.

Richard C. Rice, Battelle Columbus

Clarification of Statistical Terms

Random Variables. Any collection of test coupons, parts, components, or structures designed to the same set of specifications or standards will exhibit some variability in performance from one unit to the other. Performance can be measured by a wide variety of parameters, or some combination of those parameters, as discussed earlier. In any case, these measures of performance are not controlled, although there is often an attempt to optimize them to maximize performance, within prescribed cost constraints. Because these measures of performance are not controlled and subject to inherent random variability, they are commonly called random variables.

The tensile strength of a structural material is a practical example of a random variable. Given a single heat and lot of a material manufactured to a public specification, such as an ASTM, SAE/AMS, or DoD specification, repeated tests to determine the tensile strength of that material will produce varied results. This will be true even if the individual tests are performed identically, within the limits of engineering accuracy.

Repeated "identical" tests to determine any engineering property of a material will produce results showing some degree of variability, which means they are all random variables. Properties such as hardness, elastic modulus, and coefficient of thermal expansion tend to show relatively low variability when repeat precision measurements are made. Other material properties show more variability, such as crack initiation, fatigue life, fracture toughness, post-heat-treatment residual stress, and creep rupture strength.

The apparent randomness or variability of some material properties is also related to the complexity of the test needed to develop the property estimates. These properties can also vary significantly from one supplier to another, or even from one heat to another for a single supplier. An important goal in an engineering/statistical analysis is to develop an accurate estimate of the material/component variability that will be represented in production.

Beyond material variability, there are many other random variables that should be considered in an engineering/statistical analysis. Actual service loads often show a great deal of variability, and this variability must be accounted for in a comprehensive assessment of structural performance. Unfortunately, reliable estimates of average service loads, let alone statistically characterized service loads, are often not readily available. End-user processing of a supplier's material or component (e.g., heat treatment, coating, shot peening), and manufacturing (e.g., machining, riveting, spot welding, forming) all add variability in the performance of the final product, and are, in themselves, random variables.

In some cases, with random variables such as service loads, the engineer has little control over their variability and must simply characterize these random variables as accurately as possible and account for this variability when making service-life estimates. For example, in the case of wheel/rail loads for different kinds of rail service, there is not only significant variability in loads within a given railroad, but significant differences in the distribution of different severity loads for different kinds of rail service as shown in Fig. 2. If one is to realistically assess the structural integrity of a rail system or rail vehicle, it is necessary to characterize accurately the statistical variations in loading that apply to that system. The same is certainly true for any other transportation system or any operating system subjected to variable loads.

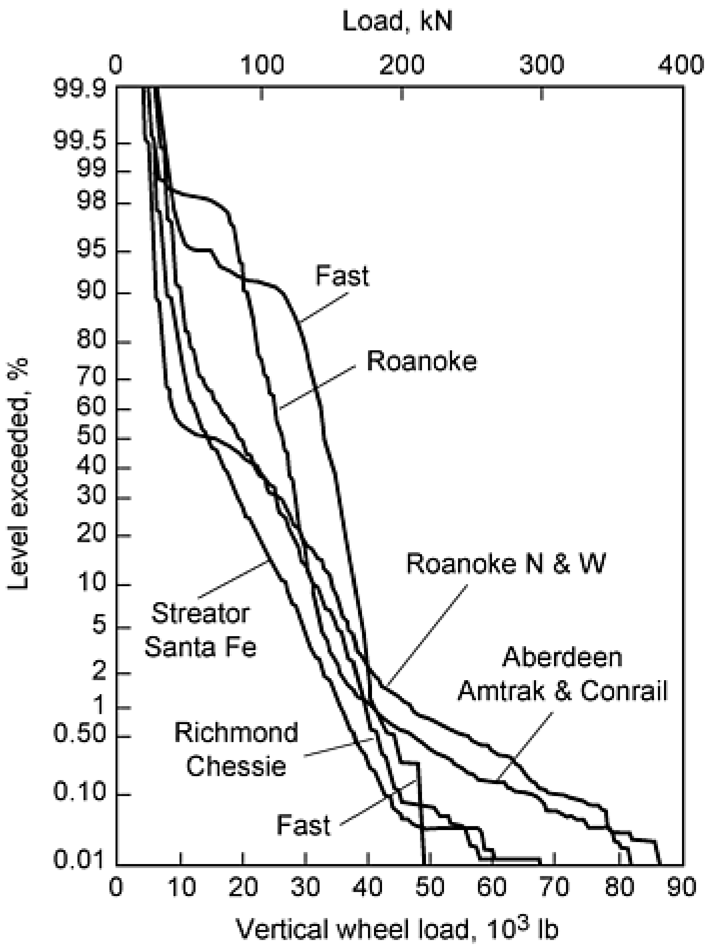

Fig. 2 Statistical characterization of wheel/rail loads on concrete ties

In other cases, with random variables such as processing and manufacturing procedures, the manufacturing or process engineer has considerable control over their variability, and a realistic goal is to minimize these "nuisance" variables to the point where they are insignificant or at least controllable from an engineering perspective.

Many engineering quantities are continuous random variables, although some others are discrete, such as the possible failure modes of a component. There are a finite number of ways that a component can fail (e.g., fatigue, corrosion, overload, brittle fracture), and those failure modes are not defined over a continuum (although service failures of engineering components often do occur due to a combination of causes). Initial designs are validated against the failure mode(s) considered to be most likely. Accumulated fleet service records for critical components eventually allow the statistical quantification of the probability of occurrence of different failure modes.

Density Functions. In statistical terms, a density function is simply a function that shows the probability that a random variable will have any one of its possible values. Consider, for example, the distribution of fatigue lives for a material as shown in Table 1. Assume that these 23 observations were generated from a series of replicate tests, that is, repeated tests under the same simulated service conditions. A substantial range in fatigue lives resulted from these tests, with the greatest fatigue life being more than ten times the lowest observation.

Table 1 Representative fatigue data showing variability in cycles to failure

Life interval, 10^6 cycles	Number of failures	Cycles to failure, 10^6 cycles
0.0-0.5	1	0.425
0.5-1.0	5	0.583, 0.645, 0.77, 0.815, 0.94
1.0-1.5	7	1.01, 1.09, 1.11, 1.21, 1.30, 1.41, 1.49
1.5-2.0	4	1.61, 1.70, 1.85, 1.97
2.0-2.5	2	2.19, 2.32
2.5-3.0	2	2.65, 2.99
3.0-3.5	1	3.42
3.5-4.0	0	. . .
4.0-4.5	0	. . .
4.5-5.0	1	4.66
Total observations	**23**	

The resulting approximate density function for these data is shown in Fig. 3. This figure shows the number of fatigue life observations within uniform cycles-to-failure intervals. Each interval of the histogram shows the frequency of occurrence of fatigue failures within the interval. It is evident that the probability of occurrence of a fatigue failure for this material and test condition is not constant over the range of possible fatigue lives. If 300 observations were available, instead of 23, the shape of the histogram would tend to stabilize. As the number of observations increase, "bumps" in the frequency diagram (as in Fig. 3) caused by random variations in fatigue life would tend to disappear, and the shape will begin to resemble that of a continuous function. A mathematical representation of such a distribution is called a density function.

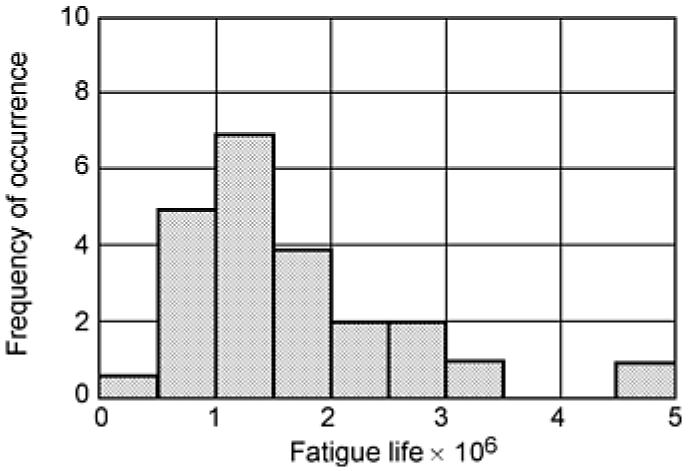

Fig. 3 Histogram of fatigue data from Table 1 showing approximate density function

In the case just described, the possible values of the random variable (fatigue life) are continuous and the resulting density function is, therefore, continuous. With discrete random variables the density function is discontinuous. For example, suppose that it was necessary to generate 27 test results before achieving 23 valid fatigue failures--one specimen might have been lost due to operator error, and three specimens could have failed in the grips. The approximate density function for the discrete random variable, failure mode, is shown for this case in Fig. 4.

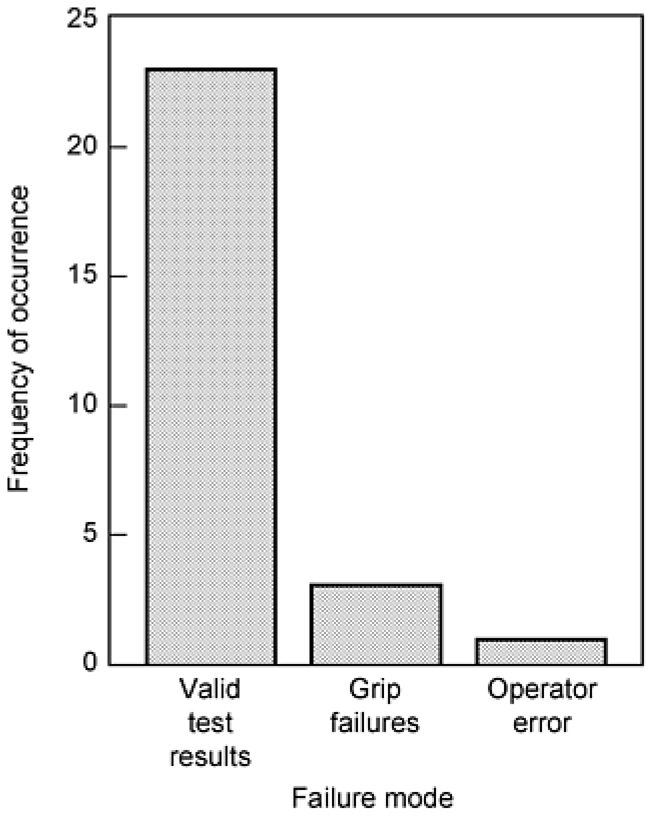

Fig. 4 Histogram of failure modes with their approximate discrete density function

Cumulative Distribution Functions. Plots of experimental data as density functions, as shown in Fig. 2 and 3, provide some useful statistical information. Inferences can be made regarding the central tendencies of the data and the

overall variability in the data. However, additional information can be obtained from a data sample like the one summarized in Table 1, by representing the data cumulatively, as in Table 2, and plotting these data on probability paper, as shown in Fig. 5. This is done by ranking the observations from lowest to highest and assigning a probability of failure to each ranked value. These so-called median ranks can be obtained from tables of these values from a statistical text, such as Ref 1, or can be computed for small samples from the following approximate formula:

$$\text{Median or 50\% rank} = \frac{j - 0.3}{n + 0.4} \quad \textbf{(Eq 1)}$$

where *j* is the failure order number and *n* is the sample size.

Table 2 Cumulative distribution of fatigue failures from Table 1

	Cycle interval × 10^6									
	0.0-0.5	**0.5-1.0**	**1.0-1.5**	**1.5-2.0**	**2.0-2.5**	**2.5-3.0**	**3.0-3.5**	**3.5-4.0**	**4.0-4.5**	**4.5-5.0**
No. of failures	1	5	7	4	2	2	1	0	0	1
Cumulative failures	1	6	13	17	19	21	22	22	22	23

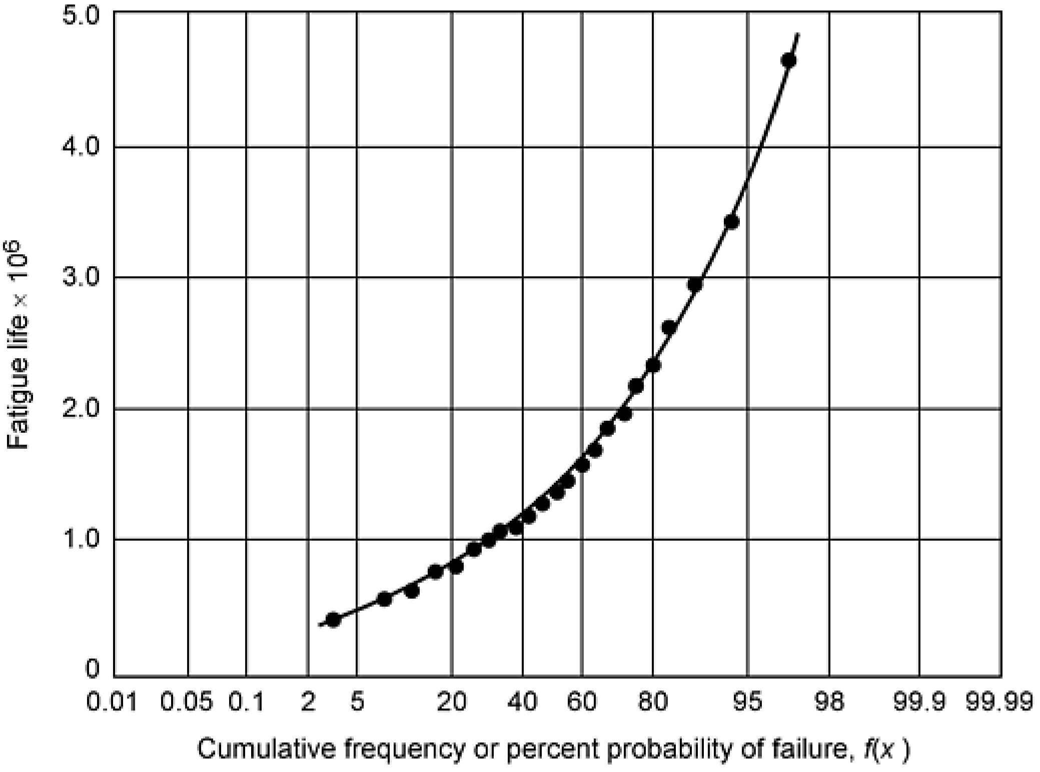

Fig. 5 Cumulative distribution function for fatigue data from Table 1 based on assumed normal distribution

For example, the first rank value in this case can be approximated as (1 - 0.3)/(23 + 0.4) = 0.030. Each of the fatigue lives, from lowest to highest, has been plotted in this manner in Fig. 5, which shows the range of fatigue lives on normal probability paper.

The best-fit representation of the cumulative data is known as a cumulative distribution function (CDF). As the name implies, a CDF provides an estimate of the cumulative percentage of total observations that can be expected at a particular value of the random variable (in this case fatigue life). In this case, where normal probability paper has been used, the data should fall in a straight line if the underlying population of fatigue lives is normally distributed. Because the data clearly do not follow a straight line, it is a fairly safe assumption that the underlying distribution is not normal. This result is not too surprising considering the lack of symmetry of the histogram of fatigue failures, shown earlier in Fig. 3, and most engineer's familiarity with the "bell-shaped" symmetry of a normal distribution.

An alternative is the effect of creating a CDF based on the logarithms of fatigue lives, as shown in Fig. 6. Using exactly the same data set, and making a simple transformation of the random variable, it is possible to see that the underlying distribution representing fatigue life (in this case) could very well be log normal.

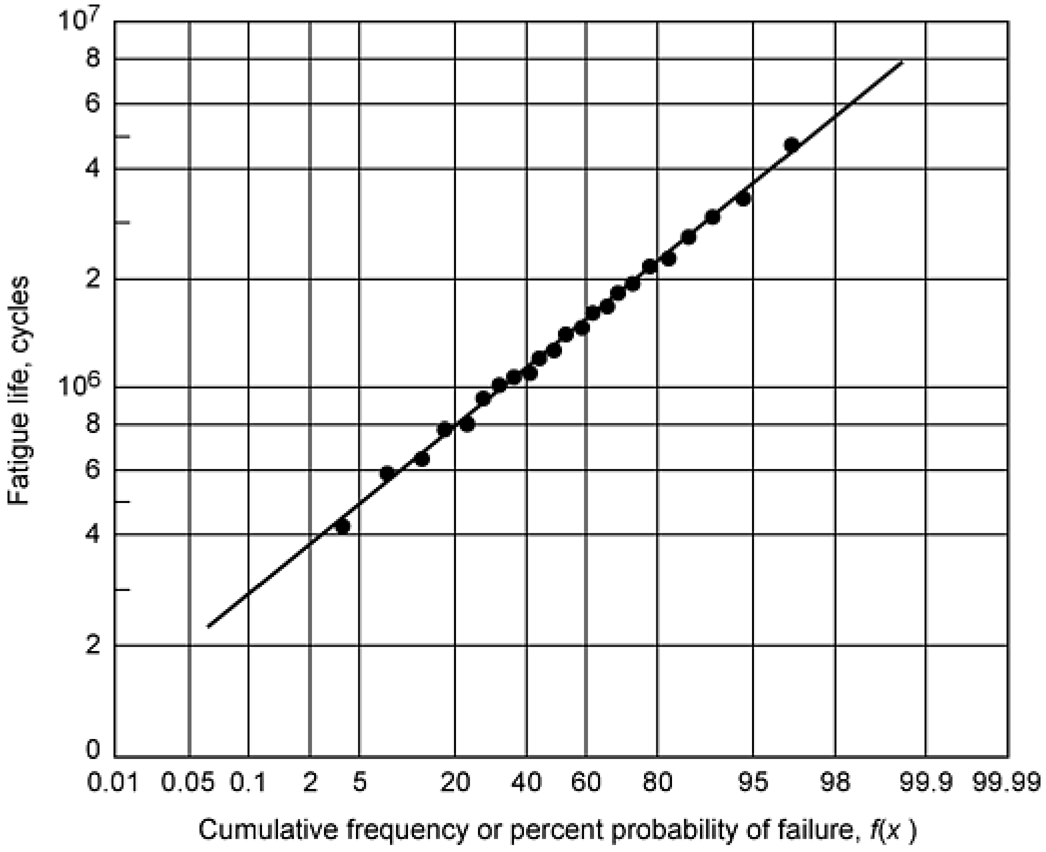

Fig. 6 Cumulative distribution function for fatigue data from Table 1 based on an assumed log-normal distribution.

Two statistical data points of significance can be drawn from Fig. 6. First, an estimate of the geometric average value of the sample can be obtained by examining the intersection of the line at a failure percentage of 50%, which in this case is a fatigue life of approximately 1.4 million cycles. Second, an estimate of the standard deviation of the sample can be obtained by examining the difference (in log life) between the 50th percentile and the 16th percentile (15.87 percentile to be exact). The 16th percentile is significant for a normal distribution because it corresponds to 1 standard deviation below the mean (of course the 84th percentile has the same connotation, i.e., 1 standard deviation above the mean), as shown in Table 3. Because the fatigue life at the 16th percentile is approximately 750,000 cycles, the standard deviation in $\log_{10}$(life) is approximately 0.271 [$\log_{10}(1.4 \times 10^6) - \log_{10}(7.5 \times 10^5) = 6.146 - 5.875 = 0.271$].

Table 3 Random sample statistics drawn from a normal distribution with a mean value of 100 and a standard deviation of 5

Observation No.	Value of observation	Estimated average	Estimated standard deviation	Estimate of error	
				Average, %	Standard deviation, %
1	97.99	97.99	. . .	. . .	. . .
2	100.81	99.40	1.41	-0.60	-71.81
3	100.47	99.75	1.26	-0.25	-74.86
4	106.08	101.34	2.95	1.34	-41.05
5	111.21	103.31	4.75	3.31	-5.05
6	98.10	102.44	4.75	2.44	-5.03
7	100.84	102.21	4.43	2.21	-11.37
8	106.16	102.71	4.35	2.71	-13.08
9	96.33	102.00	4.56	2.00	-8.77
10	105.94	102.39	4.49	2.39	-10.28
11	97.91	101.98	4.47	1.98	-10.65
12	98.41	101.69	4.39	1.69	-12.20
13	92.55	100.98	4.87	0.98	-2.59
14	102.00	101.06	4.70	1.06	-5.99
15	100.95	101.05	4.54	1.05	-9.17
16	91.06	100.42	5.02	0.42	0.37
17	98.40	100.31	4.89	0.31	-2.17

18	98.76	100.22	4.77	0.22	-4.66
19	109.37	100.70	5.07	0.70	1.40
20	94.80	100.41	5.11	0.41	2.13
21	106.41	100.69	5.15	0.69	2.90
22	103.53	100.82	5.06	0.82	1.22
23	96.28	100.62	5.04	0.62	0.72
24	103.70	100.75	4.97	0.75	-0.64
25	101.99	100.80	4.87	0.80	-2.52
26	103.34	100.90	4.80	0.90	-3.92
27	102.49	100.96	4.72	0.96	-5.52
28	96.60	100.80	4.71	0.80	-5.83
29	105.19	100.95	4.70	0.95	-6.09
30	100.58	100.94	4.62	0.94	-7.66
31	100.95	100.94	4.54	0.94	-9.16
32	99.06	100.88	4.48	0.88	-10.35
33	97.86	100.79	4.44	0.79	-11.11
34	97.42	100.69	4.42	0.69	-11.69
35	94.88	100.53	4.46	0.53	-10.84
36	103.26	100.60	4.42	0.60	-11.62
37	100.51	100.60	4.36	0.60	-12.83
38	110.72	100.87	4.60	0.87	-8.08

39	100.18	100.85	4.54	0.85	-9.24
40	91.76	100.62	4.70	0.62	-6.00
41	110.71	100.87	4.90	0.87	-2.07
42	95.90	100.75	4.90	0.75	-2.07
43	95.69	100.63	4.90	0.63	-2.02
44	105.49	100.74	4.90	0.74	-2.06
45	100.28	100.73	4.84	0.73	-3.15
46	94.05	100.59	4.89	0.59	-2.24
47	101.35	100.60	4.84	0.60	-3.26
48	102.16	100.63	4.79	0.63	-4.17
49	95.81	100.54	4.79	0.54	-4.18
50	104.25	100.61	4.77	0.61	-4.57

The same procedure could be followed with other distributional assumptions and other probability paper, such as Weibull probability paper. Although not statistically rigorous, plotting of CDFs on different types of probability paper can be very helpful in evaluating whether or not it is reasonable to assume a particular statistical distribution.

Sample versus Population Parameters. When performing a deterministic analysis, the input parameters are defined to represent the material in some specific way. For example, the input parameter may be the average or typical yield strength of a material or a specification minimum value. The implicit assumption is that, given an infinite number of observations of the strength of this material, the assumed average or minimum values would match the "real" values for this infinite population. Of course, the best that can be done is to generate a finite number of observations to characterize the performance of this material (in this case, yield strength); these observations are considered a statistical sample of this never-attainable, infinite population. Intuitively, an increase in the number of observations (the sample size), should increase the accuracy of the sample estimate of the real, or population material properties.

The mean, or arithmetic average, of a sample is defined as:

$$\bar{x} = \frac{\sum_{i=1}^{n} x_i}{n} \quad \textbf{(Eq 2)}$$

where x_i represents the ith value of n total observations, and the Greek symbol, Σ, indicates a summation of all of the values from the first value to the nth value. For example, the average elongation value for an aluminum casting might be

found to be 4.85, as shown below, based on the following sample of six experimental observations: 3.6, 5.0, 6.1, 4.7, 5.5, and 4.2:

$$e = \frac{3.6 + 5.0 + 6.1 + 4.7 + 5.5 + 4.2}{6}$$

A commonly accepted measure of the scatter, or variability in a sample, is the sample standard deviation, which is a nonnegative value calculated as follows:

$$s = \sqrt{\frac{\sum_{i=1}^{n} (x_i - \bar{x})^2}{n - 1}} \qquad \textbf{(Eq 3)}$$

It is clear from Eq 3 that a sample showing low variability, with observations closely clustered around the sample average, will produce a small standard deviation, while a sample showing high variability, with broadly dispersed observations, will produce a large standard deviation. For example, for the small sample of elongation values just noted, the standard deviation would be approximately 0.896. This value of nearly 1 for the sample standard deviation, compared to an average value of less than 5, shows a rather high level of relative variability in this sample.

Another measure of variability commonly used by statisticians is the sample variance. The sample variance is simply the sample standard deviation squared. The standard deviation is probably used most often by engineers because its magnitude relative to the mean provides a useful measure of the relative intrinsic variability in material properties, as discussed in the next section of this article "Statistical Distributions Applied to Design."

Because increased sample sizes invariably mean increased cost, there is an obvious trade-off to be made between accuracy of sample statistics and cost. The required precision of these sample statistics, and in turn the required sample sizes, are generally tied to the desired level of reliability of the final component or structure. For example, it is common practice in the design of single-load-path (nonredundant) aircraft structures to design them using 99% exceedance, 95% confidence (which translates to less than 1 failure in 100, 19 times out of 20), lower tolerance limits on yield and ultimate strength, based on at least 10 heats and lots of the material (Ref 2). Minimum sample sizes for these calculations have been set at 100 observations when the underlying distribution can be defined with high confidence and at 300 observations when the underlying distribution cannot be defined with 95% confidence. The reasons for some of these sample size requirements will become apparent in subsequent discussions.

The issue of sample size also becomes relevant when making comparisons in performance among similar materials, processes, or components. The ability to distinguish relatively subtle differences in performance at high levels of statistical confidence depends on large sample sizes. An example of this is shown in Fig. 7, where the required sample size to detect a drop in performance, with 80% confidence, is shown. For generality, the drop in performance is shown in normalized terms, that is, in tenths of a standard deviation. To put this chart into practical terms, consider a material that displays scatter in accordance with a normal distribution, with a historical mean tensile strength of 100 ksi and a standard deviation of 5 ksi. This chart shows that, in order to say (at an 80% confidence level) that a 2.5 ksi drop in the mean tensile strength (perhaps due to a processing change) had occurred, a sample size of at least 25 observations would be required.

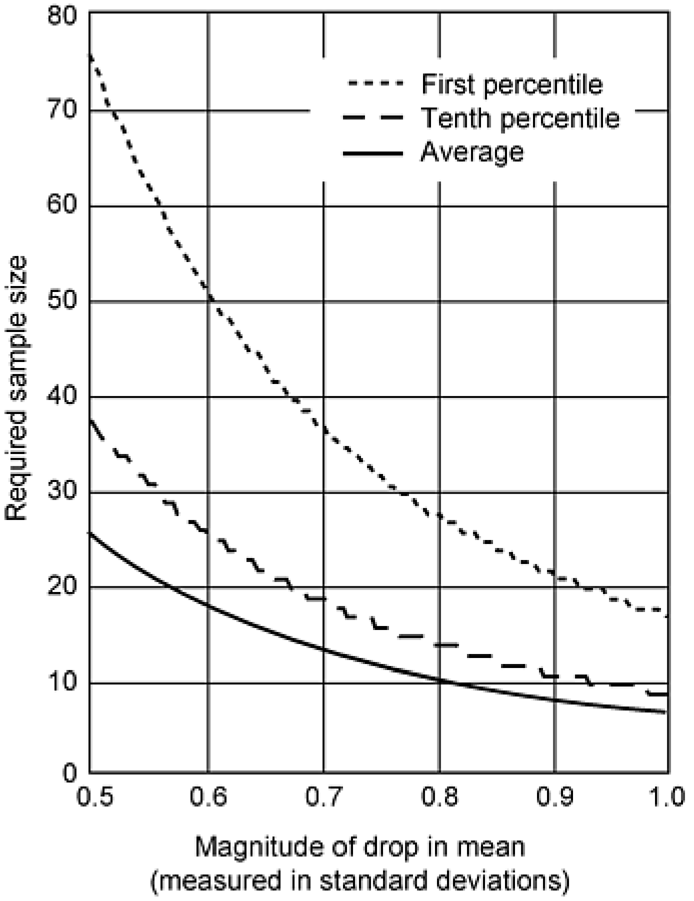

Fig. 7 Required sample size to detect a drop in material performance (with 80% confidence)

Figure 7 also shows that even larger sample sizes are required to detect similar differences in the lower "tail" of the distribution. The first and tenth percentiles noted in Fig. 7 correspond to the 1% and 10% failure percentages for the sample. For example, the expected first percentile in fatigue life for the material characterized in Fig. 6 would be approximately 330,000 cycles. This lower portion of the CDF is known as the lower tail of the distribution. Large sample sizes are required to detect statistically significant differences in the lower tails of two samples because these lower tail values depend not only on uncertainty in the mean value, but also on uncertainty in the standard deviation.

Because the standard deviation is basically the slope of the CDF, which "rotates" about the 50% failure point (which is itself uncertain), it is clear that the uncertainty in the first percentile is greater than that of the tenth percentile. This is shown schematically in Fig. 8, where the combined uncertainties in the mean (50% failure point) and the standard deviation (slope) of the CDF are added together to represent the overall uncertainty in the CDF for different failure percentages.

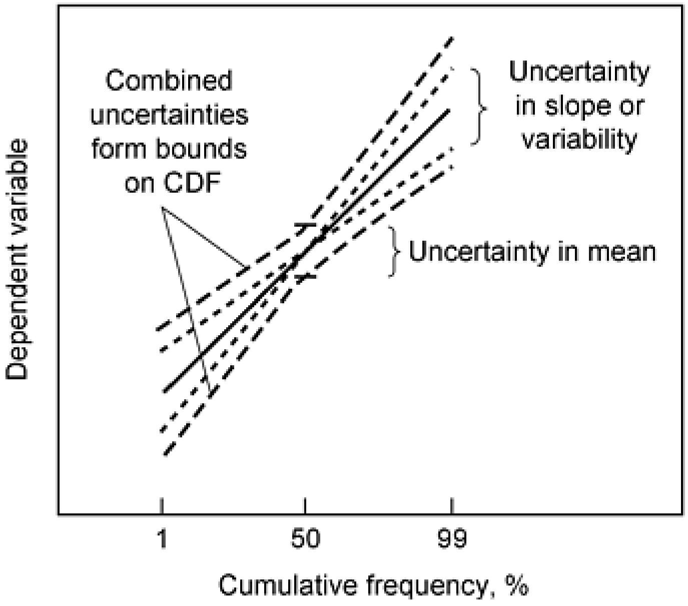

Fig. 8 Approximate confidence limits on a cumulative distribution function showing uncertainty in the mean and standard deviation

Figure 8 demonstrates the difference between a population and a sample. If the population were perfectly known (which it never is), the mean and standard deviation would be precisely defined and the CDF for the population would be known, as represented by the dark line. In the real world, only samples of the true population are available, which in turn says that the population mean and standard deviation are never known with certainty, meaning that the true CDF can only be bounded with statistical limits as shown in Fig. 8.

Variability versus Uncertainty. Variability and uncertainty are terms sometimes used interchangeably. However, it is useful when talking about statistical aspects of design to draw a distinction between them. Uncertainty is defined in most dictionaries as "the condition of being in doubt" or something similar to this. In the context of this discussion, uncertainty can be considered the bounds within which the "true" engineering result, such as the average fatigue life of a component, can be expected to fall. To establish this uncertainty in quantitative terms, it is necessary to identify and quantify all of the factors that contribute to that uncertainty. If the bounds are wide, it suggests a high level of uncertainty in the actual outcome. Generally speaking, the uncertainty in an engineering result is broad in the early stages of a design, and this uncertainty decreases significantly as more experimentation and analysis work is done. This uncertainty is commonly described in terms of confidence limits, tolerance limits, or prediction limits. Each of these limits are quantified in statistical terms later in this discussion.

Variability is an important element of an uncertainty calculation. The meaning of the term can be drawn directly from its root word, variable. Virtually all elements of a design process can be described as random variables, with some measure of central tendency or average performance and some measure of scatter or variability. For continuous variables, this variability is generally quantified in terms of a sample standard deviation, or sample variance, which is simply the standard deviation squared.

Another commonly used measure of variability is the coefficient of variation, which is defined as the sample mean divided by the sample standard deviation and generally is expressed as a percentage. This normalized parameter allows direct comparisons of relative variability of materials or products that display significantly different mean properties. For example, two different aluminum alloys might have tensile strengths that are described statistically as follows:

Aluminum alloy	Average tensile strength, ksi	Standard deviation, ksi
No. 1	70	2.5
No. 2	75	4.0

Alloy No. 1 displays a coefficient of variation (COV) of approximately 3.6%, while alloy No. 2 displays a COV of approximately 5.3%. The higher variability of alloy No. 2, as represented by a COV nearly 50% higher than alloy No. 1, could lead to a higher level of uncertainty in the performance of a structure made from the second alloy in comparison to the first.

Precision versus Bias. Precision and bias are statistical terms that are important when considering the suitability of an engineering test method or making a comparison of the relative merits between two or more procedures or processes (Ref 3). A statement concerning the precision of a test method provides a measure of the variability that can be expected between test results when the method is followed appropriately by a competent laboratory. Precision can be defined as the reciprocal of the sample standard deviation, which means that a decrease in the scatter of a test method as represented by a smaller standard deviation of the test results leads directly to an increase in the precision. Conversely, the greater the variability or scatter of the test results, the lower the precision.

The test results of two different processes (e.g., heat treatments and their effect on tensile strength) can also be statistically compared, and a statement made regarding the precision of one process compared to another. Such a statement of relative precision is only valid if no other potentially significant variables, such as different test machines, laboratories, or machining practices are involved in the comparison.

When evaluating the precision of a test method, it is generally best to select a material that is relatively uniform and to evaluate the method at several different levels of severity, as discussed in ASTM E 691 (Ref 4). In any case, there is never a single value of precision that can be associated with a particular test method; typically, precision statements apply only to the limited condition they represent, such as a single laboratory, a single machine, a single operator, or even a single location of samples taken from a large sheet, plate, or lay-up of material.

The bias of a set of measurements quantifies the difference in those test results from an accepted reference value or standard. The concept of a bias can also be used to describe the consistent difference between two operators, test machines, testing periods, or laboratories. The term accuracy is sometimes used as a synonym for bias, but it is possible to identify a bias between two sets of measurements or procedures without necessarily having any awareness of which set is most accurate. In order to make quantitative statements about absolute bias or accuracy, it is necessary to have a known baseline or reference point; such fixed points are seldom available in the real world of an engineer.

Independent versus Dependent Variables. Many engineering analyses involve the prediction of some outcome based on a set of predefined input conditions. A very simple example is the prediction of stress in the elastic range for a metal, based on a measured strain and an estimated or measured value for elastic modulus. Another more complex example is the prediction of the fatigue resistance of a part based on estimated local stress or strain amplitudes and experimentally determined fatigue parameters. In general, relationships such as these are developed through a regression analysis, in which the predicted outcome, y, is estimated from a series of terms written as a function of one or more input quantities, x_i, and regression parameters, A_i, as follows:

$$y = A_0 + A_1 f_1(x) + A_2 f_2(x) \ldots \qquad \textbf{(Eq 4)}$$

In this expression, the predicted result, y, is the dependent variable, while the defined quantity, x, is the independent variable. In some cases, multiple independent variables are needed in combination to realistically estimate the independent variable(s). (Generally, the dependent variable is taken to be the variable with largest measurement error.)

Independent and dependent variables sometimes get reversed in engineering analyses, with significant potential ramifications. A simple illustration of the erroneous mean trends that can be predicted if the independent and dependent

variables are reversed follows. Assume that triplicate fatigue test results have been generated at three evenly spaced stress levels, as shown in Fig. 9. Because the stress amplitude for each test was controlled, and therefore is known with little error, it represents the independent variable. The resulting fatigue lives were not controlled, and significant scatter in fatigue lives was observed at each stress level. Therefore, fatigue life represents the predicted or dependent variable in the analysis. If a linear regression is performed with stress as the independent variable, the continuous curve results; at each stress level the scatter in fatigue lives about the mean curve is minimized. If a linear regression is performed with fatigue life as the independent variable, the dashed curve results; at each fatigue life the "scatter" in stresses about the mean curve is minimized. Clearly, the dashed line underestimates the high-stress mean fatigue lives and overestimates the low-stress mean fatigue lives. This effect is certainly less when the scatter is lower or the overall range of the true independent variable is increased, but additional replication would have a negligible effect on the misrepresented mean curve. Therefore, an analytical expression involving fatigue life as the dependent variable is generally the most realistic from a statistical perspective.

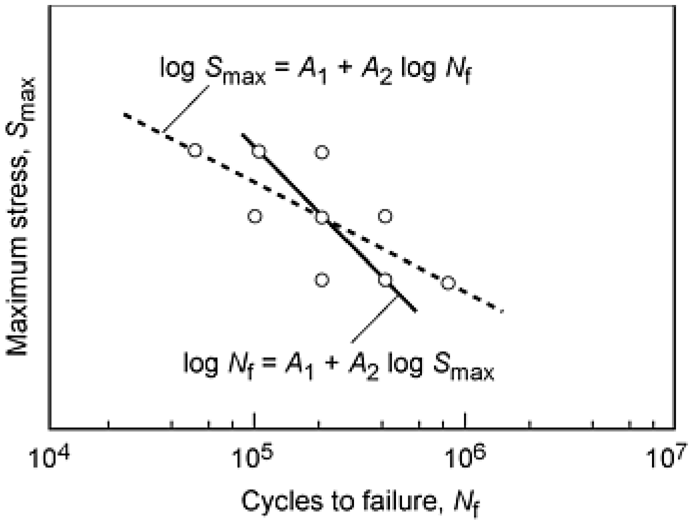

Fig. 9 Illustration of the effect of choice of dependent and independent variables in representing *S*-*N* fatigue data

When performing any type of correlation or regression analysis in addressing an engineering problem, the choice of dependent and independent variables should be made very carefully. Perhaps the simplest way to think about it is to consider that a regression analysis is meant to predict values of the dependent variable for specific, defined values of the independent variable(s). It only makes sense to predict values that are unknown at the outset of an experiment or analysis; these values are dependent on the selected or controlled (independent) variables.

Why Not Just Assume Normality and Forget the Complications? The first assumption that most engineers will make when applying statistics to an engineering problem is that the property in question is normally distributed. The normal distribution is relatively simple mathematically, is well understood, and is well characterized. The engineering statistics applications where nonnormal statistical distributions and nonparametric (distribution-free) approaches are used probably do not total the number of applications based on normal statistics.

The assumption of normality is a reasonable one in many cases where only mean trends or average properties are of interest. The importance of verifying this assumption increases when properties removed from the mean or average are being addressed, such as an estimated first percentile value of a design factor or a value 2 or 3 standard deviations below the mean.

The significance of the assumed distribution on estimated lower-bound properties can be demonstrated by a simple example. Case 1: the fatigue data presented in Table 1 are assumed to be normally distributed. Case 2: the fatigue data presented in Table 1 are assumed to be log-normally distributed. Calculate a lower-bound estimate of the fatigue behavior for this material for both cases based on two standard deviations below the sample mean.

Case 1:	**$\bar{x} = \bar{N}$ = 1.659 × 10^6**
	s = 9.98 × 10^5
	$\bar{x}$ - 2 s = N_{lower} = -3.37 × 10^5
Case 2:	$\bar{x}$ = 6.146, $\bar{N}$ = $10^{6.146}$ = 1.40 × 10^6
	s = 0.271

In Case 1 a nonsensical answer results, because the lower-bound fatigue life estimate is less than 0. In case 2 a workable answer results, based on a realistic representation of the underlying distribution of the random variable. (When dealing with transformed variables, such as in case 2, it is important to remember to untransform the variable after performing the statistical calculations.) Clearly, the assumptions that are made regarding underlying statistical distributions can have a major impact on the meaningfulness of the answers that result.

Statistical Aspects of Design

Richard C. Rice, Battelle Columbus

Statistical Distributions Applied to Design

Statistical distributions as applied to engineering design can be discussed in terms of two categories: continuous distributions and discrete distributions.

Continuous Distributions

Normal Distribution. Lacking more detailed information regarding the nature of an engineering random variable, it is often assumed that its variability can be represented by a normal distribution. The normal distribution has been used to model a wide variety of physical, mechanical, and chemical properties such as tensile and yield strength of some metallic alloys, temperature variations over a period of time, and the reaction rate of chemical reactions.

Two of the main reasons for the popularity of the normal distribution are obvious--the normal distribution is the best known of all statistical distributions, and sample estimates of its parameters are easily computed. Also, many sample statistics have a normal distribution for large sample sizes. Another pragmatic reason is that it works pretty well in many cases, especially if an accurate representation of very low probability events is not required.

The density function for a normal distribution is defined as follows:

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right] \quad -\infty \leq x \leq \infty \qquad \textbf{(Eq 5)}$$

where x is the random variable, $f(x)$ is the probability density function of x, μ is the population mean, σ is the population standard deviation, and exp stands for e (2.718) raised to the power in brackets. Normal distributions having the same mean but different standard deviations are shown in Fig. 10, while normal distributions having different means but the same standard deviations are shown in Fig. 11.

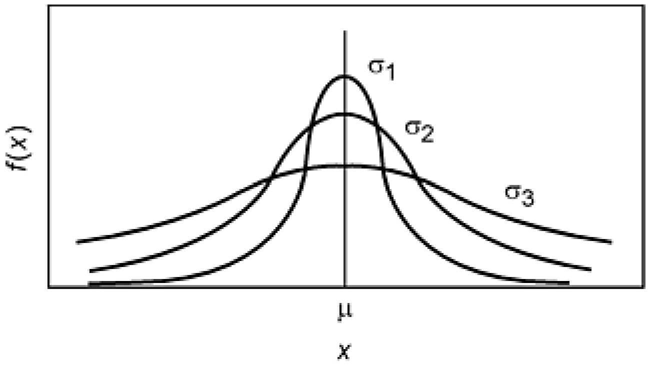

Fig. 10 Approximate effect of changing the variability in the normal distribution with no change in the mean value

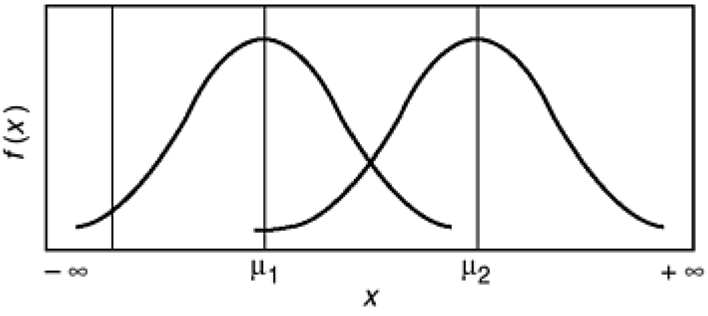

Fig. 11 Approximate effect of changing the mean value in the normal distribution with no change in the variability

The only parameters required to define a normal distribution are the mean and the standard deviation. If a material property is normally distributed, relatively accurate estimates of the mean value of the material can be obtained with small sample sizes. Larger sample sizes are required to obtain good estimates of the standard deviation of a normally distributed property. This point is illustrated in Table 3, where sample statistics are tabulated for a random variable that is normally distributed, with a true mean of 100 and a true standard deviation of 5. With as few as five observations, a fairly stable estimate of the population mean is obtained, but rather large fluctuations in the estimated standard deviation of the population are still evident. Larger sample sizes tend to improve the accuracy of the estimated values for the population mean and standard deviation, although it is evident that even sample sizes as large as 50 do not provide truly precise estimates of either statistical parameter.

Clearly, the normal distribution is symmetric about the mean, in that the upper tail is a mirror image of the lower tail when reflected about the mean. Notice in Eq 5 that the normal distribution is not bounded by 0 on the lower extreme. This means that the frequency of occurrence of low probability events of a material property represented by a normal distribution may not be well represented, especially if that property displays a large coefficient of variation.

Equation 5 applies to the probability of occurrence of a single value of *x*. If the probability of occurrence of any value of *x* greater than *b* is desired, Eq 5 can be integrated as follows:

$$P(x > b) = \int_b^\infty \frac{1}{\sigma\sqrt{2\pi}} \exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right] dx \qquad \textbf{(Eq 6)}$$

Because the integral of this equation is not available in a simple form, it is usually solved through the use of tables of "normal deviates." This process is simplified if a simple substitution is made, wherein a new variable, *z*, is defined:

$$\frac{b-\mu}{\sigma} = z_b \qquad \textbf{(Eq 7)}$$

and Eq 6 is rewritten in normalized form as follows:

$$P(z > z_b) = \int_{z_b}^\infty \frac{1}{\sqrt{2\pi}} \exp\left[-\frac{z^2}{2}\right] dz \qquad \textbf{(Eq 8)}$$

The region from z_b to ∞ is the shaded area shown in Fig. 12. Clearly, a z_b of 0 is equivalent to the mean, which gives an α value of 0.50, representing half of the area under the symmetrical normal curve. The shaded area in Fig. 12 is tabulated in many statistics textbooks and is repeated here as Table 4.

Table 4 Area under the normal curve from -∞ to the mean plus *z* standard deviations

For negative values of *z*, subtract the tabular value from unity.

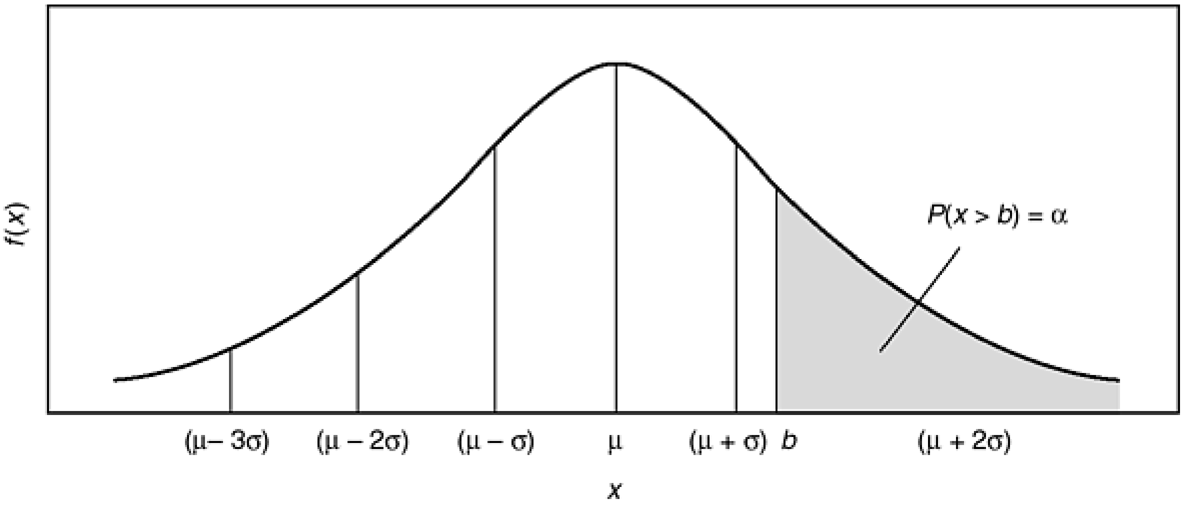

Fig. 12 Illustration of the standardized normal distribution

Log-Normal Distribution. Probably the second-most-often-assumed distribution for engineering random variables is the log-normal distribution. Of course, the log-normal distribution is really just a special case of the normal distribution, where the quantities that are assumed to be normally distributed are the logarithms of the original observations.

The log-normal distribution does offer some interesting attributes that are useful in representing some engineering random variables. First, the log-normal distribution is bounded at 0, which makes it useful in some cases to represent random variables that cannot take on negative values (such as fatigue cycles to failure). Second, the log-normal distribution is inherently positively skewed (in the untransformed variable space), with an elongated upper tail compared to the lower tail, as shown in Fig. 13. The extent of the skewness depends on the coefficient of variation in the untransformed data, with the least skewness being evident in data with low COVs.

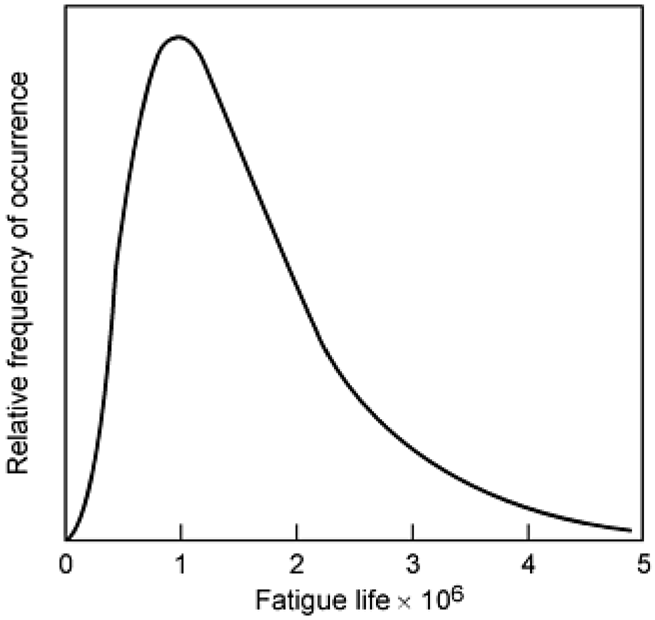

Fig. 13 Density function for a log-normal distribution

Because of the nature of the log-normal distribution, it is used most often to model life phenomena where the cycles or time to failure for a given condition tend to be skewed when viewed in normal space (Ref 5, 6). When using the log-normal distribution to represent variability in fatigue data it is important to recognize that the variability tends to increase with increasing mean fatigue lives (Ref 7, 8).

Weibull distribution is used frequently in representing engineering random variables because it is very flexible. It was originally proposed (Ref 9) to represent fatigue data, but it is now used to represent many other types of engineering data. For the modeling of fatigue strength at a given life, it has been argued that only the three-parameter Weibull distribution is appropriate (Ref 10). One of the reasons that the Weibull distribution is popular is that data can be plotted on Weibull paper and the conformance of these data to the Weibull distribution can be evaluated by the linearity of the CDF in the same way as a normal distribution.

General Three-Parameter Weibull. The general, three-parameter form of the Weibull distribution density function is:

$$f(x) = \frac{b}{\theta}\left[\frac{x - x_0}{\theta}\right]^{b-1} \exp\left[-\left(\frac{x - x_0}{\theta}\right)^b\right] \quad \text{(Eq 9)}$$

where the parameters are x_0, b, and θ, and they are defined as follows: x_0 is the expected minimum value of x, and is often referred to as the threshold parameter, b is the so-called Weibull slope or shape parameter, and θ is the so-called characteristic or scale parameter.

The Weibull density function can take on dramatically different shapes, depending on the chosen or optimized value of the shape parameter, b, as shown in Fig. 14. Values of b less than 1 produce an exponentially decaying density function, while values of b greater than 1 provide a peaked density function, with a maximum value removed from x_0. A shape factor of approximately 3.5 provides a nearly symmetrical distribution that looks somewhat like a normal distribution density function with a "pinned" lower tail. Shape factors between 1 and 3.5 provide positively skewed density functions with long upper tails, while shape factors above 3.5 provide negatively skewed density functions with long lower tails.

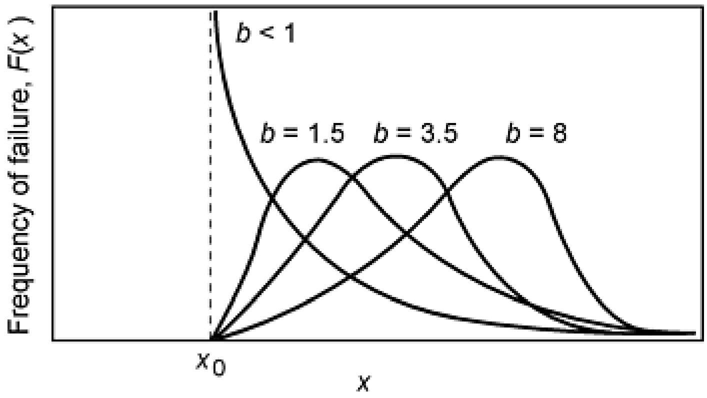

Fig. 14 Density function for the Weibull distribution with different shape factors

The relatively complex form of the density function given in Eq 9 simplifies considerably when converted to a cumulative distribution function:

$$F(x) = 1 - \exp\left[-\left(\frac{x - x_0}{\theta} \right)^b \right] \quad \text{(Eq 10)}$$

Two-Parameter Weibull. Equations 9 and 10 are simplified considerably when the threshold parameter is set to 0. Only the cumulative distribution function for the two-parameter Weibull distribution will be represented here.

$$F(x) = 1 - \exp\left[-\left(\frac{x}{\theta} \right)^b \right] \quad \text{(Eq 11)}$$

This form of the Weibull distribution is known, quite logically, as the two-parameter Weibull. There are certain kinds of engineering properties that can be well represented (or at least conservatively represented) by a two-parameter Weibull density function. For example, it is common practice to assume that the strength of polymer matrix composite materials can be represented by a two-parameter Weibull distribution (Ref 11). One significant thing to remember regarding the two-parameter Weibull distribution is that the lower tail is "pinned" at 0, meaning that very low probability, lower-tail, events predicted from this distribution may be very (possibly unrealistically) low in magnitude. The two-parameter Weibull does offer the advantage that the threshold parameter does not have to be estimated, allowing a closed-form determination of the remaining two parameters.

By taking the double natural logarithm of Eq 11 it is possible to show that:

$$\ln \ln \frac{1}{1 - F(x)} = b(\ln x) - b \ln \theta \quad \text{(Eq 12)}$$

which is the equation for a straight line in ln x, with a slope of b and intercept $-b \ln \theta$. Example Weibull CDF plots for a range of different b values are given in Fig. 15.

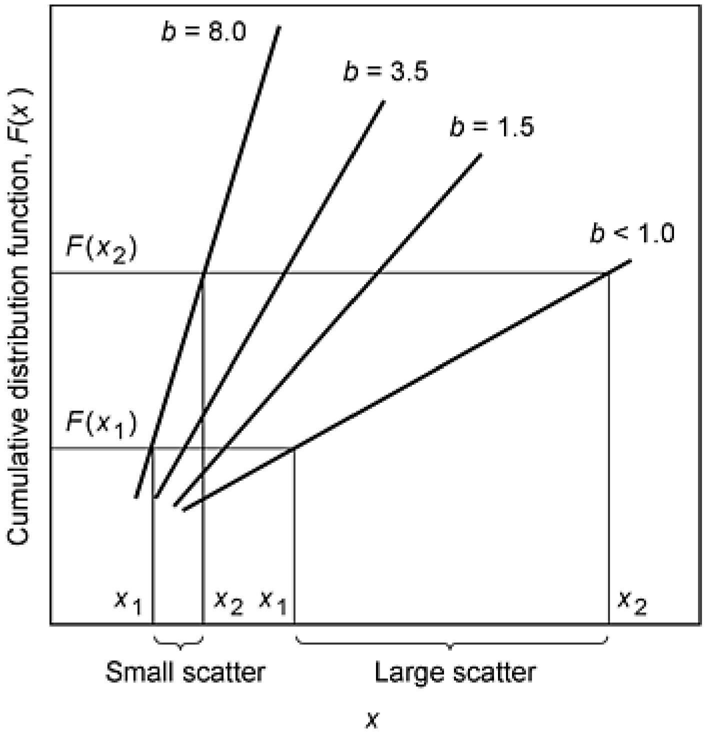

Fig. 15 CDF plots for various shape factors on Weibull probability paper

One way to evaluate whether a random variable follows a Weibull distribution and, if so whether the location parameter is nonzero is to plot the available data on Weibull probability paper, as shown in Fig. 16. This can be done, as shown earlier, by ranking the data, and assigning median ranks to the observations in ascending order. These values can then be plotted, assuming different values for the location parameter, x_0. If the CDF is linear for some nonzero value of x_0, there is evidence that a three-parameter Weibull distribution with a location parameter of x_0 would provide a reasonable representation of this random variable.

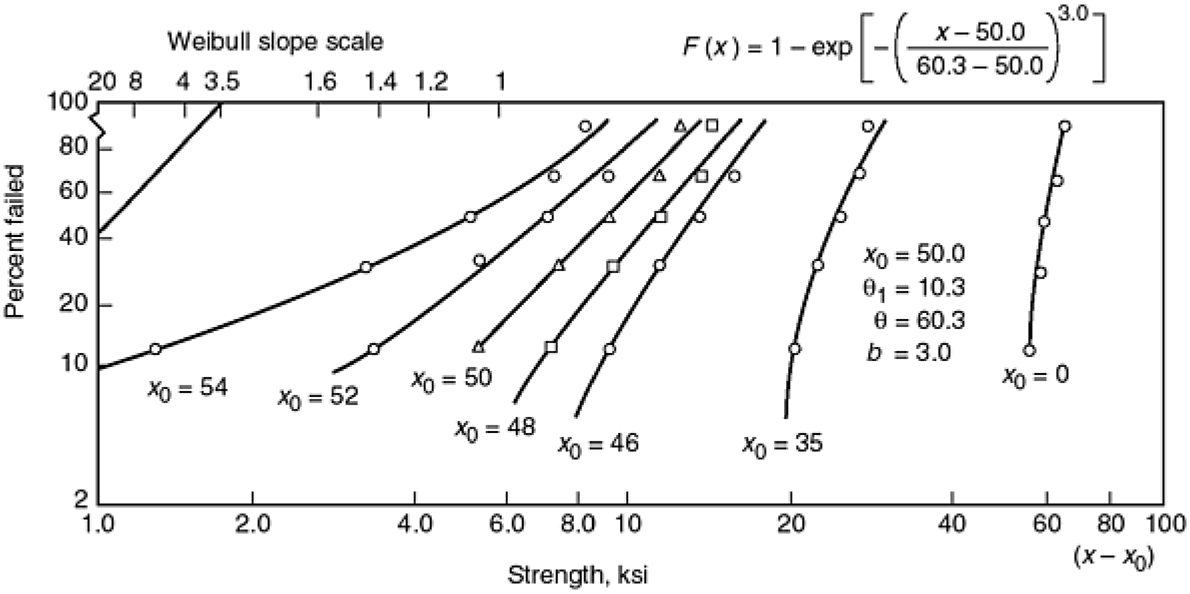

Fig. 16 Modified Weibull plot for determination of Weibull parameters

Exponential distribution can be considered a special case of the Weibull distribution (although the latter was derived from the former). In this case, the Weibull distribution has a threshold parameter, x_0, of 0, and a slope parameter, *b*, of unity. In this sense, the exponential distribution is a one-parameter Weibull distribution, with the only optimized or measured parameter being θ, the scale parameter. This distribution has been found to be useful in the analysis of failure rates of complete systems or assemblies, such as light bulbs, water heaters, and automobile transmissions, or where their failures result from chance occurrence alone, such as a wheel hitting a large pothole.

The density function for an exponential distribution can be written as:

$$f(t) = \frac{1}{\theta} e^{-t/\theta} \quad \textbf{(Eq 13)}$$

where $f(t)$ is the probability of failure, t is the operating time (the independent variable), θ is the characteristic life or scale parameter, and e is the base of natural logarithms (2.718).

The CDF for an exponential distribution:

$$F(t) = 1 - e^{-t/\theta} \quad \textbf{(Eq 14)}$$

can be plotted on Weibull probability paper, with a slope of unity.

As an example of the use of the exponential distribution, assume that the failure rate of a heat pump is known to follow an exponential distribution, and it has been found that 20% of these heat pumps fail in ten years. How long will it take for 50% of the heat pumps to fail?

In this case the variable is time, *t.* At the end of ten years $F(t) = 1 - e^{-t/\theta} = 0.20$. Solving for θ gives 44.84 years. Knowing θ and calculating *t*, based on an $F(t) = 0.50$, which corresponds to the B_{50} life, a value of 31.1 years is obtained. This calculation is straightforward. In the real world, however, the assumption of an underlying exponential distribution would have to be verified or tested in some manner, and the failure rate of 20% in ten years would have to be treated as an estimate, based on some finite sample, rather than a fixed quantity.

Discrete Distributions

Binomial distribution may be applicable where the random variable is discrete and takes on nonnegative integer values. It is used commonly in developing sampling plans for periodic inspections of manufacturing or material quality. It is also used in Bernouilli trials to evaluate the probability of occurrence of particular events, such as the likelihood that a defect of a certain size will be present in *x* components, with a known distribution of defects in the overall population.

For example, assume that it is known that defects sufficient to cause a downgrade in the usage of a component are present in 5% of the overall population. If these substandard parts are produced randomly, the likelihood of picking a part off of the line and finding it defective would be 0.05. The likelihood of randomly picking two successive parts off of the line that were defective would be $0.05 \times 0.05 = 0.0025$. This is based on the fact that the probability of the simultaneous occurrence of independent events equals the product of their individual probabilities of occurrence.

In large sample sizes, there are many different combinations of events that can occur, each with their respective probabilities of occurrence. Given an experiment consisting of *n* independent trials, with an overall probability of successful occurrence being *p*, and unsuccessful occurrence being $q = 1 - p$, the probability that the number of successful occurrences, *r*, during *n* trials is equal to r_1, and is given by:

$$p(r = r_1) = \binom{n}{r_1} p^{r_1} q^{n-r_1} \quad \text{for } r_1 = 0, 1, 2, \ldots, n \quad \textbf{(Eq 15)}$$

where:

$$\binom{n}{r_1} = \frac{n!}{r_1!(n - r_1)!} \quad \textbf{(Eq 16)}$$

and $n!$, $r_1!$, and $(n - r_1)!$ are factorials of the respective quantities. The mean value of this binomial distribution is np and the standard deviation is $\sqrt{npq}$.

For example, given a population containing 10% defective, what is the probability of finding three defective components in a sample of four components? In this case, the number of trials, n = 4, the value of p = 0.10, and q = 0.90. The probability that three defective components will be found is given by Eq 15:

$$p(r = 3) = \binom{4}{3}(0.10^3)\,(0.90^{4-3})$$
$$= \frac{4!}{3!\,1!}(0.10^3)\,(0.90^1) = 4(0.001)\,(0.9) = 0.0036$$

When evaluating the probability of all defectives or no defectives in a sample, the factorial of 0 will be required. The factorial of 0 is 1.

One very practical engineering application of the binomial distribution is in the calculation of nonparametric lower tolerance limit values on mechanical properties, such as are presented in MIL-HDBK-5 (Ref 2) for metallic materials and in MIL-HDBK-17 (Ref 6) for composite materials. These lower limit values are computed based on probabilities derived from the binomial distribution for specific rank values. For example, a so-called *B* value, which corresponds to a 90% exceedance level at 95% confidence, is associated with the lowest rank value in a sample of 29 observations. Similarly, the fifth rank value from the lowest corresponds to a *B* value in a sample of 89 observations.

Other Discrete Distributions. Two other common variations of the binomial distribution are the hypergeometric and the Poisson distributions. The hypergeometric distribution is used for the same kinds of applications as the binomial distribution, except that for the binomial the percentage of defective items is assumed to be constant throughout the experiment. This implies that the sample from which the items are drawn is essentially infinite compared to the number of items taken. Refer to one of the statistical textbooks in the References and Selected References at the end of this article for a detailed development of the hypergeometric distribution.

The Poisson distribution differs from the binomial and hypergeometric distributions in that the number of times that an event occurs is not known, but the probability of occurrence of the event is known. For example, one could determine how often a driver hit a curb in a given period of time, but it is not possible to quantify how many times the driver did not hit the curb in that same period of time. In this case, all one needs to know is the average number of occurrences of the event (hitting the curb) and the probabilities of observing a certain number of these events in a given period of time can be calculated. Again, refer to one of the statistical textbooks in the References and Selected References for a detailed development of the Poisson distribution.

In order to design a meaningful experiment or properly analyze a set of data, it is important to make a realistic choice regarding the statistical distribution that will be used to represent the data. There is no foolproof test or method available that an experimenter or analyst can apply to determine *a priori* the best distribution to use. In the absence of information that may aid in determining the suitability of a particular distribution, a normal distribution is often assumed. However, in the case of life data, a log-normal or Weibull distribution is usually assumed, lacking evidence to the contrary. For more extensive guidance, the reader should refer to Ref 1.

Statistical Procedures

Many different statistical techniques may be useful in analysis of mechanical-property data. This section presents brief descriptions of procedures that are used frequently (Ref 2). More detailed descriptions of these and other statistical techniques and tables in their various forms can be found in a number of workbooks and texts (for example, Ref 12).

Goodness-of-Fit Tests

This section contains a discussion and illustration of a method that can be used to establish whether or not a sample can realistically be assumed to follow a normal distribution. Similar, but more complex procedures are detailed elsewhere (Ref 2) for the three-parameter Weibull distribution.

The method that is presented is based on the "Anderson-Darling" goodness-of-fit test statistic for testing normality. This test is objective and indicates (at a 5% risk of error in the cases considered here) whether the sample is drawn from a normal distribution. Unfortunately, this test may reject the hypothesis of normality even though the distribution may provide a reasonable approximation within the lower tail. This is especially true for large data sets, where small deviations from the assumed distribution will be "detected." Consequently, some engineering judgment should be employed after using this, or any other goodness-of-fit test.

After a goodness-of-fit test has been performed (especially if the distributional assumption has been rejected), it is often useful to form a cumulative probability plot of the data to illustrate graphically the degree to which the assumed distribution fits the data. A method that can be used to develop normal probability plots is presented following the next section. In what follows, sample size is denoted by n, sample observations by $x_1, \ldots, x_n$, and sample observations ordered from least to greatest by $x_{(1)}, \ldots, x_{(n)}$.

The Anderson-Darling test for normality can be used to determine whether the density function that fits a given set of data can be approximated by a normal curve. The test involves a numerical comparison of the cumulative distribution function for observed data with that for the fitted normal curve over the entire range of the property being measured. The normalized deviation of individual data points from the sample average can be computed as follows:

$$z_{(i)} = (x_{(i)} - \bar{x})/s \qquad i = 1, \ldots, n \qquad \textbf{(Eq 17)}$$

where $x_{(i)}$ is the ith smallest sample observation, $\bar{x}$ is the sample average, and s is the sample standard deviation. Equations for computing sample statistics were presented earlier in the section "Sample versus Population Parameters."

The Anderson-Darling test statistic is:

$$AD = \left[\sum_{i=1}^{n} \frac{1-2i}{n} \left[\ln \left(F_o\left(z_{(i)}\right)\right) + \ln\left(1 - F_o\left(z_{(n+1-i)}\right)\right) \right] \right] - n \qquad \textbf{(Eq 18)}$$

where F_o is the standard normal distribution function (Ref 2). If:

$$AD > 0.752/(1 + 0.75/n + 2.25/n^2) \qquad \textbf{(Eq 19)}$$

it can be concluded (at a 5% risk of error) that the population from which the sample was drawn is not normally distributed. Otherwise, the hypothesis that the population is normally distributed is not rejected. For further information on this test procedure, see Ref 13 and 14.

The same procedure can be used to test the normality of the residuals:

$$e_i = y_i - (a + bx_i) \qquad i = 1, \ldots, n \qquad \textbf{(Eq 20)}$$

from a regression assuming uniformity of variance of the residuals over the range of the independent variable. When calculating the test statistic *AD*, define:

$$z_{(i)} = e_{(i)}/s_y \qquad i = 1, \ldots, n \qquad \textbf{(Eq 21)}$$

where $e_{(i)}$, $i = 1, \ldots, n$ are the ordered residuals from smallest to largest and s_y is the root mean square error of the regression defined in the section "Data-Regression Techniques." The justification for this procedure can be found in Ref 15.

Normal Probability Plot. Arithmetic normal probability paper is recommended for graphic illustration of the degree to which a normal distribution fits a set of data. Logarithmic normal probability paper can be used to determine whether the distribution of data could be normalized by a logarithmic transformation. One axis is scaled in units of the property measured, and the other is a nonlinear scale of probability.

If there are relatively few data points, all of them can be plotted individually on the chart. With larger samples, it is only necessary to plot enough points to define the curve.

The rank of each point selected for plotting is equal to the number of lower test points plus the plotted point plus one-half the number of other points equal to the plotted point (if there are points within the sample at this rank that are equal within engineering accuracy). Cumulative probability (*P*), in percent, is equal to the rank times 100, divided by one more than the total number of test points:

$$P \text{ (in percent)} = \frac{(\text{rank}) \cdot (100)}{n + 1} \qquad \textbf{(Eq 22)}$$

The measured value of each test point is plotted versus its cumulative probability and a straight line is drawn to represent the normal distribution. This line can be established by plotting any two points from the normal distribution curve for $\bar{x}$ and *s* (for example, $\bar{x}$- 3*s* at 0.13% probability, and $\bar{x}$+ 3*s* at 99.87% probability) and connecting these two points.

The plotted points should then be compared with the line to determine whether there is a reasonably good fit. With sample sizes on the order of 100 test points, only those points lying between about 10 and 90% probability should be considered

in making this evaluation. When sample sizes of less than 50 are examined, the greatest focus should be placed on the observations between 20 and 80% probability.

If normal probability paper is unavailable, a normal probability plot can be formed by plotting the measured value of each test point versus $\bar{x} + s\, F_o^{-1}(P/100)$ where F_o^{-1} is the inverse standard normal cumulative distribution function. The line representing the fitted normal distribution is the line passing through the points with equal horizontal and vertical coordinates. If the horizontal axis is labeled with cumulative probabilities (*P* values) rather than $F_o^{-1}(P/100)$ values, the plot will be a normal probability plot.

Tests of Significance

A test of significance is used to make a decision on a statistical basis. In this section, the *F*- and *t*-tests are described for use in determining whether the populations from which two samples are drawn are identical. Other, more comprehensive procedures, such as the *k*-sample Anderson-Darling procedure are described elsewhere (Ref 2).

The *F*-test is normally used first to determine whether two sample variances differ significantly or not (with a 5% risk of error in the case examined here). If the two sample variances do not differ significantly, the *t*-test is used next to determine whether the sample means differ significantly. If either the sample variances or the sample means differ significantly, it can be concluded that the populations from which the two samples were drawn are not statistically identical. Otherwise, the hypothesis that the two populations are identical should not be rejected. These tests are appropriate to use when (1) the observations within each sample are taken randomly from a single population of possible observations, and (2) the characteristic measured is normally distributed within each population. To carry out a similar procedure without requiring the assumption of an underlying normal distribution, or if three or more samples are to be compared, the *k*-sample Anderson-Darling test can be employed. This test is a nonparametric procedure and simply tests the hypothesis that populations from which the samples are drawn are identical.

The *F*-Test: Evaluation of Differences in Variability between Samples. The *F*-test is used to determine whether two products differ with regard to their variability. Consider products 1 and 2; they might represent two different processes, thickness ranges, or test directions. The statistics for the samples drawn from these products are:

Attribute	Product 1	Product 2
Sample size	n_1	n_2
Sample standard deviation	s_1	s_2
Sample mean	$\bar{x}_1$	$\bar{x}_2$

F is the ratio of the two sample variances:

$$F = s_1^2/s_2^2$$

If the true variances of products A and B are identical at a significance level of $\alpha = 0.05$, *F* should lie within the interval defined by:

$$F_{0.975} \text{ (for } n_1 - 1 \text{ and } n_2 - 1 \text{ degrees of freedom)}$$

and

$$1/F_{0.975} \text{ (for } n_2 - 1 \text{ and } n_1 - 1 \text{ degrees for freedom)}$$

If F does not lie within this interval, it can be concluded at a 95% confidence level (2.5% in each tail of the two-sided test) that the two products differ with regard to their variability. Values of $F_{0.975}$ can be obtained from Table 5. Values of $F_{0.975}$ can also be computed from the following analytical expression:

$$F_{0.975} = \exp\left[2\delta\left(1 + \frac{z^2 - 1}{3} - 4\sigma^2\right) + 2\sigma z\left(1 + \frac{\sigma^2 (z^2 - 3)}{6}\right)^{1/2} \right] \quad \textbf{(Eq 23)}$$

where z = 1.96, δ = 0.5 [1/(n_2 - 1) - 1/(n_1 - 1)], σ^2 = 0.5 [1/(n_2 - 1) + 1/(n_1 - 1)], n_1 = degrees of freedom for the numerator, and n_2 = degrees of freedom for the denominator. This expression is accurate to within 0.4% for n_1 degrees of freedom greater than or equal to 10 and n_2 degrees of freedom greater than or equal to 16.

Table 5 0.975 fractiles of the *F*-distribution associated with n_1 and n_2 degrees of freedom, $F_{0.975}$ (n_1,n_2)

n_2	n_1																		
	1	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**	**12**	**15**	**20**	**24**	**30**	**40**	**60**	**120**	**∞**

n_1, degrees of freedom for numerator; n_2, degrees of freedom for denominator

Example 1: F-Test Computation.

Assume that the following sample statistics were reported:

Attribute	Product 1	Product 2
Sample size	20	30
Sample standard deviation, ksi	4.0	5.0
Sample mean, ksi	100.0	102.0

Perform an *F*-test as follows:

$$F = s_1^2/s_2^2 = 4^2/5^2 = 0.64$$
$$df_1 = n_1 - 1 = 19$$
$$df_2 = n_2 - 1 = 29$$

where *df* is degrees of freedom. From interpolation within Table 5 (or from Eq 23) it can be found that:

$$F_{0.975\ (12,29)} = 2.23$$

and

$$1/F_{0.975\ (29,19)} = 1/2.40 = 0.42$$

Because 0.64 lies within the interval of 0.42 to 2.23, there is insufficient statistical evidence to conclude that products 1 and 2 differ with regard to their variability.

The *t*-Test: Evaluation of Differences in Means Between Samples. The *t*-test is used to determine whether two products differ with regard to their average properties. If they do, it can be concluded that the two products do not belong to the same population.

In making the *t*-test, it is assumed that the variances of two products are nearly equal, as first determined from the *F*-test. If the *F*-test shows that the variances are significantly different, there is no need to conduct the *t*-test.

Consider products 1 and 2 as before. $D\bar{x}$ is the absolute difference between the two sample means:

$$D\bar{x} = |\bar{x}_1 - \bar{x}_2| \quad \textbf{(Eq 24)}$$

If the true means of products 1 and 2 are identical, $D\bar{x}$ should not exceed *u*, which is determined as indicated by the following equation for a significance level of $\alpha = 0.05$.

$$u = t_{0.975}\, s_p \sqrt{\frac{n_1 + n_2}{n_1 \cdot n_2}} \quad \textbf{(Eq 25)}$$

where $t_{0.975}$ has $n_1 + n_2 - 2$ degrees of freedom, and:

$$s_p = \sqrt{\frac{(n_1 - 1) \cdot s_1^2 + (n_2 - 1) \cdot s_2^2}{n_1 + n_2 - 2}} \qquad \textbf{(Eq 26)}$$

Values of $t_{0.975}$ can be found through interpolation within Table 6. Values of $t_{0.975}$ can also be calculated from the approximate formula given in the footnote in Table 6. This formula is accurate to within 0.5% for degrees of freedom greater than or equal to 4.

Table 6 0.950 and 0.975 fractiles of the *t*-distribution associated with degrees of freedom (*df*)

df	$t_{0.95}$	$t_{0.975}$
1	6.314	12.706
2	2.920	4.303
3	2.353	3.182
4	2.132	2.776
5	2.015	2.571
6	1.943	2.447
7	1.895	2.365
8	1.860	2.306
9	1.833	2.262
10	1.812	2.228
11	1.796	2.201
12	1.782	2.179
13	1.771	2.160
14	1.761	2.145
15	1.753	2.131

16	1.746	2.120
17	1.740	2.110
18	1.734	2.101
19	1.729	2.093
20	1.725	2.086
21	1.721	2.080
22	1.717	2.074
23	1.714	2.069
24	1.711	2.064
25	1.708	2.060
26	1.706	2.056
27	1.703	2.052
28	1.701	2.048
29	1.699	2.045
30	1.697	2.042
40	1.684	2.021
50	1.676	2.009
60	1.671	2.000
80	1.664	1.990
100	1.660	1.984
120	1.658	1.980

200	1.653	1.972
500	1.648	1.965
∞	1.645	1.960

Note: The following equations may be used to compute 0.95 and 0.975 fractiles of the *t*-distribution in lieu of using table values:

$$t_{0.95} = 1.645 + \exp[0.377 - 0.990\ 1n(df) + 1.15/df]$$

$$t_{0.975} = 1.960 + \exp[0.779 - 0.980\ 1n(df) + 1.57/df]$$

These approximations are accurate to within 0.5% for $df \geq 4$.

Example 2: t-Test Computation.

The following sample statistics are the same as those presented earlier:

Attribute	Product 1	Product 2
Sample size	20	30
Sample standard deviation, ksi	4.0	5.0
Sample mean, ksi	100.0	102.0

Using the sample statistics presented earlier, it has already been determined that the variances of products 1 and 2 do not differ significantly. The *t*-test computations to test the sample means are as follows:

$$df = n_1 + n_2 - 2 = 48$$

$$t_{0.975} \text{ (for 48 } df) = 2.011 \text{ (from Table 6)}$$

$$s_p = \sqrt{\frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2 - 2}}$$

$$= \sqrt{\frac{(19)(4)^2 + (29)(5)^2}{48}} = 4.63 \text{ ksi}$$

$$\sqrt{\frac{n_1 + n_2}{n_1 \cdot n_2}} = \sqrt{\frac{20 + 30}{(20) \cdot (30)}} = 0.2887$$

$$D_{\bar{x}} = | \bar{x}_1 - \bar{x}_2 | = 2.0 \text{ ksi}$$

$$u = 2.011 (4.63)(0.2887) = 2.7$$

Because $D_{\bar{x}}$ (2.0) is not greater than u (2.7), it can be concluded that there is no reason to believe that products 1 and 2 differ with regard to their average strength. On the basis of both tests in this example, the conclusion would be that the two products can be assumed to be drawn from the same population.

Data-Regression Techniques

When it is suspected that the average of one measured value varies linearly or curvilinearly with some other measured value, a regression analysis is often used to investigate and describe the relationship between the two quantities. Examples are effect of product thickness on tensile strength, effect of temperature on yield strength, and effect of stress on cycles to failure or time to rupture. Mathematical techniques for performing a simple linear-regression analysis are contained in the following section. Statistical tests to determine whether or not a straight line adequately describes the data are described in the section "Testing the Adequacy of a Regression." An example is then presented using hypothetical data to illustrate the regression calculations.

Although the relationship between the dependent and independent variables may not be linear, it may be possible to linearize the relationship through a simple transformation of variables. In this case, it is important to perform all

calculations within the transformed space and then untransform the results to the original engineering units for final presentation.

Least-Squares Linear Regression. Linear regression is appropriate when there is an approximate linear relationship between two measurable characteristics. Such a relationship is expressed algebraically by an equation that, in the case of two measurable characteristics *x* and *y*, has the form:

$$y = \alpha + \beta x + \varepsilon \qquad \textbf{(Eq 27)}$$

where *x* is the independent variable, *y* is the dependent variable, α is the true intercept of the regression equation, β is the true slope of the regression equation, and ε is the measurement or experimental error by which *y* differs from the ideal linear relationship.

Aside from the error term, ε, this is the equation of a straight line. The parameter α determines the point where this line intersects the *y*-axis, and the β represents its slope. The variables *x* and *y* can represent either direct measurements or some transformation measurements of the characteristics under consideration. Knowing or assuming such an approximate linear relationship, the problem becomes one of estimating the parameters α and β of the regression equations. It is necessary to have a random sample consisting of *n* pairs of observations, which is denoted by (x_1, y_1), (x_2, y_2), . . ., $(x_n\ y_n)$. Such a sample can be represented graphically by *n* points plotted on a coordinate system, in which *x* is plotted horizontally and *y* vertically. A subjective solution can be obtained by drawing a line that, by visual inspection, appears to fit the points satisfactorily. An objective solution is given by the method of least squares.

The method of least squares is a numerical procedure for obtaining a line having the property that the sum of squares of vertical deviations of the sample points from this line is less than that for any other line. In this analysis, the least-squares line is represented by the equation:

$$\hat{y} = a + bx \qquad \textbf{(Eq 28)}$$

in which $\hat{y}$ is the predicted value of *y* for any value of *x*, and *a* and *b* are estimates of the parameters α and β in the true regression equation obtained by the least-squares method presented below.

It can be shown with the aid of calculus that the values of *a* and *b* that minimize the sum of squares of the vertical deviations are given by the formulas:

$$a = \frac{\Sigma y - b\Sigma x}{n} \qquad \textbf{(Eq 29)}$$

$$b = \frac{s_{xy}}{s_{xx}} \qquad \textbf{(Eq 30)}$$

where

$$s_{xy} = \Sigma xy - \frac{\Sigma x\ \Sigma y}{n} \qquad \textbf{(Eq 31)}$$

and

$$s_{xx} = \Sigma x^2 - \frac{(\Sigma x)^2}{n} \qquad \textbf{(Eq 32)}$$

The root mean square error of *y* is expressed as:

$$s_y = \sqrt{\frac{\Sigma(y - \hat{y})^2}{n - 2}}$$ **(Eq 33)**

where $\hat{y}$ is the predicted value of *y* defined above. This quantity is an estimate of the standard deviation of the distribution of *y* about the regression line. A convenient computational formula for s_y is

$$s_y = \sqrt{\frac{s_{yy} - b^2 s_{xx}}{n - 2}}$$ **(Eq 34)**

where

$$s_{yy} = \Sigma y^2 - \frac{(\Sigma y)^2}{n}$$ **(Eq 35)**

The quantity $R^2 = (b^2 s_{xx})/s_{yy}$ measures the proportion of total variation in the *y* data, about its average, that is explained by the regression. An R^2 equal to 1 indicates that the regression model describes data perfectly, which is rare in practice. R^2 provides a rough idea of how well data is described by a linear regression. A more precise determination of the adequacy of a linear regression is discussed in the next section.

Testing the Adequacy of a Regression. It is possible that the relationship between dependent variable *y* and independent variable *x* may not be approximately linear. In that case, a straight line would not "fit" the data very well. It is also possible that the relationships between *x* and *y,* although approximately linear, may not be very strong. In such a case, estimated slope parameter *b* would not be significantly different from 0. Both the lack of fit and the significance of a linear-regression equation can be evaluated through an analysis of variance as described in this section.

The analysis of variance for testing lack of fit and significance of regression is based on the assumption that measurement errors, ε_i, in the approximate linear relationship between y_i and x_i, that is,

$$\varepsilon_i = y_i - (\alpha + \beta x_i) \qquad i = 1, 2, \ldots, n$$ **(Eq 36)**

are independent and normally distributed with an overall mean of 0 and a constant variance of σ^2. Assuming uniformity of measurement error variance over the range of the independent variable, the normality assumption concerning unobservable ε_i can be checked by performing the Anderson-Darling test for normality on the observable residuals:

$$e_i = y_i - (a + bx_i) \qquad i = 1, 2, \ldots, n$$ **(Eq 37)**

where *a* and *b* are the least-squares estimates of α and β. See the section "Anderson Darling Test for Normality" in this article for more details. By plotting the residuals e_i against the respective x_i, an informal check on the assumption of constant variance σ^2 is possible as well. In such a plot residuals should vary approximately equally over the range of x_i values.

The analysis of variance table for testing the lack of fit and significance of a linear regression is shown in Table 7. The sums of squares for the three primary lines of the analysis of variance table (Regression, Error, and Total) are calculated using quantities defined in the section "Least-Squares Linear Regression" in this article.

Table 7 Analysis of variance for testing lack of fit and significance of linear regression

Source of variation	Degrees of freedom (linear)	Sum of square, *SS*	Mean, squares, *MS*	F_{calc}
Regression	1	*SSR*	*MSR*	F_1
Error	*n* - 2	*SSE*	*MSE*	
Lack of fit	*k* - 2	*SSLF*	*MSLF*	F_2
Pure error	*n* - *k*	*SSPE*	*MSPE*	
Total	*n* - 1	*SST*		

$$SSR = b^2 s_{xx}$$

$$SST = s_{yy}$$

$$SSE = SST - SSR$$

If multiple observations at one or more values of the independent variable *x* are available, and observations are made at three or more distinct *x* values, then it is possible to evaluate the adequacy of a line in describing the relationship between *x* and *y*. The notation in testing for this lack of fit is summarized in the analysis of variance table above. Let Y_{ij} denote the *j*th data value at the *i*th *x* level, *k* represent the number of distinct *x* levels for which there is data, and n_i represent the number of data values at the *i*th *x* level. Denote the total of the observations at the *i*th *x* level by:

$$T_i = \sum_{j=1}^{n_i} Y_{ij} \quad \text{for } i = 1, \ldots, k$$ **(Eq 38)**

and note that:

$$n = \sum_{i=1}^{k} n_i$$ **(Eq 39)**

is used to denote the total number of observations. The lack of fit and pure error sums of squares are computed as:

$$SSLF = \sum_{i=1}^{k} (T_i^2/n_i) - (\Sigma y)^2/n - SSR$$ **(Eq 40)**

and

$$SSPE = SSE - SSLF$$

The sums of squares are divided by the corresponding degrees of freedom to compute mean squares as shown below:

$$MSR = SSR$$
$$MSE = SSE/(n - 2)$$
$$MSLF = SSLF/(k - 2)$$
$$MSPE = SSPE/(n - k)$$

These mean squares are used to compute two F statistics that test for lack of fit and significance of regression. (Note: If there is only one data value for each x level, i.e., $n_i = 1$ for $i = 1, 2, \ldots, k$, or if $k = 2$, then it is not possible to test for lack of fit.)

The two F statistics, F_1 and F_2, are defined as ratios of the mean squares as specified below:

$$F_1 = MSR/MSE$$
$$F_2 = MSLF/MSPE$$

F_2 and Table 8 are used to test for lack of fit. If F_2 is greater than the 95th percentile of F distribution with $k - 2$ numerator degrees of freedom and $n - k$ denominator degrees of freedom (from Table 8), then there is significant lack of fit. In this case it can be concluded (with a 5% risk of error) that linear regression does not adequately describe the relationship between x and y. Otherwise, lack of fit can be considered insignificant and a linear-regression model can be assumed.

Table 8 0.950 fractiles of the *F*-distribution associated with n_1 and n_2 degrees of freedom, $F_{0.950}$ (n_1,n_2)

n_2	n_1

n_1, degrees of freedom for numerator; n_2, degrees of freedom for denominator

If lack of fit is not significant, the significance of regression can be tested using F_1 and Table 8. If F_1 is greater than the 95th percentile of *F* distribution with 1 numerator degree of freedom and *n* - 2 denominator degrees of freedom (from Table 8), then regression is significant. Otherwise, the regression is not significant and *x* is considered to have little or no predictive value for *y*.

Example 3: Linear Regression Computations.

In this example, *x* represents thickness and *y*, the tensile yield strength values determined from a group of tensile tests. Values of *x* and *y* are:

x	*y*
0.100	121
0.100	119
0.200	114
0.200	108
0.300	112
0.300	108
0.400	112
0.400	106
0.500	101
0.500	99

From these data, the following quantities can be calculated:

$$n = 10$$
$$\sum x = 3$$
$$\sum y = 1100.0$$
$$\sum x^2 = 1.1$$
$$\sum y^2 = 121452$$
$$\sum xy = 321.6$$
$$(\sum x)^2 = 9$$
$$(\sum y)^2 = 121{,}000$$
$$(\sum x)(\sum y) = 3{,}300$$

s_{xx} = 0.20
s_{xy} = -8.4
s_{yy} = 452

The slope of the regression line is:

$$b = \frac{s_{xy}}{s_{xx}} = \frac{-8.4}{0.20} = -42$$

The *y*-intercept of the regression line is:

$$a = \frac{\Sigma y - b\Sigma x}{n} = \frac{1100}{10} - \frac{(-42)(3)}{10} = 110 + 12.6 = 122.6$$

Thus the final equation of the least squares regression line is:

$$\hat{y} = a + bx = 122.6 - 42x$$

The total of the *y* data at each *x* level is needed to calculate lack of fit and pure error sums of squares. These totals are as follows:

x_i	T_i
0.1	240
0.2	222
0.3	220
0.4	218
0.5	200

There are data values at $k = 5$ different x levels, with $n_i = 2$ values at each level and:

$$\sum_{i=1}^{k} (T_i^2/n_i) = \frac{(240)^2}{2} + \ldots + \frac{(200)^2}{2} = 121{,}404$$

Therefore:

$$SSLF = 121{,}404 - (1{,}100)^2/10 - 352.8 = 51.2$$

and

$$SSPE = 99.2 - 51.2 = 48$$

The mean square values are computed by dividing corresponding sums of squares by their degrees of freedom. The F_1 and F_2 statistics are then calculated as ratios of mean squares. The analysis of variance is shown in Table 9. Using the fitted-regression equation, the following values of $\hat{y}$ can be computed for the values of x listed previously.

x	$\hat{y}$
0.100	118.4
0.200	114.2
0.300	110.0
0.400	105.8
0.500	101.6

The root mean square error is computed as follows:

$$s_y = \sqrt{\frac{\Sigma(y - \hat{y})^2}{\bar{n} - 2}} = \sqrt{\frac{99.2}{8}} = \sqrt{12.4} = 3.52$$

or

$$s_y = \sqrt{\frac{s_y - b^2 s_{xx}}{\bar{n} - 2}} = \sqrt{\frac{452 - (-42)^2(0.2)}{8}} = 3.52$$

Table 9 Analysis of variance for Example 3

Source of variation	Degrees of freedom, *df*	Sum of squares, *SS*	Mean squares, *MS*	F_{calc}
Regression	1	352.8	352.8	$F_1 = 28.5$
Error	8	99.2	12.4	
Lack of fit	3	51.2	17.07	$F_2 = 1.78$

Pure error	5	48.0	9.6
Total	9	452.0	

The correlation coefficient, R^2, is computed as follows:

$$R^2 = \frac{b^2 s_{xx}}{s_{yy}} = \frac{(-42)^2(0.2)}{452} = 0.78$$

Thus, 78% of the variability in the *y* data about its average is explained by the linear relationship between *y* and *x*.

The sum of squares for the regression, total, and error lines are computed as follows:

$$SSR = (-42)^2\ (0.20) = 352.8$$
$$SST = 452$$
$$SSE = 452 - 352.8 = 99.2$$

The F_2 value of 1.78 with $k - 2 = 3$ and $n - k = 5$ degrees of freedom is less than the value of 5.41 from Table 8 corresponding to 3 numerator and 5 denominator degrees of freedom. This indicates that lack of fit can be considered insignificant. Thus, it is reasonable to assume that a linear regression adequately describes the data. The F_1 value of 28.5 with 1 and $n - 2 = 8$ degrees of freedom is greater than the value of 5.32 from Table 8 corresponding to 1 numerator and 8 denominator degrees of freedom, so the slope of the regression is found to be significantly different from 0.

Additional details on goodness-of-fit testing and linear-regression procedures can be found in Ref 12, 13, 14, and 15.

Reliability in Design

Charles O. Smith, Engineering Consultant

Introduction

RELIABILITY is a measure of the capacity of equipment or systems to operate without failure in the service environment. The National Aeronautics and Space Administration (NASA) defines reliability as the probability of a device performing adequately for the period of time intended under the operating conditions encountered. *Reliability is always a probability,* thus its calculation is one form of applied mathematics.Probabilistical and statistical methods, however, like any other forms of mathematics, are aids to, not substitutes for, logical reasoning.

Reliability is identified with a state of knowledge, not a state of things. Reliability cannot be used to predict discrete, or individually specific, events; only probabilities, that is averages, are predicted. Probability is a measure of what is expected to happen on the average if the given event is repeated a large number of times under identical conditions. Probability serves as a substitute for certainty. A generalization is made from samples, and the conclusions reached cannot be considered to be absolutely correct.

The NASA definition of reliability (and any other definition) includes "adequate performance" of the specific device. There is no general definition of adequate performance. Criteria for adequate performance must be carefully and exactly detailed or specified in advance for each device or system considered. For example, performance that is adequate for a tire of a private automobile would be woefully inadequate for a tire of a race car competing in the Indianapolis 500. The precise definition of adequate performance is completely dependent on the case under consideration.

A reliability of 0.99 implies a probability of 1 failure per 100. A reliability of 0.999 does not imply greater accuracy (one more significant figure) but an order of magnitude difference, that is, a probability of failure of 1 per 1000.

Charles O. Smith, Engineering Consultant

Reliability Tasks

All general definitions, like the NASA one, are qualitative. A quantitative definition of reliability for operating time *t* is:

$$R(t) = P(T > t) \quad \textbf{(Eq 1)}$$

where *R* is reliability, *P* is probability, and *T* is the time to failure of the device. (*T* itself is a variable.) The device is assumed to be working properly at time $t = 0$. No device can work forever without failure, thus:

$$R(0) = 1 \text{ and } R(\infty) = 0 \quad \textbf{(Eq 2)}$$

where $R(t)$ is a nonincreasing (constant, at best; generally decreasing) function between these two extremes. For $t < 0$, reliability has no meaning. It is defined as unity, however, since the probability of failure for $t < 0$ is zero.

The first task in ensuring reliability is to derive and investigate Eq 1. This is first done for a single component. The reliability of an entire system is then determined in keeping with the functions and configuration of the units composing the system. This, in turn, may be a subsystem of a more complex system. The building process continues until the entire system has been treated. The complete system may be so complex that it includes entire organizations, such as maintenance and repair groups with their personnel.

The second task, after the system and its reliability are truly understood, is to find the best way of increasing the reliability. The most important methods for doing this are:

- Reduce the complexity to the minimum necessary for the required functions. Nonessential components and unnecessary complexity increase the probability of system failure, that is, decrease reliability.
- Increase the reliability of components in the system.
- Use parallel redundancy, one or more "hot" spares operate in parallel. If one fails, others still function.
- Use standby redundancy. One or more "cold" spares is switched in to perform the function of a component or subsystem that has failed.
- Employ repair maintenance. Failed components are replaced by a technician rather than switched in as with standby redundancy. Replacement is neither automatic nor necessarily immediate.
- Employ preventive maintenance. Components are replaced periodically by new ones even though they may not have failed prior to the time of replacement.

Combinations of these methods are possible. The first two methods are obviously limited by the current state of technology. The other four methods enable, in principle, the development of systems having reliabilities approaching 100% for all arbitrarily chosen mission times *t*. This is not always feasible due to various constraints.

The third task is to maximize system reliability for a given weight, size, or cost. Conversely, the task may be to minimize weight, size, cost or other constraints for a given reliability.

Charles O. Smith, Engineering Consultant

Instantaneous Failure Rate and General Reliability Function

The instantaneous failure rate, $\lambda(t)$, that is, the instantaneous probability of failure per component, is assumed to be any variable and integrable function of time. Failure rate is normally expressed as the number of failures per unit time. The most general expression of failure rate is:

$$\lambda(t) = \frac{-1}{R(t)}\left(\frac{dR(t)}{dt}\right) \qquad \textbf{(Eq 3)}$$

Reliability is also related to the failure density function, or probability density function, $f(t)$:

$$\frac{dR(t)}{dt} = -f(t) \qquad \textbf{(Eq 4)}$$

Combining Eq 3 and 4 gives an alternative expression for the instantaneous failure rate:

$$\lambda(t) = \frac{f(t)}{R(t)} \qquad \textbf{(Eq 5)}$$

In other words, the instantaneous failure rate (at time t) equals the failure density function divided by the reliability, with both of the latter evaluated at time t. This is a completely general statement. Rearranging Eq 3 and integrating, knowing that at $t = 0$ and $R(t) = 1$, the general reliability function is:

$$R(t) = e^{-\int_0^t \lambda(t)dt} = \exp\left[-\int_0^t \lambda(t)dt\right] \qquad \textbf{(Eq 6)}$$

This function is independent of the specific failure distribution involved. The case of constant failure rate, that is, $\lambda(t)$ independent of time, has special interest:

$$R(t) = e^{-\lambda t} \qquad \textbf{(Eq 6a)}$$

Charles O. Smith, Engineering Consultant

Graphical Representation of Reliability

The probability of success, $R(t)$, and the probability of failure, $Q(t)$, are mutually exclusive. Thus it is obvious that:

$$R(t) + Q(t) = 1 \qquad \textbf{(Eq 7)}$$

The relationship is shown schematically in Fig. 1. In order to determine the reliability of a system between times t_1 and t_2, after the start of a "mission" at time $t = 0$, first find the probability of failure in that interval, that is:

$$Q_{t_2-t_1} = \int_{t_1}^{t_2} f(t)dt = Q(t)\Big|_{t_1}^{t_2} = Q(t_2) - Q(t_2) \quad \textbf{(Eq 8)}$$

The probability of nonfailure in the same interval is:

$$\begin{aligned} R_{t_2-t_1} &= 1 - Q_{t_2-t_1} = 1 - [Q(t_2) - Q(t_1)] \\ &= 1 - R(t_1) + R(t_2) \end{aligned} \quad \textbf{(Eq 9)}$$

This is not, however, the reliability of the system functioning from t_1 to t_2 because the system may fail in the period between $t = 0$ and $t = t_1$. This is the a priori probability that the system will not fail in the specified interval. This is not identical with the probability that the system will operate in that time interval, that is, the system reliability. System reliability is the probability that it will not fail between $t = 0$ and $t = t_1$ and that it will not fail from $t = t_1$ to $t = t_2$. The true reliability is $R(t_2)$.

Mortality Curve

Consider a population of homogeneous components from which a very large sample is taken and placed in operation at time $T = 0$. (T is age, in contrast with t, commonly used for operational life or mission time.) The population will initially

show a high failure rate. This decreases rapidly as shown in Fig. 2. This period of decreasing failure rate is called various names, such as early life period, infant mortality period, and shakedown period. Failure occurs due to design or manufacturing weaknesses, that is, weak or substandard components.

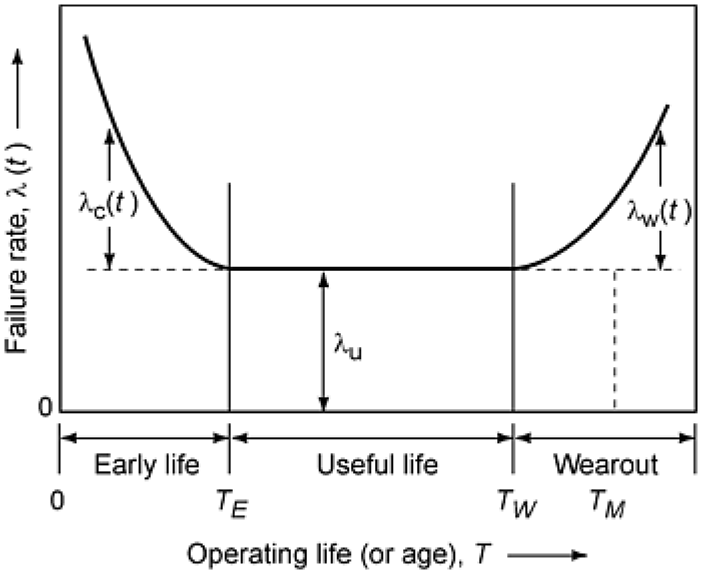

Fig. 2 Mortality curve: failure rate versus age (schematic). Source: Ref 1

When the substandard components have all failed at age T_E, the failure rate stabilizes at an essentially constant rate. This is known as useful life because the components can be used to greatest advantage. Failures during useful life are known as random, chance, or catastrophic because they occur randomly and unpredictably.

When components reach age T_W, the failure rate again increases. Failures begin to occur from degradation due to aging or wear as the components are approaching their rated life.

Early life can be made as short as desired (even eliminated) by proper design, fabrication and assembly, and/or deliberate burn-in periods. For systems that must operate satisfactorily over extended periods, incidence of wear-out can be postponed almost indefinitely by replacing units as they fail during useful life and replacing each unit (even if it has not failed or given any indication of imminent failure) no later than at the end of useful life.

Reliability in Design

Charles O. Smith, Engineering Consultant

Mean Time to Failure

The mean time to failure (MTTF), specifically the mean time to *first* failure, is:

$$\mathrm{MTTF} = \int_0^\infty R(t)dt = \int_0^\infty \left\{ \exp\left[-\int_0^t \lambda(\tau)d\tau \right] \right\} dt \qquad \textbf{(Eq 10)}$$

For the special case of useful life with constant failure rate:

$$\text{MTTF} = \int_0^\infty e^{-\lambda t}\,dt = \frac{1}{\lambda} \qquad \textbf{(Eq 10a)}$$

Strictly speaking, mean time to failure should be used in the case of simple components that are not repaired when they fail but are replaced by good components.

Mean Time between Failures

As indicated MTTF is the mean time to first failure. Mean time between failures (MTBF) is the mean time between two successive component failures. These generally will not be failures of identical components. The relationship between MTBF and MTTF of the individual components is:

$$\frac{1}{\text{MTBF}} = \sum_{j=1}^{m} \frac{1}{(\text{MTTF})_j} \qquad \textbf{(Eq 11)}$$

where the system has *m* components, all of different ages, each of which is immediately replaced on failure, and MTTF_j is the MTTF of the *j*th component.

Obviously MTBF is a function of time. When a system is first operated with all new components, the MTTF and the MTBF are identical. After that, the MTBF will fluctuate until, after many failures and replacements, it stabilizes at the value given by Eq 11. For the special case of useful life, both MTTF and MTBF have the same formula given by Eq 10a. The mathematical equality contributes to confusion between the two despite the clear difference in meaning.

Reliability in Design

Charles O. Smith, Engineering Consultant

Useful Life

The useful life period is one in which there is constant failure rate (Fig. 2). Equation 6a applies, thus:

$$R(t) = \exp\left(-\int_0^t \lambda\,dt\right) = e^{-\lambda t} \qquad \textbf{(Eq 12)}$$

Within useful life, the reliability of a device is the same for all operating periods of the same length; that is, the device is always as "good as new" since the failure rate is constant. In other words, the probability of having a random failure is the same for periods of equal length throughout the entire useful life as failure rate is not affected by time or aging.

The useful life MTBF is often much, much greater than the mean wear-out life T_M. If the failure rate is very small, the MTBF can be many thousands of hours. If a device, however, has an MTBF of 10^6 h, it does not mean the device can be used for 10^6 h. For an operating time equal to the MTBF, there is only about a 37% chance of failureless operation, that is, a reliability of 37%. For MTBF/10, the reliability is about 90%, while it is about 95% for MTBF/20 and about 99% for MTBF/100.

Example 1: Estimating Failure and Reliability for a Device.

If a device has a failure rate of 0.5×10^{-5} failures/h = 5×10^{-6} failures/h = 0.5%/1000 h, what is its reliability for an operating period of 100 h? If there are 10,000 items in the test, how many failures are expected in 100 h?

$$R(t) = R(100) = e^{-0.5\times 10^{-5}\times 10^{2}} = e^{-0.0005}$$
$$R(100) \cong 1 - 0.0005 = 0.9995$$
$$N_s = N_0\, R(t) = 10{,}000 \times 0.9995 = 9995$$
$$N_f = N_0 - N_s = 5 \text{ failures expected}$$

MTTF and MTBF are equal to each other and to $1/\lambda$. For the above device, MTBF is 200,000 h. What is the reliability for an operating time equal to the MTBF? For operating time t = MTBF:

$$R(t) = e^{-t/t} = e^{-1} = 0.3679$$

If the useful life is 100,000 h, what is the reliability for operating over its useful life?

$$R(t) = e^{-0.5\times 10^{-5}\times 10^{5}} = e^{-0.5} = 0.6065$$

What is the probability for its surviving the first 100 h? If the device has survived for 99,900 h, what is the probability for its surviving the next 100 h? In both cases, $R(t) = 0.9995$, which is the reliability for any 100 h operating period during useful life.

Reliability in Design

Charles O. Smith, Engineering Consultant

Series and Parallel Systems

Many systems consist of various components that can be considered to be in series, in parallel, or in combinations of series and parallel. In a series system, all components are so interrelated that the entire system will fail if any one component fails. A parallel system will fail only if all components fail.

Figure 3 shows a schematic series system. Assuming the n components are independent and the system will function for time t if, and only if, each of the components functions to time t, then the system reliability is:

$$R_{SS}(t) = R_1(t)R_2(t) \ldots R_n(t) = \prod_{i=1}^{n} R_i(t) \qquad \textbf{(Eq 13)}$$

For useful life with all failure rates constant, the effective failure rate of a system of nonredundant components (not necessarily identical) is equal to the sum of the failure rates of the individual components. The system MTBF can be found by taking the reciprocal of this sum.

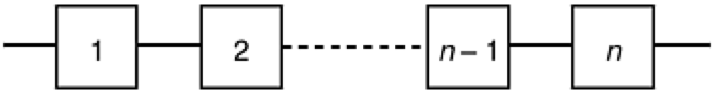

Fig. 3 Schematic system with units in series. Source: Ref 1

A schematic parallel system is shown in Fig. 4. Assuming the *n* components are independent and the system will function for time *t* if any one of the components functions (system fails only if all components fail), then the system reliability is:

$$R_{SP}(t) = 1 - \prod_{i=1}^{n} Q_i(t) = \prod_{i=1}^{n} [1 - R_i(t)] \qquad \textbf{(Eq 14)}$$

The MTBF of a parallel system can be evaluated by using Eq 11. ***Reliability in a parallel system cannot be determined by simple substitution of MTBF in Eq 12.*** In a parallel system, reliability increases as the number of possible paths (or routes) increases. The rate of increase decreases as the number of paths (*n*) increases. The greatest gain in reliability comes when a second path is added to a single path.

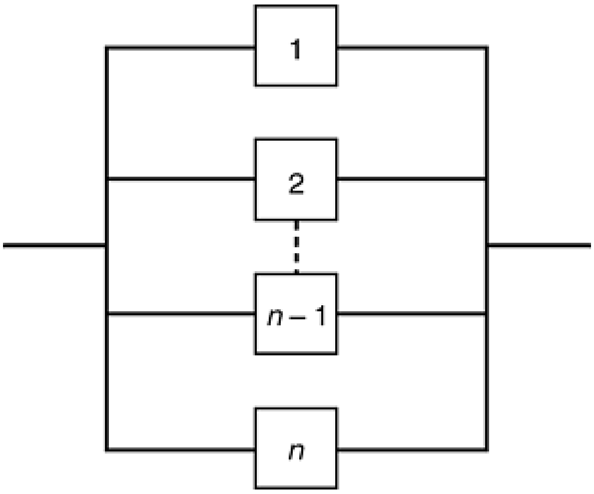

Fig. 4 Schematic system with units in parallel. Source: Ref 1

Complete systems generally consist of several components or units in series. Some of these units may not have sufficient reliability to give the desired system reliability and thus may have parallel units to increase system reliability. This implies use of series-parallel and/or parallel-series arrangements such as shown in Fig. 5. The reliability of a system with *n* series units with *m* parallel elements (reliability of a single element is *p*) in each unit is:

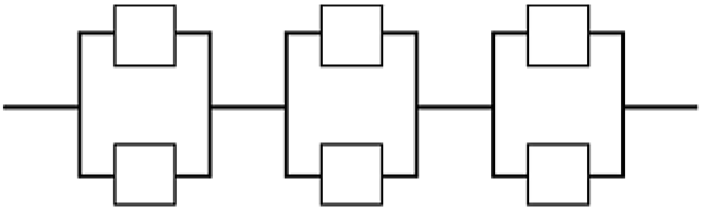
$$\text{series-parallel } R = [1 - (1 - p)^m]^n \qquad \textbf{(Eq 15)}$$

The reliability of a system with *m* parallel paths of *n* elements each (reliability of a single element is *p*) is:

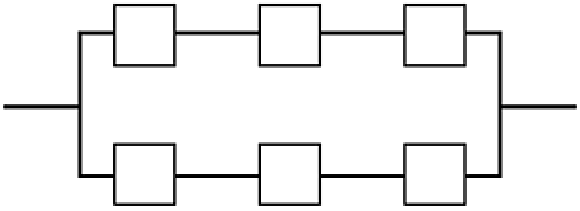
$$\text{parallel-series } R = 1 - (1 - p^n)^m \qquad \textbf{(Eq 16)}$$

Series-parallel arrangements give higher reliability than equivalent parallel-series arrangements. A basic *n*-element system replicated *m* times has m^n possible paths for system success for the series-parallel system; there are only *m* possible paths in the parallel-series system. It follows that the lower the system level at which redundancy is introduced,

the more effective redundancy is in increasing reliability. It is also true that as the unit reliability (*p*) increases, the difference between series-parallel and parallel-series reliabilities decreases.



(a)



(b)

Example 2: Calculating Reliabilities for Series and Parallel Arrangements of a System.

A three-element system, each element having a reliability of 0.90, was considered. Figure 6 shows system reliabilities calculated for four different arrangements of the system.

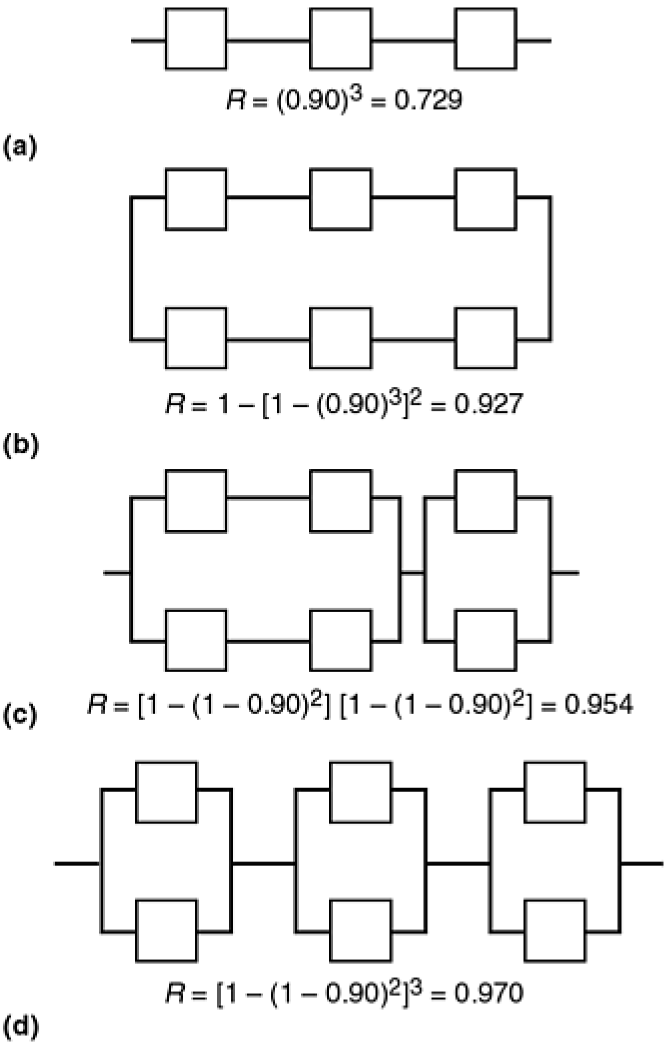

Fig. 6 Reliability calculations for four different arrangements of a three-element system, each element having a reliability of 0.90 (a) Series arrangement. (b) Parallel-series arrangement. (c) Mixed-parallel arrangement. (d) Series-parallel arrangement

Reliability in Design

Charles O. Smith, Engineering Consultant

Logic Diagrams

Use of reliability block diagrams is very helpful when solving reliability problems. A block diagram (or logic diagram) shows the functional relationships among system elements. A schematic physical diagram shows the physical relationships. The logic diagram consists of groups of blocks, signifying system elements, connected together in a manner that traces the system function. In some cases, the two diagrams are identical, but they differ in others.

Example 3: Creating a Logic Diagram for Pipeline Valve Operation.

Figure 7 shows the physical diagram of two valves in a pipeline. Should the logic diagram appear as a series or as a parallel system? The answer depends on the criterion of adequate performance. If the two valves are normally shut but expected to open on command to provide flow, this is a series system. If the two valves are normally open but expected to shut on command to stop flow, this is a parallel system.

Fig. 7 Schematic diagram of a pipeline with two valves in the line. Source: Ref 1

More Complex Parallel Systems

Equation 14 is based on the criterion for system success requiring successful functioning of only one of the n components in the system. In many systems, there will be a requirement for successful functioning of more than one of the n components. Reliability can be calculated using the binomial distribution. This assumes each component functions properly (p) or it fails (q). From this, the probability of an event not occurring k times in n trials (if P is the probability of the event in each trial), or the probability of the event occurring (n - k) times in n trials is:

$$P(\text{exactly } k \text{ failures})\ P_n(k) = C_k^n p^{n-k} (1-p)^k \qquad \textbf{(Eq 17)}$$

where

$$C_k^n = \frac{n!}{k!\,(n-k)!}$$

The probability of k or fewer failures is:

$$P(k \text{ or fewer failures}) = \sum_{k=0}^{k} P_n(k) \qquad \textbf{(Eq 18)}$$

Use of the binomial distribution is limited to samples of known size (n is known) with a count of the number of times a certain event is observed.

If the sample size is indefinite, that is, n is not known, the Poisson distribution can be used. In this case, the probability of exactly k failures occurring in time t is:

$$\frac{e^{-\lambda t} (\lambda t)^k}{k!} \qquad \textbf{(Eq 19)}$$

The probability of k or fewer failures is:

$$\sum_{k=0}^{k} \frac{e^{-\lambda t}(\lambda t)^k}{k!} \quad \textbf{(Eq 20)}$$

The Poisson distribution can be used to determine the probability of a specified number of failures in a given mission or to calculate the number of spares required when units operate in useful life.

The binomial distribution, as noted above, applies only to "go-no-go" cases. This is not adequate when a unit can function in more than two ways, that is, function properly and malfunction in two (or more) ways. Such cases can be handled using the multinomial distribution, which is essentially a generalization of the binomial distribution.

Example 4: Calculating Reliabilities for Different Arrangements of a Complex System.

A diode that can function properly but can malfunction by short circuiting or by open circuiting was considered with these probabilities: p_n is probability of proper operation, p_s is probability of short circuiting, and p_o is probability of open circuiting. (Normally p_n is very close to 1, and p_s and p_o are very small.) The diode was certain to do one of these three; therefore, $p_n + p_s + p_o = 1$.

Four identical diodes were considered for improving the reliability. These were arranged in two possible configurations as shown in Fig. 8. What was the improvement in using a diode quad? (Criterion for system success is flow of a controlled quantity of electrical current.)

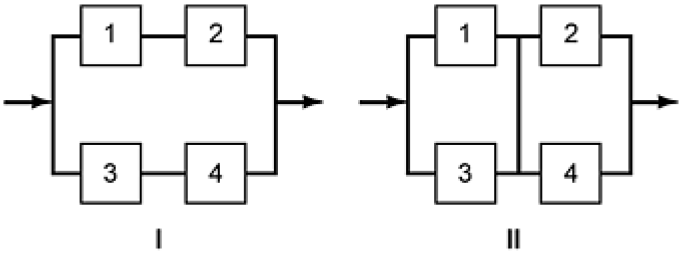

Fig. 8 Diode configurations. See text for discussion.

Applying the multinomial theorem and expanding:

$$(p_n + p_s + p_o)^4 = p_n^4 + 4p_n^3 p_s + 4p_n^3 p_o + 6p_n^2 p_s^2 + 12p_n^2 p_s p_o + 6p_n^2 p_o^2 + 4p_n p_s^3 + 12p_n p_s^2 p_o + 12p_n p_s p_o^2 + 4p_n p_o^3 + p_s^4 + 4p_s^3 p_o + 6p_s^2 p_o^2 + 4p_s^3 p_o + p_o^4 = 1 + 12p_n p_s^2 p_o$$

This expansion automatically gives all possible permutations of the four diodes among the three possible modes of function, independently of configuration. The next question was that of satisfactory function of a configuration, each of which must be considered separately. The expansion was examined term by term considering configuration I:

- p_n^4 is all normal. System is a success.
- $4p_n^3 p_s$ is three normal and one short circuited. System is a success. Any single diode can be short circuited with quad operating properly. All four terms apply.

- $4p_n^3p_o$ is three normal and one open circuited. System is a success. If only one is open circuited, the path containing it is out, but the other path will function properly. All four terms apply.
- $6p_n^2p_s^2$ is two normal and two short circuited. If diodes 1 and 2 or 3 and 4 are short circuited, there is a direct short circuit, and the quad cannot function. If there is one short circuit in each branch (there are four ways of doing this: 1-3, 1-4, 2-3, and 2-4), then the quad can function. Therefore, four terms are successes, and two terms are failures.

Each remaining term of the expansion was examined, and the following table was developed for configuration I.

Success	Failure
p_n^4	
$4p_n^3p_s$	
$4p_n^3p_o$	
$4p_n^2p_s^2$ **2**	$2p_n^2p_s^2$
$12p_n^2p_sp_o$	
$2p_n^2p_o^2$	$4p_n^2p_o^2$
	$4p_np_s^3$
$8p_np_s^2p_o$	$4p_np_s^2p_o$
$4p_np_sp_o^2$	$8p_np_sp_o^2$
	$4p_np_o^3$
	p_s^4
	$4p_s^3p_o$

	$6p_s^2 p_o^2$
	$4p_s p_o^3$
	p_o^4

R = system reliability = probability of quad success
Q = system unreliability = probability of quad failure

$$R = p_n^4 + 4p_n^3 p_s + 4p_n^3 p_o + 12p_n^2 p_s p_o + 4p_n^2 p_s^2 + 2p_n^2 p_o^2 + 8p_n p_s^2 p_o + 4p_n p_s p_o^2$$

$$Q = 2p_n^2 p_s^2 + 4p_n^2 p_o^2 + 4p_n p_s^3 + 4p_n p_s^2 p_o + 8p_n p_s p_o^2 + 4p_n p_o^3 + p_s^4 + 4p_s^3 p_o + 6p_s^2 p_o^2 + 4p_s p_o^3 + p_o^4$$

Eliminating p_n by substitution, that is, $p_n = (1 - p_s - p_o)$ and collecting terms:

$$Q = 2p_s^2 + 4p_o^2 - 4p_o^3 + p_o^4 - p_s^4$$

If p_s and p_o are small, the last three terms can be neglected. Then:

$$Q \cong 2p_s^2 + 4p_o^2$$

The improvement factor is:

$$G_I \equiv \frac{Q \text{ for single}}{Q \text{ for quad}} = \frac{p_s + p_o}{2p_s^2 + 4p_o^2}$$

If $p_s = p_o = 0.01$, then $G_I = 33.33$.

In the above example, quad I was analyzed. What are the reliability and improvement factors if quad II is used? Under what conditions, if any, is quad I preferable? Under what conditions, if any, is quad II preferable?

An analysis for quad II (similar to that for quad I) gives:

$$R = p_n^4 + 4p_n^3 p_s + 4p_n^3 p_o + 2p_n^2 p_s^2 + 12p_n^2 p_s p_o + 4p_n^2 p_o^2 + 4p_n p_o p_s^2 + 8p_n p_s p_o^2$$

$$Q \cong 4p_s^2 + 2p_o^2$$

The improvement factor is:

$$G_{II} = \frac{p_s + p_o}{4p_s^2 + 2p_o^2}$$

if $p_s = p_o$, then there is no difference. If $p_s > p_o$, quad I is preferred. If $p_o > p_s$, quad II is preferred.

Standby Systems

All the previous discussions assumed that the reliabilities of components in a system were independent. This is not always true. For example, if four generators are required to provide the required output, but five are operating in parallel, none will be working at full capacity. Thus they will have a lower failure rate than if operating at full capacity. Reliabilities of individual units in a parallel system, therefore, are generally not independent. When requirements for high reliability make redundancy necessary, a good arrangement has one unit operating until it fails. At that time, a second unit, which has been idly standing by, is switched into the system, commonly by a sensing and switching subsystem.

For a two-unit standby system, the reliability is the probability that unit 1 succeeds for the entire period (t) or that unit 1 fails at some time t_1 prior to t ***and*** the sensing and switching unit does not fail by t_1 and standby unit 2 does not fail by t_1 ***and*** successfully functions for the rest of time t. Assuming 100% reliability of the sensing and switching system and unit 2 while idling, the reliability can be written as:

$$R_{SB}(t) = R_1(t) + Q_1(t_1)R_2(t - t_1) \qquad \textbf{(Eq 21)}$$

where $t_1 < t$. This is shown graphically in Fig. 9. For more complex systems, the above process is expanded, making sure all terms are included.

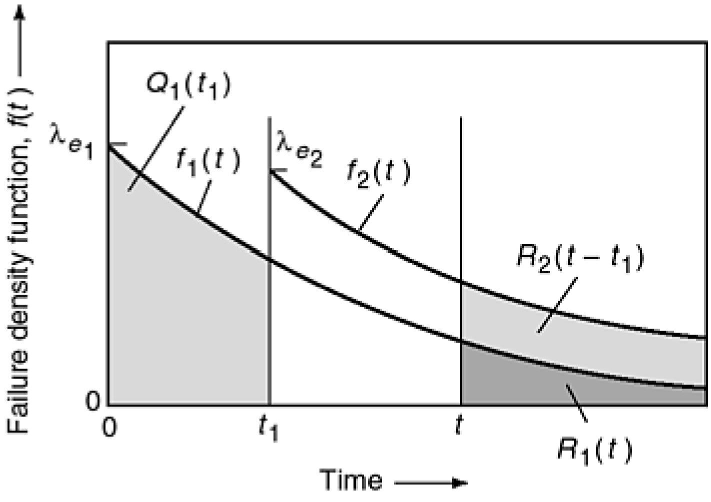

Fig. 9 Graphical representation of terms in Eq 21 in useful life. Source: Ref 1

Example 5: Effect of Standby Arrangements on Reliability.

The reliabilities of the four simple systems shown in Fig. 10 were considered. The operating period in each case is 200 h, and the unit failure rate is 2.5×10^{-4} failures/h:

$$\lambda t = (2.5 \times 10^{-4})(200) = 0.050$$
$$\text{Individual unit reliability} = e^{-0.050}$$
$$R = 0.95123$$

For the system shown in Fig. 10(a):

$$R_{sys} = (e^{-\lambda t})^2 = 0.90484$$

For the system shown in Fig. 10(b):

$$R_{sys} = 1 - (1 - e^{-\lambda t})^2 = 0.99762$$

For the system shown in Fig. 10(c), the reliability of the sensing switch unit is assumed to be 100%:

$$R_{sys} = e^{-\lambda t} + (\lambda t)e^{-\lambda t} = 0.99879$$

For the system shown in Fig. 10(d), the sensing element failure rate is $\lambda_{se} = 3 \times 10^{-5}$ failures/h, and the switch failure rate is $\lambda_{sw} = 10^{-5}$ failures/cycle:

$$R_{sys} = e^{-\lambda_1 t} + \frac{\lambda_1 e^{-(\lambda_{sw})(1)} e^{-\lambda_2 t}}{\lambda_1 + \lambda_{se} - \lambda_2}[1 - e^{-(\lambda_1 + \lambda_{se} - \lambda_2)t}] = 0.99879$$

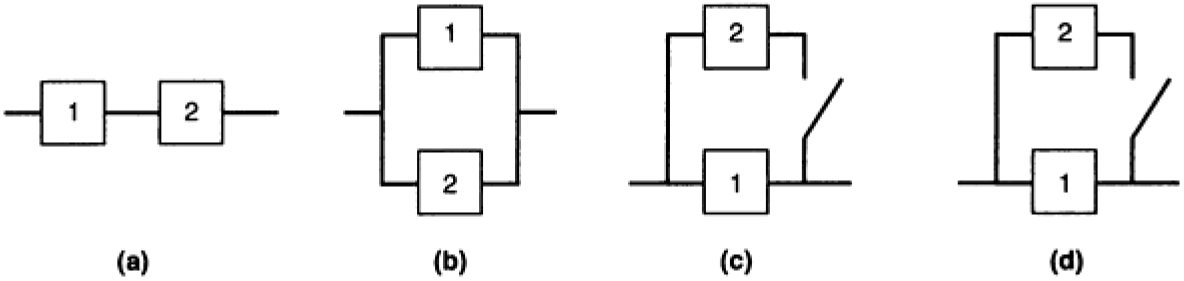

Fig. 10 System configurations for Example 5. See text for discussion.

If operating time is increased from 200 h, all the calculated reliabilities will decrease.

The calculated reliability of each of the two standby arrangements is slightly better than the arrangement with two units in parallel. This is often the situation when comparing standby arrangements with parallel arrangements. The actuality, however, could be somewhat different. In the parallel arrangement, the two units operate at partial load while the operating unit in either standby arrangement operates at full load.

Also, both standby arrangements have the same calculated reliability. If the failure rates of the sensing and switching units were greater, there would be a difference in the reliability. In general, inclusion of failure rates for sensing and switching is more realistic.

Calculation of reliabilities to five significant figures is questionable when the given data have no more than two significant figures. The use of the greater number of significant figures is for comparison purposes.

Conditional Probability

Many system configurations cannot be reduced to simple series, parallel, standby models, or obvious mixtures of these. In this situation, reliability can be calculated using conditional probabilities. Use of Bayes' theorem requires identification of a keynote component, that is, a component that enhances reliability by its addition but still lets the system operate if it fails. Bayes' theorem then says: The probability of system function is the probability that the system functions given the keynote component is good, multiplied by the probability the keynote component is good *plus* the probability the system functions if the keynote component is bad, multiplied by the probability that the keynote component is bad. In this context, Bayes' theorem can be very helpful (Ref 1, 2, 3).

A combination of Smith (Ref 1) and O'Connor (Ref 4, 5, or 6) provides an excellent starting point for anyone who needs a good comprehensive introduction to reliability. Neither book alone is really adequate.

Reliability in Design

Charles O. Smith, Engineering Consultant

Probabilistic versus Deterministic Design

There has been recognition over the years (however implicit) that demands and capacities do have variations. The statistical nature of design parameters has generally been ignored as shown by efforts to find unique representative values such as minimum guaranteed values, limit loads, etc. The usual approach is to use a safety factor or a worse-case approach. The results have not necessarily been bad. In fact, the most common result has been overdesign, that is, conservative design. It is impossible, however, to determine readily, or even estimate, how conservative the design may be. Nor can marginal or underdesigned situations be identified.

A different approach is to recognize the variations of demand and capacity as indicated schematically in Fig. 11. For this situation, there is a safety factor, based on the mean values. Failure probability is indicated by the extent of overlap of the demand and capability distributions. Using the small standard deviations (A) in Fig. 11, there is very little overlap and thus a very small probability of failure. Using the large standard deviations (C) in Fig. 11, there is much overlap and thus a rather large probability of failure, that is, when a component with low capacity is subjected to a large demand.

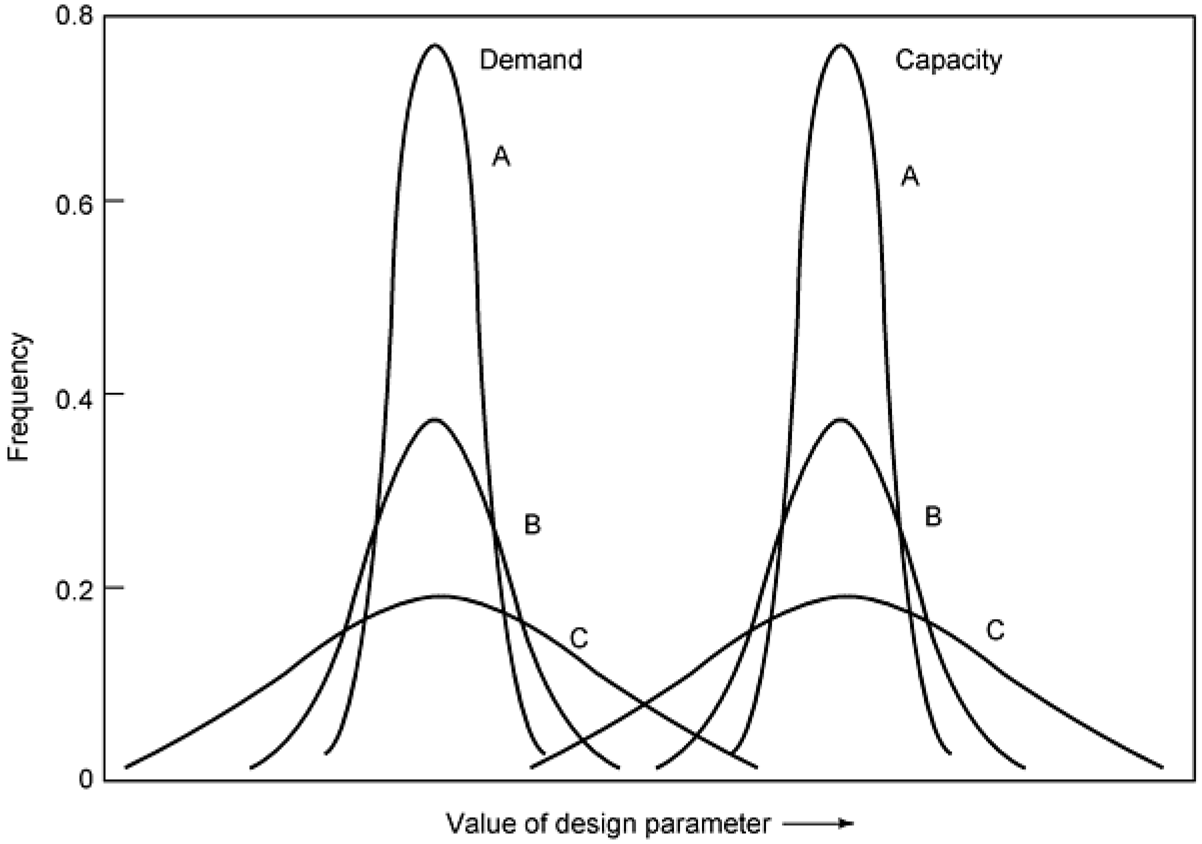

Fig. 11 Schematic distribution of demand (all with same mean values) and capacity (all with same mean values) for three situations: A, small standard deviations; B, moderate standard deviations; and C, large standard deviations. Source: Ref 7

Example 6: Probabilistic and Deterministic Design Calculations for a Simple Thin-Wall Cylinder under Internal Pressure (Ref 7).

Some data and results for the cylinder are given in Table 1. The safety factor in this example is determined as the ratio of mean yield stress to mean tangential stress. The minimum safety factor is determined as the ratio of minimum yield stress (mean minus 3 standard deviations) to maximum demand (mean plus 3 standard deviations). Cases 1 and 2, using one material but with different standard deviations in applied pressure, have the same safety factor. Case 1 predicts 7 failures in 10^4 while case 2 predicts 18 in 10^4. Cases 3 and 4, with a different material, have the same safety factor. Case 3 predicts less than 3 failures in 10^7 while case 4 predicts 13 in 10^7.

Table 1 Deterministic versus probabilistic calculations for a thin-wall cylinder under internal pressure

See Example 6 in text for discussion.

Case No.	Pressure, MPa	Standard deviation pressure, MPa	Mean yield stress, MPa	Standard deviation yield stress, MPa	Safety factor	Minimum safety factor	Reliability	Predicted No. of failures
1	16.0	0.80	310.0	33.0	1.61	1.85	0.999298	$7/10^4$
2	16.0	1.60	310.0	33.0	1.61	2.01	0.998204	$18/10^4$
3	16.0	0.80	340.0	21.0	1.77	1.54	>0.9999997	$<3/10^7$

4	16.0	1.60	340.0	21.0	1.77	1.68	0.9999987	$13/10^7$

Source: Ref 7

Cases 3 and 4 have a material with a greater mean strength than cases 1 and 2. (These materials values are from actual materials.) The nominal safety factor is increased about 10%. The stronger material, however, has a smaller standard deviation, which results in predictions of far fewer failures, actually by a factor of 1000. This prediction is not remotely indicated by the 10% increase in safety factor.

In cases 1 and 2, the nominal safety factor is less than the minimum safety factor (approximately worst-case treatment). In cases 3 and 4, the nominal safety factor is greater than the minimum safety factor. By inference, comparatively more failures should be expected in cases 1 and 2 than in cases 3 and 4. The probabilistic calculations, however, predict how many failures should be expected in each case. A minimum safety factor cannot be determined without knowledge of ranges of design parameters. If the standard deviations are known, a quantitative prediction can be made of the number of failures instead of relying on an extremely crude prediction from safety factors.

Failure probabilities of 10^{-5}, 10^{-6}, and 10^{-7} may have no real meaning because they are far out of the range that can be verified by experiment or field practice unless one is working with a large number of items. While the lack of verification is real (for small numbers of large items), the probabilistic approach at least provides a scale against which safety of different designs can be compared on a rational basis. Using a safety factor provides no such scale.

Choosing between Probabilistic and Deterministic Approaches. Whether using a probabilistic or deterministic approach, the designer must make a design decision. The deterministic approach can be used with a decision made on the safety factor selected. The probabilistic approach can be used with a decision made on selecting an acceptable number of failures. The latter approach seems more rational.

There is much in the literature regarding the relative merits of probabilistic versus deterministic design. Some representative papers include Smith (Ref 8, 9, 10, 11, 12) and Mischke (Ref 13, 14). O'Connor (Ref 5, 6) has a chapter on load-strength interference. In making calculations, common stress (and/or strain) deterministic relationships can be converted to probabilistic relationships by using the "algebra of normal distribution functions" as given in Haugen (Ref 15).

Distributions

There are at least 20 different probability distributions, several of which are very useful in reliability theory and application. Useful life, noted above, uses the (negative) exponential distribution, which has a single parameter. Also as noted above, the binomial and Poisson distributions are very useful in certain situations. The Poisson distribution has a single parameter while the binomial distribution has two parameters.

The Weibull distribution was developed in the late 1940s. It applies to a large number of diverse situations and has found extensive use in general engineering practice. There are three parameters, which are usually determined experimentally from data obtained during testing. All three parameters have physical significance: (a) a lower bound of the variable in question; (b) a characteristic value, related to the median, thus an indicator of central tendency, and (c) Weibull slope, a direct function of the uniformity of the item; the larger the slope, the greater the uniformity. When the Weibull slope is 1, this is a special case, becoming the (negative) exponential distribution. When the Weibull slope is about 3.5, the Weibull distribution is a good approximation to the normal distribution. The Weibull distribution is very good for use with material and mechanical failures and with wear-out (Fig. 2).

Additional information relative to distributions can be found in the section "Statistical Distributions Applied to Design" in the article "Statistical Aspects of Design" in this Volume.

Reliability in Design

Charles O. Smith, Engineering Consultant

Reliability Testing

Reliability tests measure or demonstrate the ability of equipment to operate satisfactorily for a prescribed time period under specified operating conditions. Assuming a system with ten components in series, which must operate for 1000 h with a reliability of 0.99, then the characteristic life of a component must be about 10^6 h, or about 115 years. To obtain a state of knowledge to determine this requires *more* than 115 years of *failure-free* testing (115 components for 1 year or 1150 components for 6 weeks) for each of 10 components. If the number of parts is several hundred and the desired reliability is 0.999 (not at all uncommon), it is obvious the required number of tests becomes absurdly impossible. Yet, such products are designed, built, and meet guaranteed performance.

Although maximum use is made of past performance data and engineering judgment, it is essential for the designer to know as soon as possible if a design objective for reliability and/or life will be met. To meet a production schedule, it is rarely realistic to test under normal operating conditions. Thus accelerated testing is desired. Three factors control the degree of acceleration: environment, sample size, and testing time. Environment includes any operating condition to which the part is subjected and that may affect its performance and/or durability. Two broad categories of testing are implied: (a) tests to determine which aspects of the environment are truly significant and (b) tests to determine performance as quickly as possible.

Tests for Environmental Factors. Univariate testing (one parameter at a time) is not always useful because there is no indication of any effect of interaction between two or more factors.

Factorial experiments can be used to estimate the main (direct) effect of each "stress," interactions between two (or more) stresses, and experimental error (Ref 16, 17, 18, 19, 20). Related information is contained in the articles "Statistical Aspects of Design" and "Robust Design" in this Volume.

To run a complete factorial experiment, especially if one wishes to replicate it, may require a very large number of individual tests or runs. Fortunately, in such a situation, most of the desired information can be obtained by performing only a fraction of the full factorial. In one unusual (and outstanding) situation with 19 variables, a complete full factorial study would have required more than 500,000 samples. A judiciously selected fractional factorial design provided the desired information from a study of only 20 samples (Ref 16, 17, 18, 19, 20, 21).

Response surface methodology (RSM) consists of a group of techniques (based on experimental effort as indicated above) for empirical study of relationships between one response (or more responses) and a number of input variables (Ref 16, 22, 23, 24). The technique uses a method of steepest ascent to get close to a maximum and then approximates the surface in the vicinity of the maximum with a fitted second-degree equation.

Evolutionary operation (EVOP) is a mode of using a full-scale process so that information on how to improve the process is generated from a simple experiment while the process continues (Ref 16, 25, 26). Evolutionary operation has less applicability in determining effects of environment in reliability than other types of statistical testing, but in some situations it can be of major importance.

Accelerated testing, which is reducing the time required for testing, can be accomplished by: (a) taking a large sample and testing only part of the sample to failure; (b) magnifying the stress; or (c) sudden-death testing. Alternatives (a) and (c) are especially useful in testing a large number of relatively inexpensive components. Sequential testing is more useful when there are only a few relatively expensive units.

If a number of identical units are tested simultaneously, failure will occur in an ordered sequence with the weakest failing first, etc. Such ordering is unique with life testing (Ref 27). The choice of a test involving failure of r units out of n ($n > r$) rather than the choice of a test involving failure of r out of r units will, in general, permit determination of an estimate of characteristic life in a relatively shorter time. For example, if 20 units have to be operated for 200 h to induce all 20 failures, then on the average, only 46 h are needed to observe the first 10 failures in a sample of 20.

Use of magnified loading does reduce testing time and possibly the number of items required for the test. Correlation is a major problem because "normal" must be defined and enough overload data must exist to correlate with normal. Rabinowicz et al. (Ref 28) suggested a technique based on cumulative damage. Test procedure is to run a series of tests to failure at a high stress (S_1) and a second set of tests partly at S_1 and partly at a lower stress (S_2). These two points are plotted with time at S_1 as the ordinate and time at S_2 as the abscissa. A straight line extrapolation between the two points gives the life expected at S_2, which presumably would be the normal operating stress. Caution should be exercised as this is similar to the Palmgren-Miner rule in fatigue failures, which is recognized as a crude approximation in many cases.

Abu Haraz and Ermer (Ref 29) used the cumulative damage theory with some success. They also were successful in using the Arrhenius equation in accelerated testing in a case where the physical law leading to failure was known.

An excellent example of acceleration in fatigue testing was developed by Conover et al. (Ref 30). Intensified loading of programmed fatigue tests developed from field data was used to reduce time to failure in steels for automotive components by a factor of 10. These results were applicable for unnotched specimens, notched specimens, and automotive components.

Sudden-death testing (Ref 1, 17) is especially useful with a large number of relatively inexpensive units. For example, if 50 specimens are available for testing, these could be randomly divided into ten sets of five each. All five are tested simultaneously until one item in the set fails. The rest of the set is removed from the test. Testing in this manner continues until all ten sets have been tested. Then there are 10 numbers, each of which represents the least value in a set of five. These also represent separate estimates of the life of the weakest 12.94% of the population. A Weibull plot gives a straight line describing the distribution of the 12.94% life. The median 50% life point is located, allowing the 12.94% life point to be found on the population line. The population line is drawn through this second point parallel to the first line. (The slopes of the sudden death and population lines are assumed to be identical.) Characteristic life of the population is

associated with the 63.2% point on the population line. The use of 50 specimens divided into 10 sets of 5 each is arbitrary for discussion. Any number of specimens can be used divided in whatever manner is desired.

Sequential testing (Ref 1, 17) is especially useful for tests of a small number of relatively expensive units. Specimens are tested in sequence with the test result reviewed after each test is completed. The decision is then made to accept, reject, or continue sampling. This decision is based on predetermined criteria. The sample size is established only after an "accept" or "reject" decision has been made, although an average sample size can be computed once the criteria have been established.

Reliability in Design

Charles O. Smith, Engineering Consultant

Human Reliability

Human reliability is defined as the probability that a task will be successfully completed by personnel at any required stage in system operation within a required minimum time (if, indeed, a time requirement exists). Successful performance, however, is not errorless performance. It is performance without errors that have a significant effect on

correct completion of the task. Related information can be found in the article "Human Factors in Design" in this Volume. Still further information can be found in Ref 31, 32, 33, and 34.

Availability and Maintainability

The focus of this article is reliability. Other aspects ultimately relate to reliability and operation of reliable systems but cannot be included in this article. These include availability and maintainability.

Availability. Dovich (Ref 2) defines this as a measure of the degree to which an item is in the operable and committable state at the start of the mission when the mission is called for at an unknown (random) time. O'Connor (Ref 6) defines this as the probability that an item will be available when required *or* the proportion of total time that the item is available for use. Total time includes operating time, active repair time, logistic time, and administrative time.

Maintainability. Dovich (Ref 2) defines this as a measure of the ability of an item to be retained in, or restored to, specified condition when maintenance is performed by personnel having specified skill levels, using prescribed procedures and resources, at each prescribed level of maintenance and repair. This also could be stated as a probability.

Reliability Growth

It is common for new products to be less reliable during the early stages of development than later when improvements have been made as a result of testing and/or failures observed and corrected. In addition, items in service often show reliability growth. It is appropriate for designers to track and/or encourage this growth. This was first analyzed by Duane (Ref 35), who observed an improvement of MTBF of a range of items used on aircraft. Duane found that the cumulative MTBF (θ_c), which is total time divided by total failures, gave a straight line when plotted against total time on log-log paper. The slope (α) gave an indication of reliability growth:

$$\log \theta_c = \log \theta_o + \alpha(\log T - \log T_o)$$

where θ_o is the cumulative MTBF at the start of the monitoring period T_o. Therefore:

$$\theta_c = \theta_o \left(\frac{T}{T_o}\right)^{\alpha} \quad \textbf{(Eq 22)}$$

The slope α gives an indication of the rate of MTBF growth and thus of the effectiveness of the reliability program in correcting failure modes. Duane (Ref 35) observed that α typically ranges between 0.2 and 0.4 and correlates with the intensity of effort on improvement with higher numbers indicating greater intensity. O'Connor (Ref 6) provides a good discussion with an example. Spradlin (Ref 36) provides an excellent example of using the Duane method to improve reliability. Other examples are provided in Ref 37, 38, 39, 40, 41, 42, 43, 44, and 45.

Conclusions

Determining the reliability of a complex system can be difficult. In principle, proceeding methodically by starting with the simplest units, combining them into subsystems, and then combining the subsystems into the complete system, and

determining reliability at each step will lead to the final system reliability. A most important aspect is establishing the criterion of adequate performance of the system. Although difficult, reliability of a system can be established; it is done regularly.

Life-Cycle Engineering and Design

ASM International Materials Life-Cycle Analysis Committee*

Introduction

ENVIRONMENTAL CONSIDERATIONS play an increasingly important role in design and development efforts of many industries. "Cradle to grave" assessments are being used not only by product designers and manufacturers, but also by product users (and environmentalists) to consider the relative merits of various available products and to improve the environmental acceptability of products.

Life-cycle engineering is a part-, system-, or process-related tool for the investigation of environmental parameters based on technical and economic measures. This article focuses on life-cycle engineering as a method for evaluating impacts, but it should be noted that similar techniques can be used to analyze the life-cycle costs of products (see the article "Techno-Economic Issues in Materials Selection" in this Volume).

Products and services cause different environmental problems during the different stages of their life cycle. Improving the environmental performance of products may require that industry implement engineering, process, and material changes. However a positive change in one environmental aspect of a product (such as recyclability) can influence other aspects negatively (such as energy usage). Therefore a methodology is required to assess trade-offs incurred in making changes. This method is called life-cycle analysis or assessment (LCA).

Life-cycle analysis aims at identifying improvement possibilities of the environmental behavior of systems under consideration by designers and manufacturers. The whole life cycle of a system has to be considered. Therefore it is necessary to systematically collect and interpret material and energy flows for all relevant main and auxiliary processes (Fig. 1).

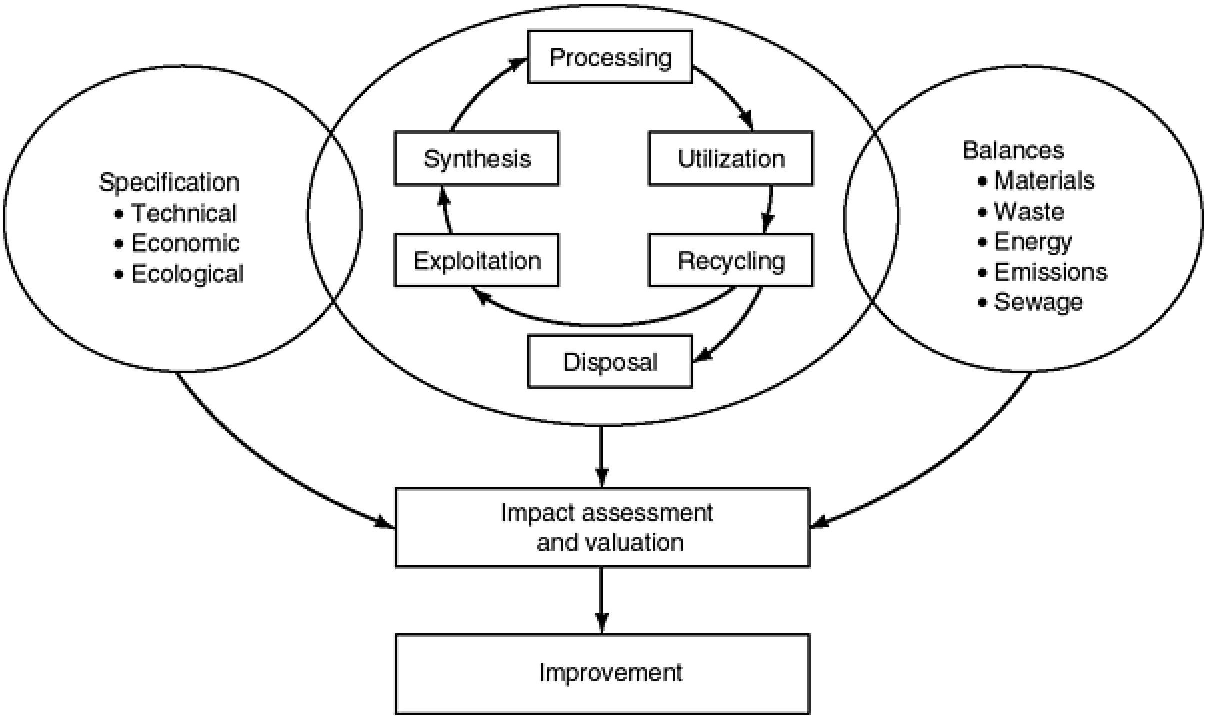

Fig. 1 Factors considered in the life-cycle engineering approach. Source: Ref 1

Life-cycle analysis methods have been developed by governmental, industrial, academic, and environmental professionals in both North America and Europe. Technical documents on conducting LCA have been published by the Society of Environmental Toxicology and Chemistry (SETAC), the U.S. Environmental Protection Agency (EPA), the Canadian Standards Association (CSA), the Society for the Promotion of LCA Development (SPOLD), and various practitioners.

For meaningful comparisons of the life-cycle performance of competing and/or evolving product systems, it is important that associated LCAs be conducted consistently, using the same standards. Although the common methodologies developed by SETAC, EPA, CSA, and SPOLD are a step in that direction, a broad-based international standard is needed. Such an effort is being undertaken by ISO 14000 series (TC207).

Life-cycle thinking and techniques can be applied to products, processes or systems in various ways: it can help assess life-cycle economic costs (LCA_{econ}), social costs (LCA_{soc}) or environmental costs (LCA_{env}).

A primary objective of LCA is to provide a total life-cycle "big-picture" view of the interactions of a human activity (manufacturing of a product) with the environment. Other major goals are to provide greater insight into the overall environmental consequences of industrial activities and to provide decision makers with a quantitative assessment of the environmental consequences of an activity. Such an assessment permits the identification of opportunities for environmental improvement.

Life-Cycle Engineering and Design

ASM International Materials Life-Cycle Analysis Committee*

Life-Cycle Analysis Process Steps

Life-cycle analysis is a four-step process; each of these steps is described in detail below. The process starts with a definition of the goal and scope of the project; because LCAs usually require extensive resources and time, this first step limits the study to a manageable and practical scope. In the following steps of the study, the environmental burdens (including both consumed energy and resources, as well as generated wastes) associated with a particular product or process are quantitatively inventoried, the environmental impacts of those burdens are assessed, and opportunities to reduce the impacts are identified.

All aspects of the life cycle of the product are considered, including raw-material extraction from the earth, product manufacture, use, recycling, and disposal. In practice, the four steps of an LCA are usually iterative (Fig. 2).

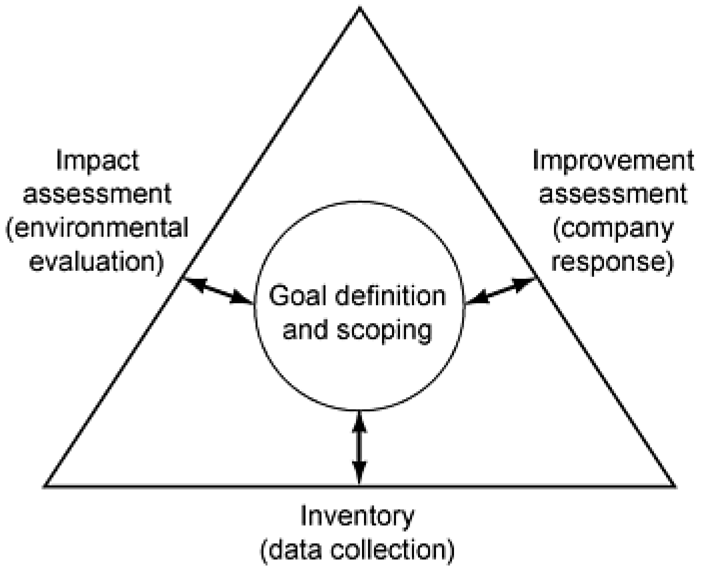

Fig. 2 The life-cycle assessment triangle. Source: Ref 2

Step 1: Goal Definition and Scoping. In the goal definition and scoping stage, the purposes of a study are clearly defined. Subsequently, the scope of the study is developed, which defines the system and its boundaries, the assumptions, and the data requirements needed to satisfy the study purpose. For reasons of economy and brevity, the depth and breadth of the study is adjusted, as required, to address issues regarding the study purpose. Goal definition and project scope may need to be adjusted periodically throughout the course of a study, particularly as the model is refined and data are collected.

Also during this stage, the functional unit is defined. This is an important concept because it defines the performance of a product in measured practical units and acts as a basis for product system analysis and comparison to competing products. For example, the carrying capacity of a grocery bag might be a sensible functional unit.

Finally, the quality of the life-cycle data must be assessed in order to establish their accuracy and reliability. Typically, factors such as data age, content, accuracy, and variation need to be determined. Clearly, data quality affects the level of confidence in decisions that are based on study results.

Step 2: Inventory Analysis. The second stage of LCA is a life-cycle inventory (LCI). It is in this stage that the various inputs and outputs (energy, wastes, resources) are quantified for each phase of the life cycle. As depicted in Fig. 3, systems boundaries are defined in such a way that the various stages of the life cycle of a product can be identified. The separation of burdens (inputs and outputs) for each stage facilitates improvement analysis.

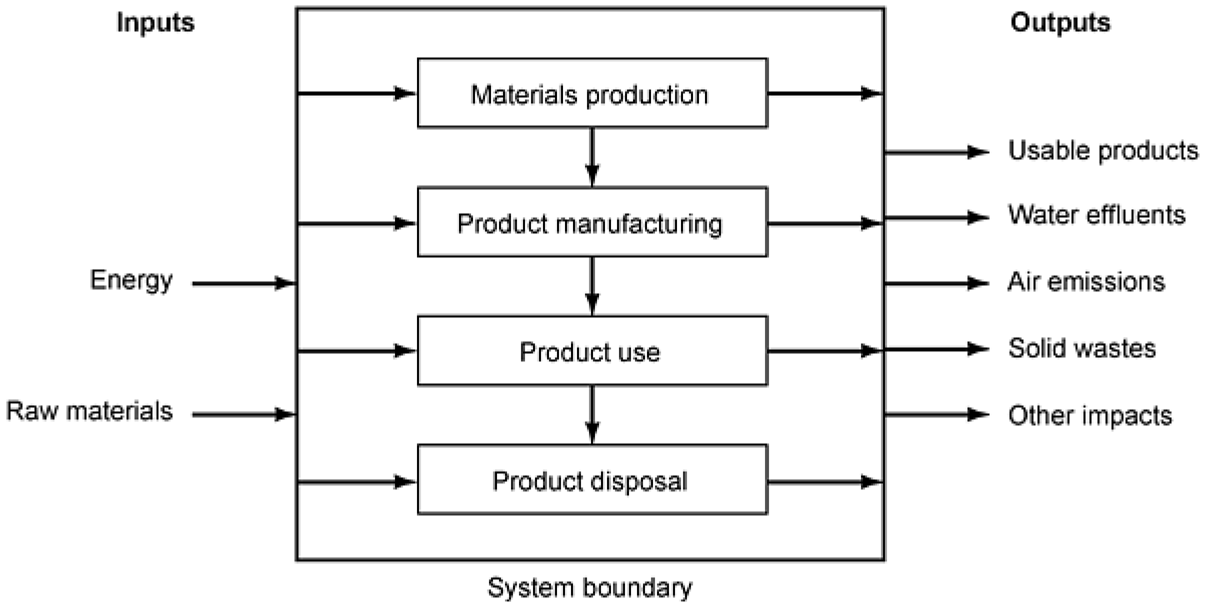

Fig. 3 Generalized system boundaries for a life-cycle inventory of a generic product. Source: Ref 2

For the purposes of LCI, a "product" should be more correctly designated as a "product system." First, the system is represented by a flowchart that includes all required processes: extracting raw materials, forming them into the product, using the resulting product, and disposing of and/or recycling it. The flowchart is particularly helpful in identifying primary and ancillary materials (such as pallets and glues) that are required for the system. Also identified are the sources

of energy, such as coal, oil, gas, or electricity. Feedstock energies, which are defined as carbonaceous materials not used as fuel, are also reported.

After system definition and materials and energy identification, data are collected and model calculations performed. The output of an LCI is typically presented in the form of an inventory table (an example is shown in Table 1), accompanied by statements regarding the effects of data variability, uncertainty, and gaps. Allocation procedures pertaining to co-product generation, recycling, and waste treatment processes are clearly explained.

Table 1 Example of a life-cycle inventory for an unspecified product

	Amount
Inputs	
Energy from fuels, MJ	
Coal	2.75
Oil	3.07
Gas	11.53
Hydro	0.46
Nuclear	1.53
Other	0.14
Total	**19.48**
Energy from feedstocks, MJ	
Coal	<0.01
Oil	32.75
Gas	33.59
Other	<0.01
Total feedstock	**66.35**
Total energy input, MJ	**85.83**

Raw materials, mg	
Iron ore	200
Limestone	150
Water	18×10^6
Bauxite	300
Sodium chloride	7,000
Clay	20
Ferromanganese	<1
Outputs	
Air emissions, mg	
Dust	2,000
Carbon monoxide	800
Carbon dioxide	11×10^5
Sulfur oxides	7,000
Nitrogen oxides	11,000
Hydrogen chloride	60
Hydrogen fluoride	1
Hydrocarbons	21,000
Aldehydes	5
Other organics	5

Metals	1
Hydrogen	1
Solid wastes, mg	
Mineral waste	3,100
Industrial waste	22,000
Slags and ash	7,000
Toxic chemicals	70
Nontoxic chemicals	2,000
Water effluents, mg	
COD	1,000
BOD	150
Acid, as H^+	75
Nitrates	5
Metals	300
Ammonium ions	5
Chloride ions	120
Dissolved organics	20
Suspended solids	400
Oil	100
Hydrocarbons	100

Phenol	1
Dissolved solids	400
Phosphate	5
Other nitrogen	10
Sulfate ions	10

COD, chemical oxygen demand; BOD, bacteriological oxygen demand.

Step 3: Impact Assessment and Interpretation. Impact assessment is a process by which the environmental burdens identified in the inventory stage of an LCA are quantitatively or qualitatively characterized as to their effects on local and global environments. More specifically, the magnitude of the effects on ecological and human health and on resource reserves are determined.

Life-cycle impact assessment is at this time still in an early phase of development. Although some impact assessment methods have been advanced as either complete or partial approaches, none has been agreed upon. Nevertheless, an approach to impact analysis, known as "less is better," is typically practiced. With this approach, process and product changes are sought that reduce most, if not all, generated wastes and emissions and consumed resources. (Additional information is provided in the article "Environmental Aspects of Design" in this Volume.) However, situations in which such reductions are realized are not yet typical. Usually a change in product systems is accompanied by trade-offs between burdens, such as more greenhouse gases for fewer toxins. A fully developed impact analysis methodology would help in the environmental impact assessment of such cases.

As advanced by SETAC, impact analysis comprises three stages: classification, characterization, and valuation.

Classification. In this stage, LCI burdens are placed into the categories of ecological health, human health, and resource depletion. Within each of these categories, the burdens are further partitioned into subcategories, for example, greenhouse gases, acid rain precursors, and toxins of various kinds. Some burdens might fall into several categories, such as sulfur dioxide, which contributes to acid rain, eutrophication, and respiratory-system effects. Environmental burdens are sometimes called "stressors," which are defined as any biological, chemical, or physical entity that causes an impact.

Characterization. In the characterization step of impact assessment, the potential impacts within each subcategory are estimated. Approaches to assessing impacts include relating loadings to environmental standards, modeling exposures and effects of the burdens on a site-specific basis, and developing equivalency factors for burdens within an impact subcategory. For example, all gases within the global-warming category can be equated to carbon dioxide, so that a total aggregate "global-warming potential" can be computed.

Valuation. In the valuation step of impact assessment, impacts are weighted and compared to one another. It should be noted that valuation is a highly subjective process with no scientific basis. Further, attaching weighting factors to various potential impacts for comparison purposes is intrinsically difficult. For example, what is more important: the risk of cancer or the depletion of oil reserves? Who would decide this? Because a consensus on the relative importance of different impacts is anticipated to be contentious, a widely accepted valuation methodology is not expected to be adopted in the foreseeable future, if ever.

It is important to recognize that an LCA impact assessment does not measure actual impacts. Rather, an impact in LCA is generally considered to be "a reasonable anticipation of an effect," or an impact potential. The reason for using impact potentials is that it is typically difficult to measure directly an effect resulting from the burdens of a particular product. For example, are the carbon dioxide emissions of any individual's vehicle specifically causing the world to get warmer? It

is unlikely that this could ever be shown, though it is reasonable to assume that any individual vehicle contributes its share to the possible effect of global warming caused by human-generated carbon dioxide in proportion to the amount of emissions.

Inventory Interpretation. It is argued by some that, due to the difficulties cited above, the notion of impact assessment should be dropped and replaced by *inventory interpretation.* Classification and characterization could still be used, but all suggestion that environmental effects are assessed is avoided. In comparative assessments, "less is better" is the principle in identifying the environmentally preferable alternative.

Step 4: Improvement Analysis. This step involves identifying chances for environmental improvement and preparing recommendations. Life-cycle assessment improvement analysis is an activity of product-focused pollution prevention and resource conservation. Opportunities for improvement arise throughout an LCA study. Improvement analysis is often associated with design for the environment (DFE) or total quality management (TQM) (see the articles "Environmental Aspects of Design" and "Design for Quality" in this Volume). With both of these methodologies, improvement proposals are combined with environmental cost and other performance factors in an appropriate decision framework.

Application of Life-Cycle Analysis Results

The results of an LCA can be used by a company internally, to identify improvements in the environmental performance of a product system; and externally, to communicate with regulators, legislators, and the public regarding the environmental performance of a product. For external communications, a rigorous peer-review process is usually required. Virtually all of the peer-reviewed studies conducted to date represent analyses of simple product systems. However, studies for systems as complicated as automobiles are being conducted.

Whether used qualitatively or quantitatively, LCAs often lead to products with improved environmental performance. In fact, an often-overlooked, important qualitative aspect of LCA is that it engenders a sense of environmental responsibility. Beyond this development within manufacturers, LCA has the potential to become a tool to regulate products, or perhaps even for "eco-labeling." However, such uses are contentious and are expected to remain so.

The bulk of LCA efforts to date have been focused on preparing LCIs, with the impact assessment stage currently seen as the weakest link in the process. Indeed, some companies have even decided to skip this phase of the process altogether, opting to carry out a brief life-cycle review (LCR) before moving straight on to the improvement stage.

Large or small companies and other users will find LCA of value at a number of different levels. Indeed, groups like SETAC and SPOLD now see LCA playing a key role in three main areas:

- *Conceptually,* as a framework for thinking about the options for the design, operation, and improvement of products and systems
- *Methodologically,* as a set of standards and procedures for the assembly of quantitative inventories of environmental releases or burdens--and for assessing their impacts
- *Managerially,* with inventories and--where available--impact assessments serving as a platform on which priorities for improvement can be set

Not surprisingly, perhaps, the bulk of current LCA efforts is devoted to the second of these areas, particularly initiatives such as the 1993 Code of Practice by SETAC (Ref 3). However, the scope of LCA is rapidly spreading to embrace the other two application areas. The "supplier challenges" developed by companies such as Scott Paper, which has incorporated environmental performance standards in its supplier selection process, underscore the very real implications of the managerial phase for suppliers with poor environmental performances. Also, the "integrated substance chain management" approach developed by McKinsey & Company Inc. (Denmark) for VNCI (Association of the Dutch Chemical Industry), covering three chlorine-based products, shows that LCA can produce some fairly pragmatic tools for decision making.

Longer term, the prospects for LCA are exciting. Within a few years, product designers worldwide may be working with "laptop LCAs"--small, powerful systems networked with larger data bases and able to steer users rapidly around the issues related to particular materials, products, or systems. This process would be greatly aided by a widely accepted, commonly understood environmental accounting language.

In the meantime, however, LCA is still quite far from being simple or user-friendly, as is illustrated in the following example.

Example: Life-Cycle Analysis of a Pencil.

Anyone who has had even a brief encounter with an LCA project will have seen flow charts rather similar to the one in Fig. 4, which shows the key life-cycle stages for one of the simplest industrial products, a pencil. Most such diagrams are much more complicated, but, as is evident in the figure, even the humble pencil throws an extraordinarily complex environmental shadow.

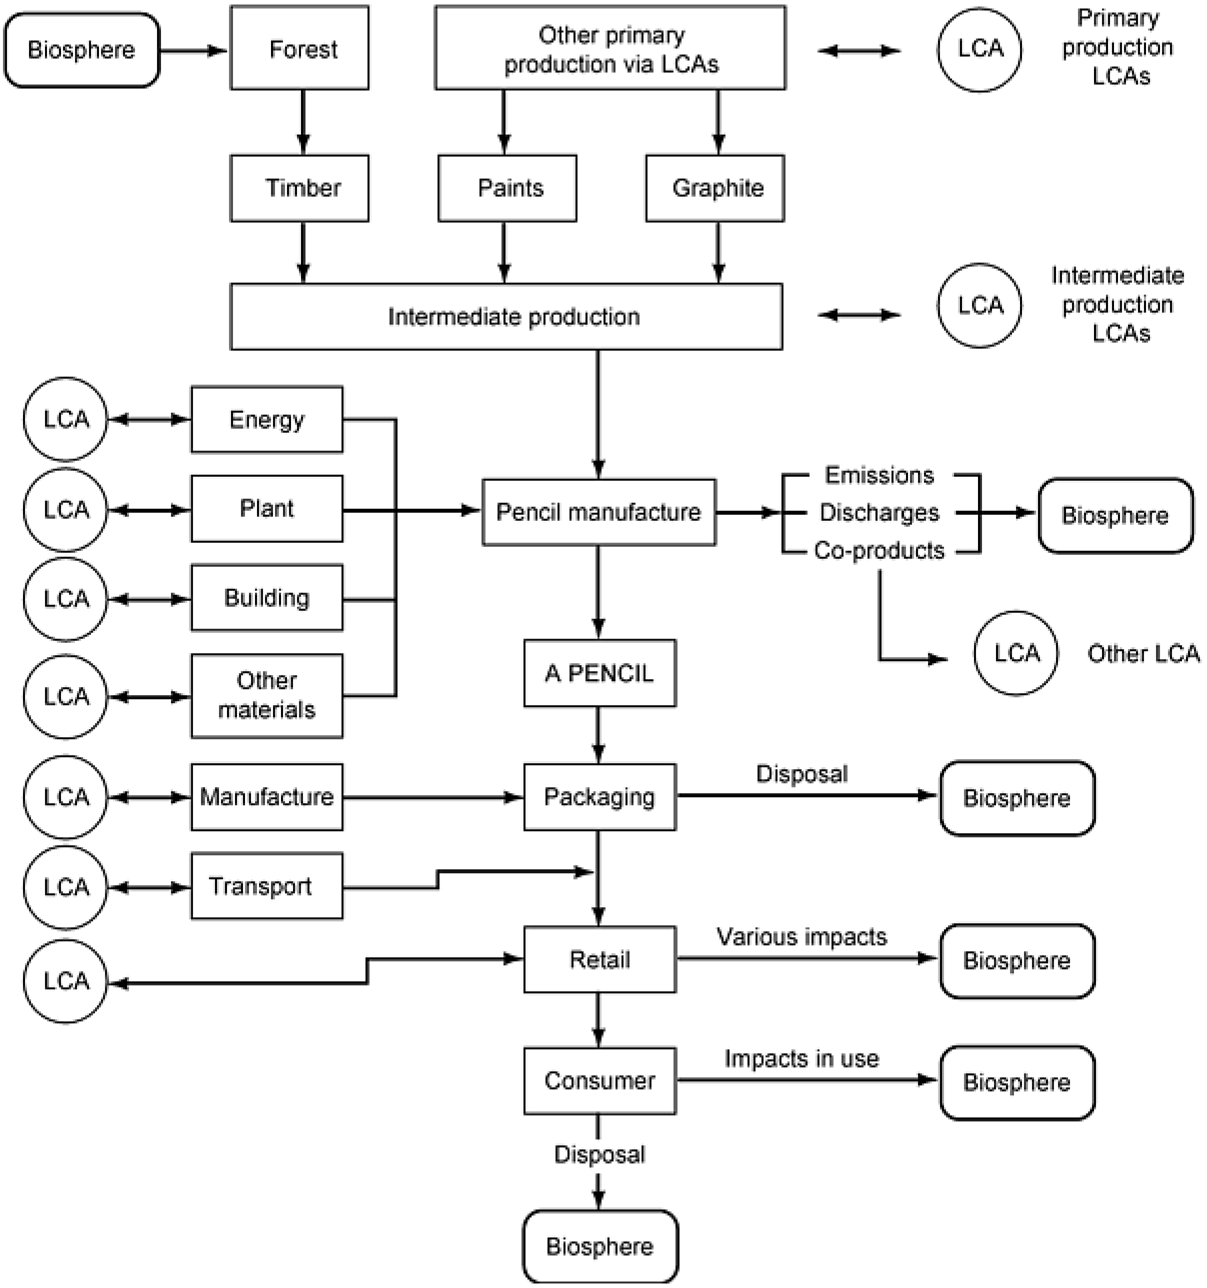

Fig. 4 Simplified life-cycle analysis process for a pencil. Source: Ref 4

For example, imagine the flow chart in Fig. 4 is on the pencil maker's PC screen as the computer menu for an electronic information system. When the pencil maker clicks on "Timber," a wealth of data begins to emerge that makes one realize things are not as simple as may have been imagined. Not only is there a potential problem with tropical timber because of the rain forest issue, but the pencil maker now notes that suppliers in the U.S. Pacific Northwest have a problem with the conflict between logging operations and the habitat of the Northern Spotted Owl.

At this point, a pencil maker recognizes the need to examine the LCAs produced by the companies supplying timber, paints, and graphite. Working down the flowchart, the pencil maker sees a total of ten points at which other LCA data should be accessed. This is where complex business life gets seriously complicated. At the same time, however, LCA projects can also be fascinating, fun, and a potential gold mine of new business ideas.

Different Approaches to LCA. As Fig. 5 indicates, the LCA practitioner can look at the life cycle of a product through a number of lenses, focusing down on life-cycle costs or focusing out to the broader sociocultural effects. One example is the Eco-Labeling Scheme (Fig. 6) administered by the European Commission Directorate General XI

(Environment, Nuclear Safety, and Civil Protection). This scheme is committed to assessing environmental impacts from cradle to grave.

	Raw material acquisition	Bulk processing	Engineered materials processing	Assembly and manufacture	Use and service	Retirement	Treatment and disposal
1. Cost							
2. Value/ performance							
3. Environment: compliance							
4. Environment: beyond compliance							
5. Socio-economic							
6. Socio-cultural							

Fig. 5 Matrix showing some possible different approaches to LCA. Source: Ref 4

ENVIRONMENTAL FIELDS	Product life cycle				
	Preproduction	Production	Distribution	Utilization	Disposal
Waste relevance					
Soil pollution and degradation					
Water contamination					
Air contamination					
Noise					
Consumption of energy					
Consumption of natural resources					
Effects on ecosystems					

Fig. 6 The European Community eco-labeling scheme "indicative assessment matrix." Source: Ref 4

The sheer variety of data needs, and of data sources, makes it very important for LCA producers and users to keep up to date with the debate and build contacts with other practitioners. Among the biggest problems facing the LCA community today are those associated with the availability of up-to-date data and the transparency of the processes used to generate such data.

Most LCA applications, however, focus--and will continue to focus--on single products and on the continuous improvement of their environmental performance. Often, too, significant improvements will be made after a relatively simple cradle-to-grave, or perhaps cradle-to-gate, analysis.

A detergent company, for example, may find that most of the energy consumption associated with a detergent relates to its use, not its manufacture. So instead of just investing in a search for ingredients that require less energy to make, the company may decide to develop a detergent product that gives the same performance at lower wash temperatures.

In short, LCA is not simply a method for calculation, but, potentially, a completely new framework for business thinking.

Life-Cycle Engineering and Design

ASM International Materials Life-Cycle Analysis Committee*

Case History: LCA of an Automobile Fender

A detailed LCA for an automotive fender as performed by IKP (University of Stuttgart, Germany) and PE Product Engineering (Dettingen/Teck, Germany) is included to illustrate the present status and limitations of this methodology (Ref 1).

Goal and Scope. The specific goal of this investigation was to compare four different fender designs for an average compact class automobile in Germany. The comparison should result in the identification of the best material in terms of resource use, impact on global climate, and recyclability.

The four options were steel sheet; primary aluminum sheet; an injection-molded polymer blend of polyphenylene oxide and nylon (PPO/PA); and sheet molding compound (SMC), a glass-fiber reinforced unsaturated polyester resin. The mechanical requirements for the four fenders were identical; this ensures that the functional unit is well defined and that they are equivalent. Table 2 shows the materials and weights of the four different fender designs.

Table 2 Material and weight of the different fender designs

Material	Thickness		Weight	
	mm	**in.**	**kg**	**lb**
Steel	0.7	0.0275	5.60	12.35
Sheet molding compound	2.5	0.10	4.97	11.00
Polyphenylene oxide/polyamide	3.2	0.125	3.35	7.40

Source: Ref 1

Data Origin and Collection. *Data* in this context means all pieces of information that might be relevant for the calculation of processes and materials. Such information includes material and energy flows of processes, process descriptions, materials and tools, suppliers, local energy supply, local energy production, production and use of secondary energy carriers (e.g., pressurized air, steam), and location of plants. Which processes are the most relevant and must be considered in more detail depends on the goal and scope of the study. Within this study, the following information (supplier specific, if possible) had to be identified, collected, and examined:

- *Production processes*, with all links in the process chain
- *Primary data* concerning energy and material flow with respect to use of energy carriers (renewable and nonrenewable), use of mineral resources (renewable and nonrenewable), emissions into the air, waterborne emissions, and waste and production residues
- *Coupled and by-products* as well as entries from other process steps (internal loops)
- *Transportation needs* with respect to distance, mode, and average utilization rate
- *Primary energy carriers* and their means of production and distribution
- *Secondary energy carriers* and their means of production and distribution
- *Air and water treatment measures* and disposal of residues

Data collection is not a linear process. Good data collection and evaluation requires iteration steps for identifying relevant flows or additional information, and experience is needed to interpret the collected data. Calculation of modules should be carried out with special regard to the method of data collection (e.g., measured, calculated, or estimated) and the complexity of the system.

Materials Production. The consideration of aluminum shows that not only the main production chain has to be considered, but also the process steps for alumina production (Fig. 7). The steps in electrolysis must be calculated, and the energy use connected with caustic soda and the anode coke has to be examined. The four steps shown in Fig. 7, which must be considered along with a long list of others, demonstrate the difficulty of balancing costs and environmental impacts.

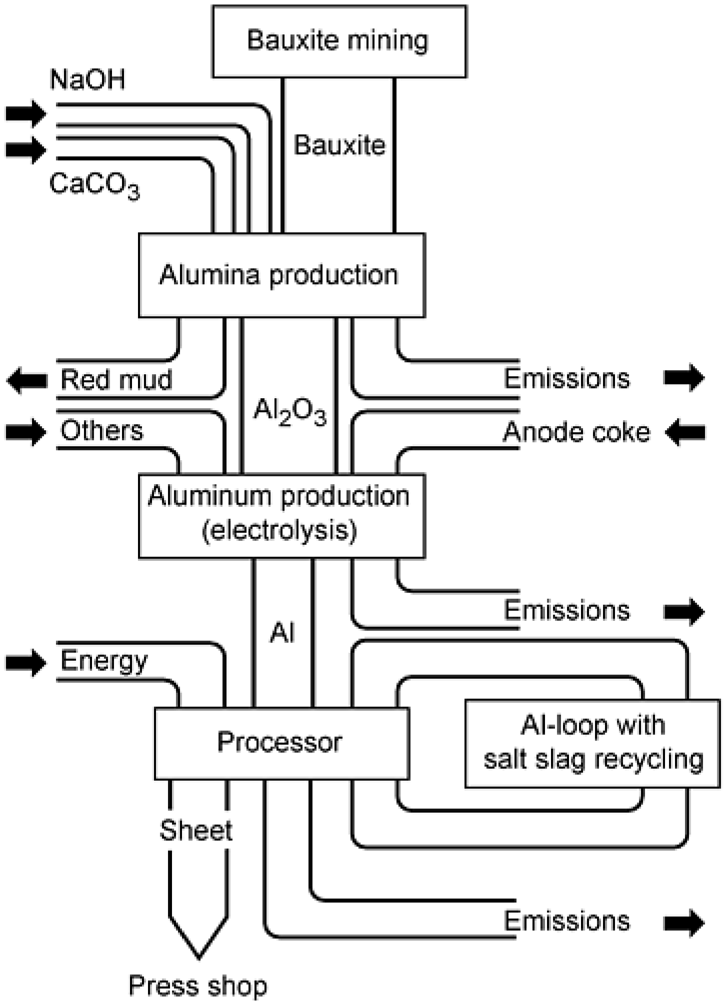

Fig. 7 Main material flow for the production of aluminum sheet parts. Source: Ref 1

In electrolysis, the source of electric power is important because of the differences in carbon dioxide emissions between plants that are water-power driven and those that burn fossil fuels. Another significant factor is how electrolysis is controlled. Modern plants use technologies that prevent most of the anode effects responsible for the production of fluorocarbon gases, but many older plants emit four or five times as much. This shows the importance of calculating on a site-specific or at least on a country-specific basis.

Because aluminum is globally merchandised, the user frequently does not know the exact source of the metal. The solution to this problem is to calculate the average aluminum import mix. However, this calculation requires detailed information about the different ways aluminum is produced all over the world.

Material Weight. In selection of automotive parts, the usage phase is of great interest. The main environmental factor during this phase is weight difference. Each part contributes to the energy demand for operating an automobile. The share a fender contributes depends only on its mass. However, no data are available for the same car carrying different fenders. Therefore, this study calculated the fuel consumption assuming a steel fender, because average fuel consumption is known for the complete car with the traditional fender. In the same way, possible weight savings are known. Measurements and judgments from all automobile producers show that the assumptions for fuel reduction from weight savings vary within a range of 2.5 to 6% fuel reduction per 10% weight savings. For this study, 4.5% was assumed to be an average value for the kind of cars considered.

Recycling of the SMC fender shows another weight-related issue. After the useful life of the product, a decision has to be made about whether the part should be dismantled for recycling, or otherwise disposed of. Within this study, the recycling solution was considered because the SMC part can be dismantled easily and ground into granules. Furthermore, SMC can replace virgin material as reinforcement, and granules can be used as filler up to 30%. In addition to the possibility of

using recycled material in new parts, the SMC recycling process offers another advantage because the reformulated material has a lower density than the primary material. This means that the use of recycled SMC leads to further weight savings of approximately 8%, while fulfilling the same technical requirements. This example shows that recycling is not only useful for the purpose of resource conservation but may provide other benefits as well. (Unfortunately, at the time this was written the only U.S. company recycling SMC had gone out of business. This shows that successful recycling requires more than technical feasibility, which is generally achievable--it is highly dependent on viable economics.)

Inventory Results. The discussion of the whole inventory process is not possible here, because it includes up to 30 resource parameters, approximately 80 different emissions into the air, more than 60 water effluents, and many different types of waste. Therefore, this example concentrates on energy demand, selected airborne emissions, and resource use (recyclability).

Energy use is one of the main parameters to consider when selecting automotive parts. It is a reliable basis for judgment because energy use generates waste and emissions, and it requires depletion of resources. Figure 8 shows the energy demand for the different fender materials over two complete usage phases, including production out of raw material and recycling for the second application.

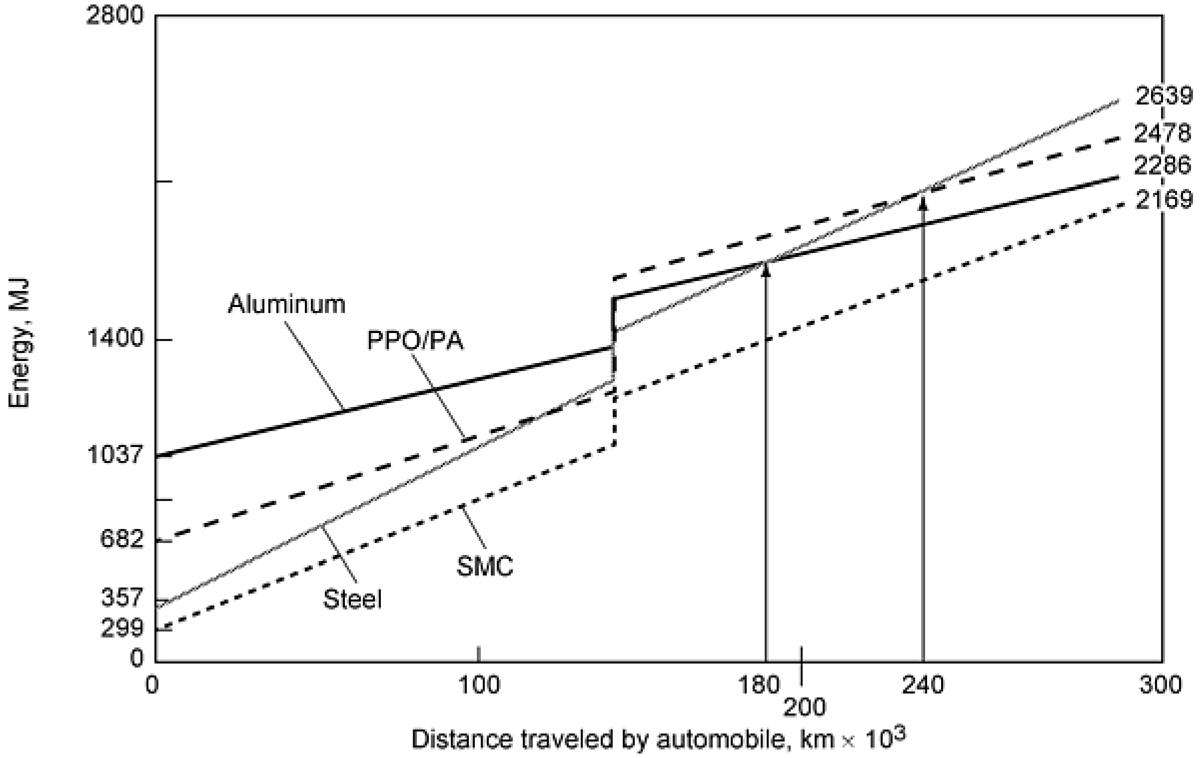

Fig. 8 Energy consumption for the production, use, recycling, and reuse of different fender materials considering the distance traveled by the automobile. Source: Ref 1

The values at the zero kilometer line represent the energy needed for both material and part production. It is easy to see that aluminum has the highest energy demand of all four materials. This comes mainly from the electrolysis process and the alumina production process.

SMC has the lowest energy demand, needing approximately one-third of the energy required for the aluminum fender. This is due to the fact that SMC is a highly filled material in which the extender is a heavy, relatively inexpensive material. Second best is steel, which requires only a little more energy than SMC. Somewhere in the middle is the PPO/PA blend; the reason for the relatively high energy demand is the feedstock energy of the materials used in polymer production.

The ascending gradients represent the differences arising from the weights of the fenders. The larger the gradient, the higher the weight. It is easy to see that steel, as the heaviest material, loses a lot of its advantage from the production

phase. This points out the importance of lightweight designs. The energy demand for the usage phase is approximately four times higher than that required for part production. As a result, the most significant improvements can be made in the usage phase. Nevertheless, SMC still has the lowest energy demand after the first usage phase, and aluminum is still the worst.

Recycling. After the first life cycle of the fender, it is recycled into a new part. The energy needed for recycling of SMC, steel, and aluminum is relatively low; PPO/PA requires much more energy for recycling. The disadvantage of PPO/PA is that although recycling is possible and very energy efficient, the production of the 70% virgin material required in the part is very energy intensive.

Second Use. The second utilization phase shows the same results as the first. In the final analysis, steel turns out to be the most energy-intensive material, followed by the PPO/PA blend. While steel has the disadvantage of its weight, the polymer blend has disadvantages concerning recyclability for external body parts. The situation would be totally different if more material could be recycled, or if the polymer blend could be used more extensively in heavier cars with a longer usage phase. The weight advantage is especially high for aluminum. However, SMC turns out to be the most energy efficient material overall.

Airborne Emissions. Emissions of carbon dioxide, nitrogen oxides, sulfur dioxide, and fluorocarbons were estimated for each material because of their effects on ozone depletion and global warming (Fig. 9). These pollutants were also chosen because they are generated by nearly every manufacturing process, all over the world.

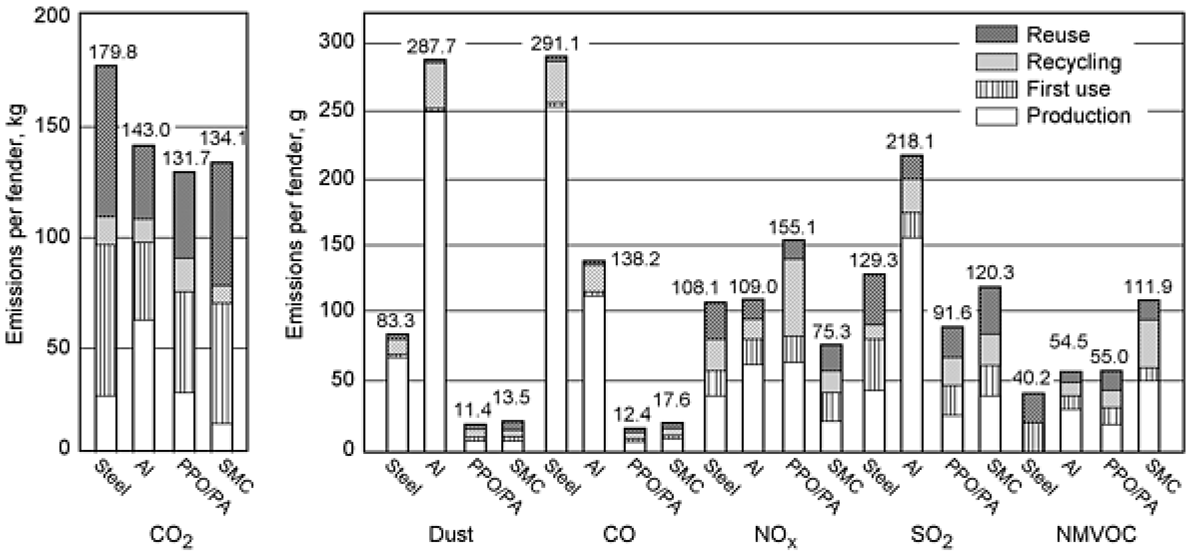

Fig. 9 Selected airborne emissions for the production, use, recycling, and reuse of different fender materials. NMVOC, nonmethane volatile organic compound. Source: Ref 1

As mentioned before, a high percentage of atmospheric emissions is caused by energy generation. In the case of polymers, emissions are lower than expected because so much energy is stored as material feedstock. Aluminum is the material with the highest energy demand, but emissions are comparatively low because water power is used for a high percentage of aluminum electrolysis. The highest levels of carbon dioxide are emitted during steel production, mainly from the ore reduction process. Carbon dioxide emissions for the production of both polymers are dominated by hydrocarbon processing and refining.

For aluminum, most emissions come from earlier process steps. Alumina is produced mainly in bauxite mining countries, where the least expensive locally available energy is typically generated by burning heavy fuel and coal. Carbon dioxide emissions from aluminum production are dominated by this source, plus the electric power demand of those electrolysis processes that are not based on water power.

Carbon dioxide emissions during usage are directly related to fuel consumption: heavier fenders result in the generation of more carbon dioxide. This is also true for all other emissions considered here. One important approach for a possible improvement is certainly to reduce this main impact on global warming.

Impact assessment is a special step within the framework of life-cycle assessment. Based on the results of the inventory, conclusions can be drawn, and judgments and valuations are possible. The impact assessment supplies additional information that enables the practitioner to interpret the results from the inventory.

Impact assessment also should allow the practitioner to draw the right conclusions concerning improvement approaches. However, it should be noted that consideration of environmental effects as a consequence of environmental releases is additional information that is not covered by the inventory step. This case history provides only a brief overview.

Impact assessment involves three steps. First is the definition of "environmental problems" or "themes." The problems to be addressed are defined in the scope of the project. Second, emissions are grouped to show their specific contribution to the environmental themes. Third, their shares are calculated. A standard list covers the following themes, which are more or less identical with most of the approaches taken in LCA literature:

- *Global criteria:* Resource use (energy carriers and mineral resources, both renewable and nonrenewable, and water and land use), global warming, ozone depletion, and release of persistent toxic substances
- *Regional criteria:* Acidification and landfill demand
- *Local criteria:* Spread of toxic substances, eutrophication, and formation of photochemicals
- *Others:* Noise, odor, vibration, etc.

In most of the studies conducted by IKP and PE Engineering, resource use and the global climate problems are considered. The methodology for their consideration is broadly accepted. Sometimes acidification or eutrophication is considered as well. All others are more difficult to handle, and appropriate methods are still under discussion.

For the fender example, the contribution to the global-warming problem is calculated by taking into account production, use, recycling, and second use of each material (Fig. 10). The results are mainly influenced by carbon dioxide emissions and energy use and show that lightweight materials have advantages during utilization. However, aluminum is far worse than the others during production because electrolysis is accompanied by fluorocarbon emissions (CF_4 and C_2F_6), which have a very high global warming potential.

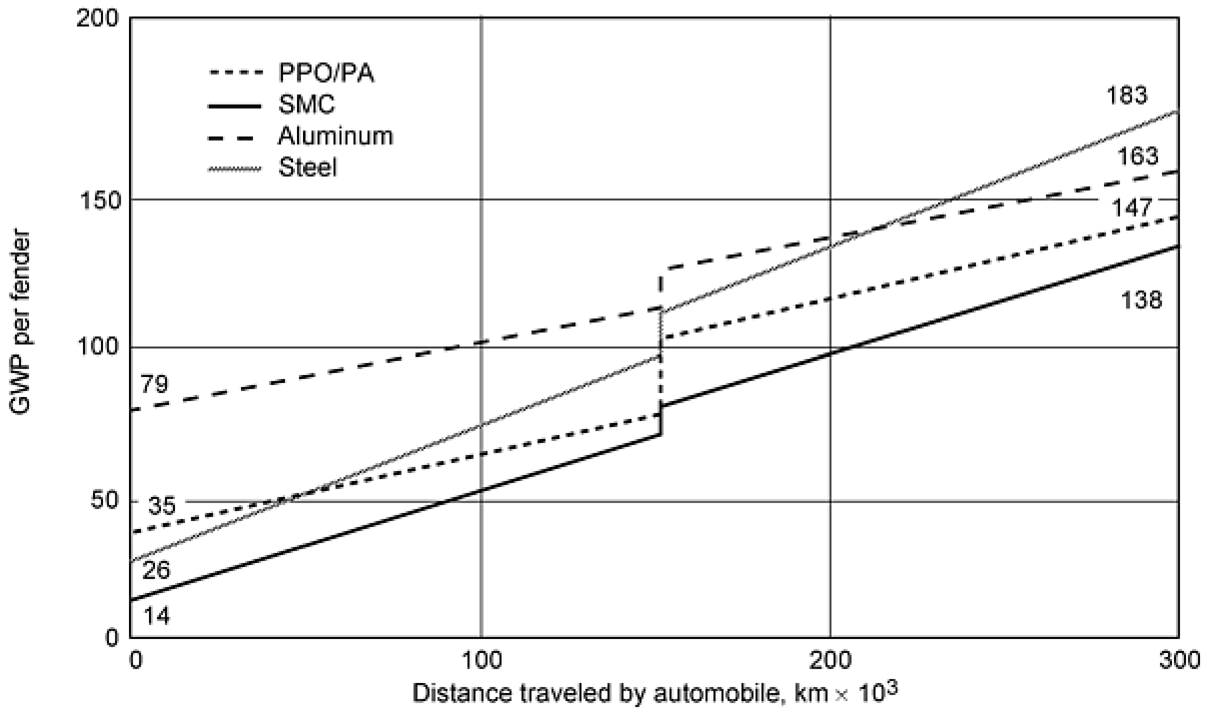

Fig. 10 Calculated contribution to global warming for the production, use, recycling, and reuse of different fender materials considering the distance traveled by the automobile. GWP, greenhouse warming potential (CO_2 equivalents). Source: Ref 1

Valuation. The second step in the judgment of the environmental impacts is the valuation step. This step may be divided into the normalization process and the final weighing.

Normalization involves scaling absolute contributions to single environmental themes on the same level because absolute numbers may vary within six to ten decades. The effect scores are normalized with the amount of the annual global effect score or the contribution of one process to the theme per year, and so on.

Final weighing involves a personal judgment about the importance of each environmental theme, and the effect of each score on overall impact. This final step is part of the decision-making process. Scientists create tools for this process and help decision makers use and understand them, but the final decisions depend on company policies, not scientific or consultancy work.

Improvement Options. From this study the following conclusions for improvement can be drawn:

- The usage phase is dominated by fuel consumption and the resulting carbon dioxide emissions. For other emissions, the production phase and recycling is also of great importance.
- Reducing part weight may improve energy use and reduce the contribution to global warming. However, reducing part weight may require higher environmental investments during production or recycling. In some cases, these investments are very useful.
- Recycling is more important for expensive and energy-intensive materials.

Experience gained from the evaluation of fender materials shows that the following general conclusions can be made:

- The fuel production has great impact and is not well known today.
- The best basis for decision making is a supplier-specific LCA.
- Close cooperation between producers and suppliers is necessary to find processes that will reduce

environmental impacts.

Conclusions

Life-cycle engineering--in particular, life-cycle assessment--is gaining importance for design and materials engineers because environmental considerations are increasingly important factors in design and materials selection. The creation and development of environmental management systems, including extended producer responsibility and product stewardship responsibility, pollution prevention strategies, "green" procurement guidelines, and eco-labeling programs are evidence of the growing importance of life-cycle concerns.

To make a proper assessment the total life cycle of a material, all forms of energy use, waste production, reuse, and recycling have to be considered. Many of these factors are site specific, which complicates calculations and comparisons.

Not all of the steps of a complete LCA are well developed at this time. However, efforts in this direction, particularly regarding standardization of data and methods are in progress. While LCAs for simple products have been performed, more complicated systems are only now being tackled.

Many industry trade organizations have developed or are in the process of developing life-cycle inventory data bases for their products. The Association of Plastics Manufacturers in Europe (APME), the European Aluminum Association (EAA), Finnboard, and the International Iron and Steel Institute are just a few examples. A wide variety of reports and software packages containing inventory data are available. In addition, a large number of national and international database projects exist. A comprehensive listing can be found in Ref 5. Also, Ref 4, while concentrating on Europe, gives an excellent overview and many useful examples and addresses.

Simplification and standardization will lead to more reliable, timely, and cost-effective life-cycle inventories. When consensus about an acceptable impact assessment methodology is reached, life-cycle assessment for simple and then more complex units and systems will be possible.

Design for Quality

James G. Bralla, Manufacturing Consultant

Introduction

CONSUMERS have come to expect high quality and dependability in manufactured products. Competitive pressures with respect to quality are stronger than they were in prior years, perhaps thanks to Japanese competition in many product lines (most notably in automobiles). Therefore, designed-in quality is a vital facet to current product design. According to Joseph M. Juran, "One-third of all quality control problems originate in the product's design" (Ref 1).

Design for Quality

James G. Bralla, Manufacturing Consultant

What Is Quality?

What do customers expect when they purchase products? For both consumer and industrial products, the answers are very nearly the same. Function, performance, and the low price that can result from successful design are important to customers. However, their expectations are not limited to these factors. Customers also want benefits that last as long as

the product is owned and used. In the broadest sense of the word, they want products of high lasting quality. In this sense, the word *quality* defines the attributes that an ideal product should have.

D.A. Garvin's classic paper, "What Does Product Quality Really Mean?" (Ref 2) lists "eight dimensions of quality." These form a good starting point for a list of desirable attributes for a product design. Garvin's list includes the following:

- *Performance:* How well the product functions
- *Features:* How many secondary characteristics the product has to enhance its basic function
- *Reliability:* Defined by some as quality in the time dimension; how well the product maintains its quality
- *Conformance:* How well the product conforms to the specifications or standards set for it
- *Durability:* How long the product lasts in use
- *Serviceability:* How easy the product is to maintain
- *Aesthetics:* How attractive the product is
- *Perceived quality:* How high the users believe the quality of the product is, that is, quality reputation of the product

To these desirable attributes, *manufacturability,* how easy and economical the product is to make, should certainly be added. Other desirable characteristics, not mentioned by Garvin, are safety, environmental friendliness, user friendliness or ergonomics, short time to market, and upgradability. Many of these attributes are discussed in other articles in this Section of the Handbook.

Perhaps Garvin's eighth dimension, *perceived quality* is the most important, provided the perception is based on ownership experience. In other words, quality is whatever it is judged to be by the customers of the product in question. Quality is whatever the customer wants. However, this must not be interpreted to mean that quality is whatever sells the product in the store or showroom. It is more a result of how satisfied customers are with the product after they have owned it for some time and have had a chance to weigh its features: ease-of-use, freedom from maintenance, ease of regular service, economy of operation, safety, and other attributes, and, overall, whether the product has met the customers' expectations.

If customers are satisfied with the product after, for example, a year of ownership and at least moderate use and would recommend it to other potential buyers, then perhaps it can be said that the product is of high quality. Other measures, such as whether it conformed to some specifications, whether it had an acceptable reject rate, whether it was made under ISO 9000 conditions, or whether the company producing it got the Malcolm Baldrige award are less meaningful, in the author's opinion, than the customer's evaluation. Customer satisfaction is the prime measure of product quality.

Quality and Robust Design. Taguchi's approach to quality evaluation (see the article "Robust Design" in this Volume) is more quantitative than Garvin's. The highest quality, he contends, is that which minimizes the life-cycle costs of the product. These life-cycle costs include the acquisition cost by the purchaser, which is normally, but not always, closely related to the manufacturing cost. They also include the cost to operate the product, the maintenance expenses for it (including the cost for regular service, repair, and use of a substitute product during maintenance), the cost of any injury resulting from safety flaws, the cost of overcoming any defects it has, including safety defects, and the expense of disposing of it. These life-cycle costs may not all accrue to the same person but, ultimately, are paid by some member or members of society (see the article "Life-Cycle Engineering and Design" in this Volume). In summary, Taguchi's quality cost function measures quality in terms of the cost to any and all members of society who have expenditures resulting from the manufacture, sale, ownership, and disposal of the product. The lower such cost, the higher the product quality. (Taguchi's measure excludes costs due to misuse of the product. For example, an automobile repair due to careless driving is not part of the quality cost of the automobile; an accident due to poor brakes, sloppy steering, or a horn that is awkward to sound would be.)

Phadke's approach (Ref 3) is from a different direction, but perhaps it is not less meaningful. He says that ideal quality means that the product delivers its target performance:

- Each time it is used
- Under all intended operating conditions

- Throughout its intended life
- With no harmful side effects

There may be a conflict between quality and cost, but the conflict is in the initial manufacturing cost, not the life-cycle cost as Taguchi defines it. Many managerial steps taken to enhance quality require a significant initial expense in training, organization, and redirection of systems, procedures, and operating philosophy. Also, corrective action in the product design to solve quality problems often requires an investment in engineering time, new tooling, gaging, or equipment.

Quality and Design for Manufacturability. Many DFM changes, implemented to reduce manufacturing costs, improve quality; however, some may impair quality. One example is the use of free-machining metals for machined parts. They ease and speed up manufacturing operations, but generally have slightly less favorable physical properties than the standard grades so the resulting product may not be quite as strong. Another example is the use of thin walls in injection-molded plastic parts. These speed the molding cycle and save material, but may result in a less-rigid part than one with thicker walls. Another example is the elimination of adjustments, advocated to improve ease of assembly. Such an elimination can have strong beneficial effects on quality, if engineered correctly, because incorrect adjustments are a source of quality defects. If the engineering carried out to eliminate the adjustment is not done soundly, or if specifications on components are not held in production, the lack of capability to adjust may result in a product slightly off in some characteristic, that is, a defective product. Adjustments are normally specified when the designer believes that this is the best way to achieve some precision in dimension or setting as a result of variations in parts or other factors. Eliminating the adjustment may cause the variation to get through to the operation of the product, reducing its quality. Care is required in deciding which approach is best overall.

On the other hand, there are many DFM guidelines that facilitate improved quality. For example, DFM specialists advocate keeping wall thickness in injection-molded plastics parts as *uniform* as possible. This improves the molding operation and also prevents the formation of unsightly sink marks and distortions that impair the fit and quality of plastic parts. In metal stamping, standard DFM guidelines to make bends across the grain of the metal rather than along it and to space punched holes adequately from the edge of a workpiece have the primary purpose of avoiding quality problems.

Additional information about DFM is provided in the article "Design for Manufacture and Assembly" in this Volume.

James G. Bralla, Manufacturing Consultant

Management of Quality

Even though initial product design is a strong determinant of eventual product quality, it is far from the only factor. The quality improvement task is dependent on a wide range of factors including company objectives; management and employee attitudes; training; systems and procedures used; the condition of tools, equipment, and facilities; the control exercised by vendors; and many other factors. In short, product quality is heavily dependent on how well the company is managed. J.M. Juran has said, "The most important thing to upgrading quality is not technology, but quality management" (Ref 4). And the management of quality is a broad and complex task.

American industry awoke to the need for improved quality in the 1980s, when Japanese and other international suppliers made large inroads in the U.S. markets for many consumer and industrial products. Analysis showed that *quality cost,* the cost of inspection; scrap; rework; warranties; field service due to quality problems; product call-backs; and most

importantly, lost sales due to a poor quality reputation, was a major part of the operating cost of a manufacturing concern. Crosby and others claim that these expenses amount to 25, 30, or even 40% of the cost structure of a company (Ref 5). The corollary is that by spending more money "up front" in quality assurance provisions, manufacturing costs could actually be reduced because scrap, rework, and all the other costs of poor quality would be reduced and sales, market share, and production volumes all would increase when quality was improved.

The up-front costs may be considerable, and the journey from mediocre to superior quality may be a long one. The prioritizing of quality must permeate the whole organization, and considerable careful communication and training will usually be required to obtain it. If all this is done correctly, the savings from reduced quality costs should provide a good return on the up-front investment. The U.S. automobile industry has learned how long it takes to change. Ford Motor Company began its quality improvement program in the early 1980s and, by the 1990s, it is still in progress, not only at Ford but in the rest of the U.S. automobile industry.

A first essential step in managing quality improvement is a firm, sincere commitment by management that quality is a prime priority. The word "sincere" is used advisedly. If management preaches quality, but ships substandard products at the end of the month to meet its monthly billing quota, workers and others in the organization will get the message that quality is not as important to the company as it is touted to be. "Employees are pretty clear on reading signals" (Ref 4). Management must lead the way, but all employees must share a determination to exercise great care in ensuring that all company activities lead to the production of high-quality products.

Statistical Process Control. A prime tool of quality improvement, advocated by Deming and others, is *statistical process control* (SPC) (Ref 6). This is a procedure, using statistical mathematics, which signals that some extraneous factor is affecting the output of a production process. The signal alerts production and quality personnel that some process fault should be looked for and eliminated. In this way, the procedure aids in identifying and correcting the causes of product component defects. Because there are natural random variations in the results of any manufacturing process, the ability to differentiate between these random variations and those caused by some change in process conditions is a critical part of maintaining good control over specified characteristics and dimensions. Broken or worn cutting tools, slipped adjustments, leaks in a pressurized system, and an accidental change to a less-active solder flux are some examples of the kinds of process changes that might otherwise not be noticed, but which may cause a quality deterioration that would be detected by SPC analyses.

Additional information about SPC is provided in *Nondestructive Evaluation and Quality Control,* Volume 17 of *ASM Handbook.*

Total Quality Management. Deming also states that 85% of quality problems are caused by systems, procedures, or management and only 15% by bad workmanship (Ref 6). Blaming workers is not his way to cure quality problems. Incidentally, the 85% attributable to management includes problems traceable to weaknesses or errors in the product design.

Current thinking on the best managerial approaches to control and improve quality involve heavy worker participation in both the monitoring of quality and the corrective actions taken to solve quality problems. One approach that encompasses worker involvement and includes worker empowerment is *total quality management* (TQM). Total quality management is more a broad management philosophy and strategy than a particular technique. Referred to earlier as total quality control, it originated in Japan. It involves:

- A strong orientation toward the customer in matters of quality.
- Emphasis on quality as a total commitment for all employees and all functions including research, development, design, manufacturing, materials, administration, and service. Employee participation in quality matters is standard at all levels. Suppliers also participate.
- A striving for error-free production. Perfection is the goal.
- Use of statistical quality control data and other factual methods rather than intuition to control quality.
- Prevention of defects rather than reaction after they occur.
- Continuous improvement.

Total quality management programs usually stress that quality must be designed into the product rather than tested for at the end of the production process. Additional information is provided in Ref 7.

Quality Function Deployment. Another well-known quality technique is *quality function deployment* (QFD). This is a system that reflects the belief that the customer's viewpoint is the most important element in product quality. Quality function deployment is a technique "for translating customer requirements into appropriate company requirements at each stage--from research and product development through engineering and manufacturing, to marketing, sales, and distribution" (Ref 8). The objective of the approach is to ensure that the customer's preferences are incorporated in all facets of the product. A matrix chart is prepared. Customers' preferences for product attributes (what the customer wants) are listed on the left-hand side of the sheet. Product design features intended to satisfy the customers' requirements are listed across the top of the same sheet. Where a product feature satisfies a customer preference, a mark is placed in the matrix chart. Normally, the mark is coded to indicate the degree to which the customers' preference can be satisfied by the design feature. The objective of this matrix and the whole QFD procedure is to ensure that customers' preferences are satisfied by the product design.

Additional discussion of QFD, including examples of QFD matrices, is provided in the articles "Conceptual and Configuration Design of Products and Assemblies" and "Concurrent Engineering" in this Volume.

Worker Involvement. The strong worker-participation aspect of TQM is one of its most important components. If workers are given the task of monitoring the quality of their own output, especially by plotting their own SPC charts, and are then encouraged to recommend systems, layout, or workplace changes, quality has the best chance of being improved. Workers know more about the details of their operations than anyone and normally care about the quality of their workmanship. If their knowledge is properly channeled, the best results can be obtained. Utilizing worker suggestions tends to give workers ownership of the quality improvement project and helps to keep them more quality conscious.

Training is a necessary part of a quality improvement effort. The training will encompass not only an appreciation of the quality philosophy but also, for many people, specific statistical and charting know-how. The installation of SPC procedures throughout a factory will take time.

Continuous Improvement. There is much to be said for small-scale incremental improvements in processes, methods, and systems. This is in contrast to the historical pattern in the United States, wherein large-scale, capital-intensive automation projects are used as a means to reduce costs and improve quality. There is nothing wrong with such an approach if the changes are technically and managerially sound and economically justifiable. However, sometimes a series of grass-roots, incremental improvements can yield the same results in the long run with much less investment and upheaval. The *continuous improvement approach,* a major element of TQM, has much to be said for it.

Design of Experiments. Other worthwhile tools for quality improvement are the design of experiments methods discussed in the article "Robust Design" in this Volume. Called *design of experiments* (DOE), *controlled experiments, orthogonal arrays,* or *Taguchi methods,* the approaches are most often noted as quality improvement tools, but they are also quite useful for raising process yields and making other manufacturing and product improvements.

Teams. The right way to implement design for quality is through a team approach. To ensure that high product quality is incorporated in the design, an experienced quality person should participate actively in the design process as a member of the project team. This person can supply information about which characteristics, dimensions, and other specifications are likely to be critical to product quality and can make recommendations for testing and testability. Experience with the product line involved or with similar products is obviously important.

Additional information about team-based approaches is provided in the article "Cross-Functional Design Teams" in this Volume.

Principles of quality management can be summarized as follows:

- Management leadership to better quality must be strong and sincere.
- A steady series of small incremental improvements may be preferable to a few major changes.
- Worker involvement is necessary if quality is really going to be improved. In fact, the whole organization must be quality-minded and involved.
- Statistical controls are invaluable in identifying when corrective action needs to be taken.
- Training in statistical methods and quality philosophy are essential elements of a quality improvement program and should be provided.
- Designed experiments are a useful tool, where appropriate.

- Production people should be given the responsibility for quality and the tools and authority to carry out that responsibility.
- It should be remembered that high quality means meeting customer expectations. All kinds of audit approvals are useless if the customer is not satisfied that the product is good. The customer is king.
- Experienced quality-control analysts and engineers should participate as team members in the design project.
- Be aware of the costs of poor quality including the costs of such items as inspection, screening, rework, scrap, production downtime, delayed deliveries, warranty costs, product returns, lost market share and sales, and lost margin in product pricing.
- Product and process design should take place at the same time.
- Quality faults should be prevented rather than corrected. In other words, quality should be built into manufacturing processes and not achieved by inspection.
- Quality requirements of each product should be well defined.
- If quality problems arise, it is best to concentrate on the most important ones, the ones that Juran calls "the vital few" rather than expending the organization's energy and time on minor problems (Ref 9).
- Sound product design from a quality standpoint must start with some understanding of the actual customer requirements for the product (Ref 10).

Design for Quality

James G. Bralla, Manufacturing Consultant

How Can Design Unfavorably Affect Product Quality?

As indicated, proper design is a prerequisite for high product quality. Designers must optimize the quality potential of their products. (Proper design doesn't guarantee high quality, however, since poorly managed manufacturing can turn even an optimum design into a defective product.) The following are common causes of inadequate designed-in product quality:

- Separation or isolation of the design activity from production and other support functions
- Failure to consult with or have the participation of experienced quality personnel during the design process
- Failure to address customer wants and needs in the product
- Failure to match the design, particularly the dimensional precision needed, with the capabilities of the manufacturing processes used
- Insufficient thoroughness in initial design efforts, leading to late design changes that tend to cause

quality problems in manufacturing

- Insufficient testing of prototypes and pilot production units
- Too great a tendency to reinvent the wheel; that is, not utilizing existing, proven components and designs
- Failure to make the product design simple enough, for example, failure to make the product easy to assemble, potentially leading to assembly and adjustment errors

---

Design for Quality

James G. Bralla, Manufacturing Consultant

Evaluating a Product Design for Quality

Granted that design is a major determinant of product quality, how does the designer evaluate a prospective design to judge whether it has the intrinsic high quality that is wanted? Having an objective method of evaluating the product design in terms of quality would be very desirable. Unfortunately, little methodology for this exists as yet. Three limited methods are described below.

U.S. Navy producibility tool No. 2 is a means of evaluating product quality as indicated by the yield of acceptable components from the manufacturing processes that are used to make them. The quality rating of the product (yield) is the product of the yields of each of the parts.

For example, a product composed of five components that have yields of 0.99, 0.98, 0.99, 0.95, and 0.97 would have a yield of $0.99 \times 0.98 \times 0.99 \times 0.95 \times 0.97 = 0.88$. This rating is based on the assumption that the product is defective if any of the five components in it are defective. In other words, the effect of defects in the parts is cumulative. The mathematics applicable is identical to that commonly used to evaluate the reliability of a product in terms of the probability that it will perform for a certain period. If the probabilities for the components operating satisfactorily for the same period are known, the resulting probability of successful operation of the product can be calculated.

The limitation of this method is that it applies only to rejectable defects in components. Sometimes there is a combined effect that is not satisfactory when "good" components are assembled. Usually, components apt to be defective are inspected and sorted before use. Sometimes, also, good components are improperly assembled causing the total product to be defective. The measure also deals with the conformance of characteristics to specifications, not with whether customers accept the product. The mathematics in the system is correct, but the basis for the calculation may not correspond to true quality measurement from the customer's viewpoint. A further limitation, perhaps the most important one, may be the lack of reliable data on the yield of each component of the product, particularly newly designed parts.

Design for Quality Manufacturability Method. S. Das at the New Jersey Institute of Technology (NJIT) is working on another evaluation system that could provide projected quality yield for new parts based on their configuration. The system is still in the initial stages. The fact that product quality is a result of so many factors, many design related but many more manufacturing related, complicates the problem. Figure 1 illustrates Das' interpretation of the spectrum of sources of product quality problems. Das' system also is intended to provide data on assembly as well as individual parts quality. He has analyzed factors that can result in assembly errors, even if the parts assembled do not have defects; for example, part misalignments, misplaced or missing parts, or part interferences. His system is designed to aid the designer in evaluating the potential quality of particular configurations before the design is finalized.

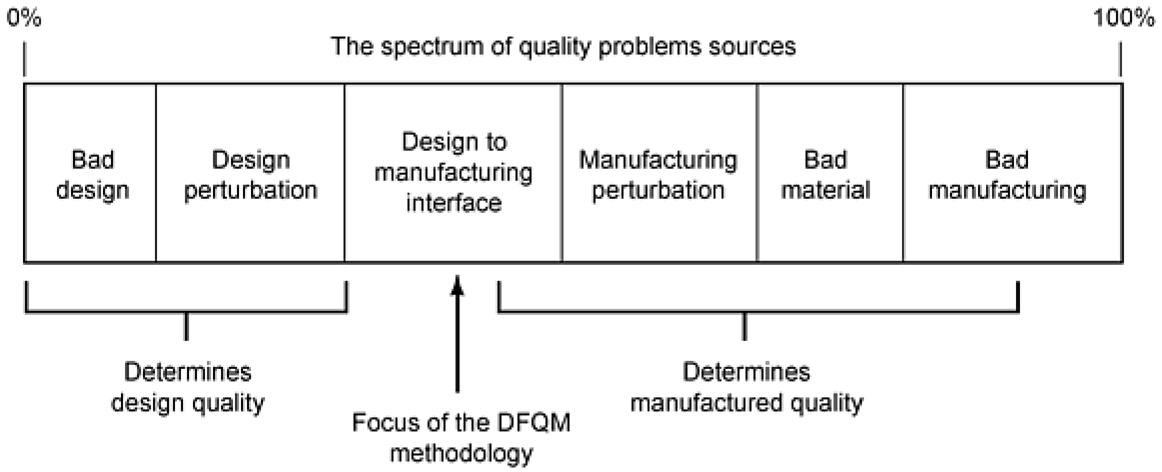

Fig. 1 Summary of the various sources of product quality problems according to the design for quality manufacturability (DFQM) approach. Bad design refers to fundamentally inappropriate design concepts of configurations. Design perturbation refers to minor weaknesses in the design that are capable of correction. Design to manufacturing interface refers to potential sources of quality problems in manufacturing, although the product design is basically sound. Manufacturing perturbation refers to areas where there are weaknesses in the manufacturing process but not full inadequacies. These weaknesses may require improvement to enhance yield, etc. Bad material, perhaps, is more obvious--defects in materials or components purchased. Bad manufacturing refers to errors in workmanship, inadequate training of manufacturing personnel, and defects in equipment and/or tooling due to initial inadequacies or poor maintenance. Source: Ref 11

Matrix Method. The third potential approach for quality evaluation of a proposed design is the matrix method. A matrix for quality evaluation could include managerial as well as technical factors. Figure 2 illustrates a proposed matrix that could aid the designer in ensuring that his or her new component has high quality potential. This kind of evaluation is quite subjective, depending on the knowledge, experience, and judgment of the person making the evaluation. It may not be so suitable for differentiating between subtle differences between two design concepts, an application that is perhaps most important. On the other hand, the procedure lends itself to easy modification so that factors that are particularly important to a particular product line can be included and emphasized, as deemed important.

Matrix chart evaluation of potential quality					
		Ratings alternative		Weighted ratings alternative	
Factor	Weight	No. 1	No. 2	No. 1	No. 2
Does the design reflect customer-indicated preferences for product or component capabilities?	5				
Are proven, existing components and design approaches used in all possible instances?	4				
Do the design specifications and dimensional tolerances conform to the normal capabilities of the process to be used?	3				
Did knowledgeable quality personnel participate in the design process for this item?	4				
Has the item been adequately tested?	3				
Is the item easy to test or inspect for all critical specifications?	3				
Is dimensioning clear and consistent with prior practice?	3				
Are critical dimensions controlled by tooling rather than individual workmanship or machine set up?	4				
Is assembly easy and straightforward with visibility of assembly locations, easy fits, prevention of missing parts, incorrect sequence, or incorrect positioning of parts?	3				
Total weighted ratings:

Design for Quality

James G. Bralla, Manufacturing Consultant

Guidelines for Promoting Quality

The design guidelines described below are intended to help provide products with a potential for higher levels of quality.

Design the Product, Its Major Subassemblies, and Other Components So That They Can Be Easily Tested. Generally, this means providing space and access for testing devices. The testing should be performable when the component is in process, before its installation in the product. This is when corrective action can be taken most easily and before additional operations or components, not involved in the test, have been added. What kind of test to allow for depends on the product and its specifications. Printed circuit boards often are designed with accessible points for electronic testing. Mechanical components may be tested for the position or adjustment of parts; completeness of assembly; freedom from containing extra, loose parts like dropped fasteners; leaks; actuating force; color, or sound level or other acoustic property. Electronic products are tested primarily for proper function. Testing may be automatic in the case of products manufactured at high production levels. In all cases, the component to be tested must have space for the test device, and the product must be properly supported so that the test can be valid.

Not only must the design provide a product that can be easily tested, the designer must also ensure that there is thorough testing of the design before it is committed to production. Many product quality problems are due to unexpected, unforeseen reactions or interactions or unexpected operating conditions in the product. The more thoroughly the proposed product is tested, the better the chance of detecting potential problems before the product reaches the user.

Utilize Standard, Proven Parts (Ideally, Proven Commercial Parts) Whenever Possible. If standard parts cannot be used, use parts from standard, proven manufacturing processes and proven existing quality control procedures and equipment. If newly designed parts are required, the less the new design departs from existing designs, the less chance there will be for problems that lead to quality deficiencies. Existing, standard mechanisms and circuits should always be employed in favor of new approaches unless there is some specific need for a new approach. In other words, do not reinvent the wheel!

Use Clear, Standardized Dimensioning of Drawings. Dimension as much as possible from the same reference plane. Try to use rectilinear, not angular dimensions. Do not dimension from theoretical points in space but from specific points on the component (Fig. 3).

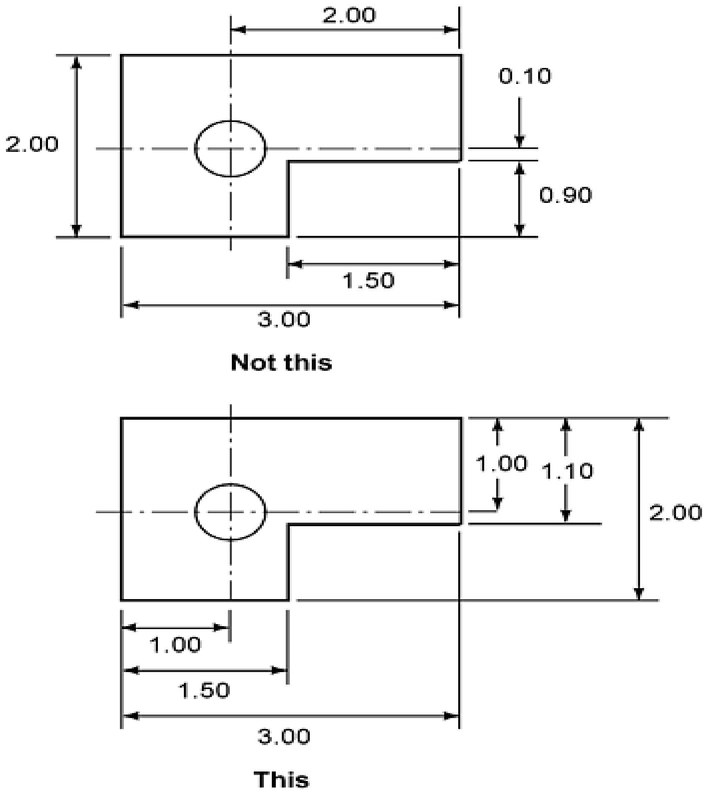

Fig. 3 Dimensioning on engineering drawings. Dimensions should be made from points on the part itself rather than from points in space. It is also preferable to base as many dimensions as possible from the same datum line. These steps help avoid errors when the parts enter production. Source: Ref 12

Design Parts and Set Tolerances To Reduce or Eliminate Adjustments. These, aside from being costly, have been found to be potential sources of quality problems. (This applies to both mechanical and electrical adjustments.) Adjustments also necessitate extra parts in an assembly to provide for both movement and locking. Eliminating the adjustment usually eliminates some parts. Eliminating adjustments normally requires greater precision in some dimension, but often this can be obtained with a process or tooling change. Use of parts with compliance may also, in some cases, eliminate the need for incorporating adjustments in an assembly (Fig. 4).

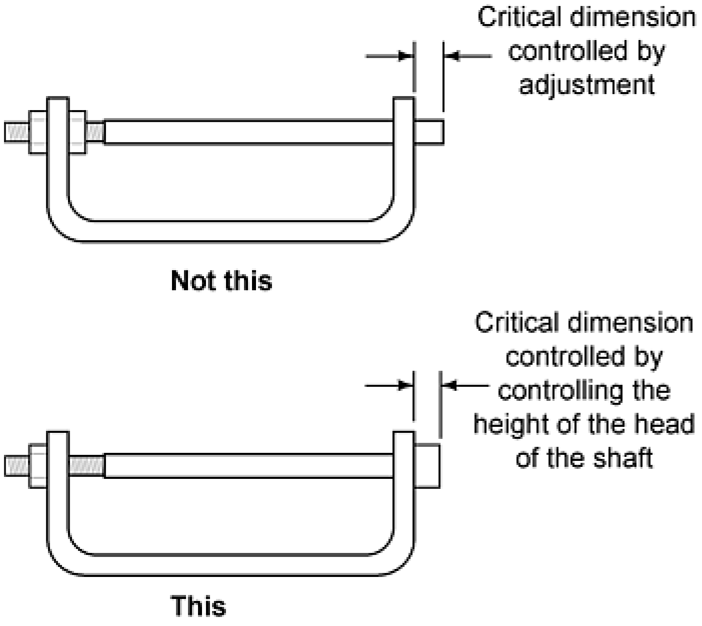

Fig. 4 Example of a design change made to eliminate an adjustment operation. The assembly in the upper sketch is adjusted to set the distance that the pin protrudes from the vertical surface. In the lower view, the adjustment is not needed, but the pin is manufactured with a controlled head height. This design has one less locking nut.

Design parts so that critical dimensions can be controlled by tooling, rather than by the setup of production equipment or by individual workmanship. (This requires designing for a particular process, always a sound design principle.) Examples of processes in which tooling can be used to control critical dimensions include injection molding, progressive die stamping, die casting, lost-foam casting, and powder metallurgy.

Be Careful of Dimensional Tolerances. The assignment of tolerances can be a critical element that justifies considerable attention from the product designer (see the article "Dimensional Management and Tolerance Analysis" in this Volume). Looser tolerances in component parts almost always result in lower parts cost, but may cause trouble in assembly and in the performance of the finished product if they result in parts fits that are too loose or too tight or in misalignment. Excessively tight tolerances require additional operations or additional care that can dramatically increase costs. However, tight tolerances are generally better from a quality standpoint. Additionally, the Taguchi quality philosophy calls for the closest adherence to nominal dimensions. This implies that close manufacturing control over dimensions is valuable from a total-product-quality standpoint. The designer should specify what dimensions and other specified characteristics are important to the product and should tighten tolerances for these. Noncritical dimensions and other specifications should be more liberally toleranced. Overall, according to Anderson, "The best procedure is to optimize tolerances for a balance of function, quality, safety, and manufacturability" (Ref 1).

Minimize the Number of Different but Similar Part Designs. In other words, standardize on the fewest number of part varieties in order, among other things, to prevent the wrong part from being inadvertently assembled in a product. If this cannot be done, make sure that similar but slightly different parts cannot be accidentally interchanged. Make them very obviously different or, better still, not able to fit into each other's application (Fig. 5).

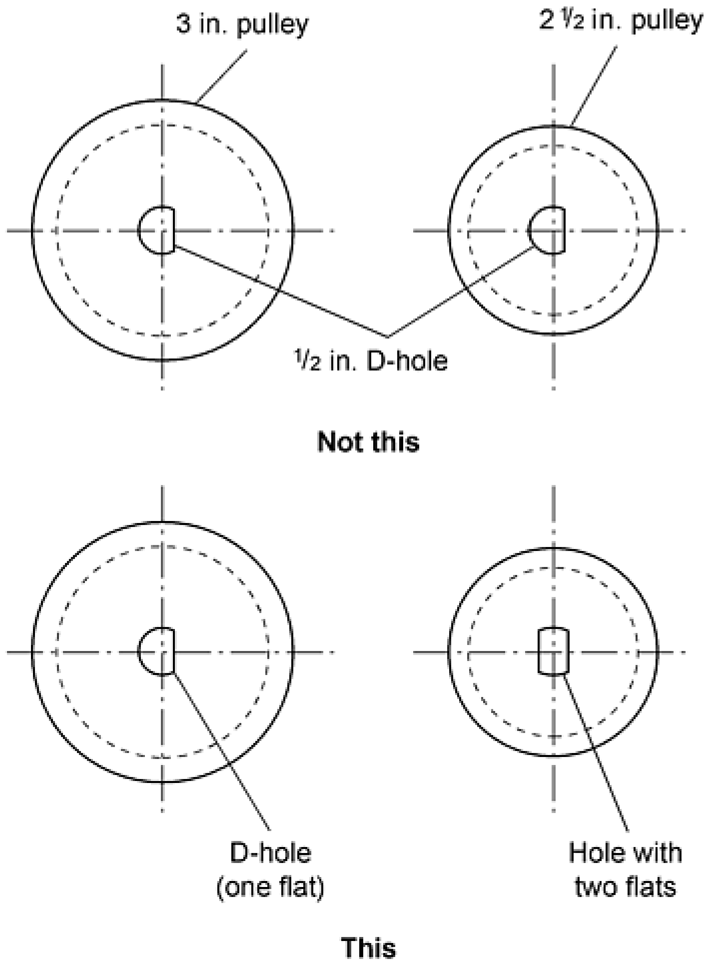

Fig. 5 Two pulleys used in a product, each of a slightly different size. In the upper view, both pulleys use the same design D-hole for mounting on a shaft, and it is possible to put the wrong pulley on a shaft. In the lower view, each pulley has a different mounting hole with different end configurations on the mounting shafts so that the wrong pulley cannot be assembled to each shaft.

Use Modular Construction. Modules usually can be tested easily and in other ways have their quality verified.

Thoroughly Analyze Quality Ramifications of Engineering Changes. If engineering changes are made, make sure that their quality ramifications are thoroughly analyzed because quality problems sometimes stem from incompletely engineered design changes. Changes should be clearly and promptly transmitted to manufacturing and promptly implemented (Ref 1). The earlier that the change is made the less chance there will be to encounter quality problems and the lower the cost of the change will be.

Develop More Robust Components and Assemblies. Use Taguchi or other designed experiment methods to develop components and assemblies that are less sensitive to process variations and variations of other conditions.

Design for Ease of Assembly. There are a number of recommendations concerning how parts should be designed to fit together that can have a strong bearing on product quality. Some of these are noted in the article "Design for Manufacture and Assembly" in this Volume. Ease of assembly and freedom from quality problems tend to go together. A simple, easy-to-assemble product design is more apt to provide higher product quality. Some assembly recommendations that bear particularly on product quality can be summarized as follows:

- Design parts so that they can be assembled only in the correct way. This normally involves incorporating some feature that prevents the component from fitting its mating part if it is not oriented correctly. One other possible approach is to make the parts symmetrical, so that there is no feature that can be misplaced (Ref 1).

- Design parts so that if they are omitted in assembly, it will be visually or otherwise obvious. (For example, make it a different color than the surrounding parts or design it so that subsequent parts will not fit correctly if it is omitted.)
- Design parts so that they cannot be assembled out of sequence or in the wrong place or so that they can get damaged during assembly. This may involve some change in shape such as an added boss, arm, or other element or a change to make the mounting surface of the part curved or angled.
- Design parts so that they nest into the previously assembled part. This may obviate the need for additional fixtures and will help ensure that parts are assembled correctly.
- Design parts so that access to them in the product and vision of them is unobstructed (Ref 4). (This is a design for service guideline as well.) This will promote correct assembly and will help verify that it is correct. It will facilitate testing and replacement of parts, if necessary.

Robust Design*

Lance A. Ealey, McKinsey & Company

Introduction

ROBUST DESIGN, also known as Taguchi Methods or quality engineering, is an integrated system of tools and techniques that allow engineers and scientists to reduce product or process performance variability while simultaneously guiding that performance toward the best possible level. The techniques, which are useful across a spectrum from the research laboratory to the factory floor and beyond, have been developed and refined by Dr. Genichi Taguchi over the past forty years. Dr. Taguchi, long a respected consultant to Japanese industry, has in the past decade become well known outside of Japan, particularly in the United States and Europe. Thousands of companies routinely apply robust design techniques to achieve rapid, simultaneous improvements in cost and quality, as well as reductions in the time required to develop and optimize products and processes.

Major robust design techniques, tools, and concepts include the quality loss function, parameter design, tolerance design, signal-to noise ratio, technology development, and orthogonal arrays. Each of these is discussed briefly in this article. First, however, this article addresses some of the problems associated with traditional approaches to quality.

The "In Spec" Dilemma

Quality, according to the traditional American manufacturing interpretation, is inexact. Imagine that engineers at a company making axle shafts come up with two tolerance limits, one upper and one lower, for a critical seal fit. If the axle shafts fall within those tolerance limits, they are all thought to be of equally good quality. This is known as conformance to specification. Theoretically, if products conform to specification, they are perfect. Conformance to specification has been characterized as a go/no go or pass/fail type of control: If the part is in specification, it's a "go" or good part; if it doesn't fall within specification limits, it's a "no go" or defective part (Fig. 1). When all axles are "in spec," there are zero defects, and all is right with the world. But is it really? The more uniform the axles are, the more balanced or controllable the next event or process on the assembly line will be. Suppose all the axle shafts conform to specification, although all are grouped near the specification's lower limit--that is, the axle shafts are consistently smaller in diameter than the target specification. Suppose also that the oil seal manufacturer builds parts that conform to specification, although they tend to conform on the high side, consistently greater in diameter than target. The problem begins when the final assembler fits the large-diameter seals on the small-diameter axle shafts. The possibility of leaks occurring in the field is high, because the seals have a looser-than-target fit on the shaft. This phenomenon is known as tolerance stackup.

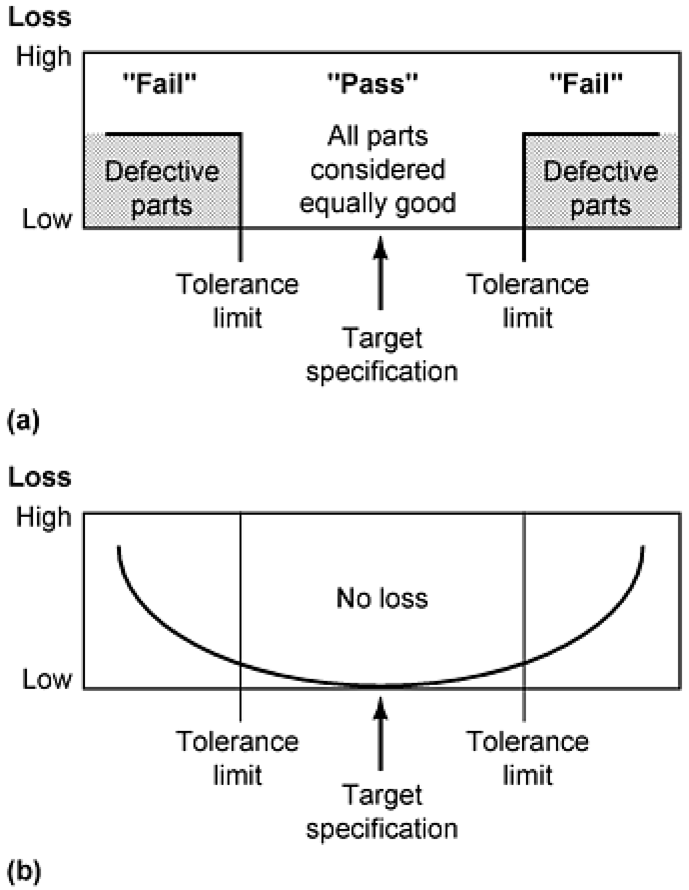

Fig. 1 Two approaches to quality. (a) Traditional conformance to specification (pass/fail) approach. A problem with this approach is that it makes no distinction between on-target performance and marginal, "almost-fail" performance. (b) Taguchi quality loss function approach. Loss increases quadratically as the product or process drifts away from the target specification.

Tolerance stackup may not be a critical reliability problem when only two variables--the axle shaft and the seal--are involved. Nonetheless, it's what produces variability in final product quality. Tolerance stackup is the reason that one car's transmission shifts so smoothly, while the next works like a stick twirling in a bucket of bolts. In areas where many critical tolerances meet, tolerance stackup can be disastrous.

Example 1: Tolerance Stackup in Automobile Doors.

Automobile door closing effort is a famous example of how tolerance stackup can affect a customer's perception of product quality. An automobile door closes over a virtual crossroads of tolerances (Fig. 2). The complexity of this stackup is so great that, even if all door-system components are assembled within specification but not to target, it's sometimes impossible to build a door system that meets all closing-effort and weather-sealing specifications.

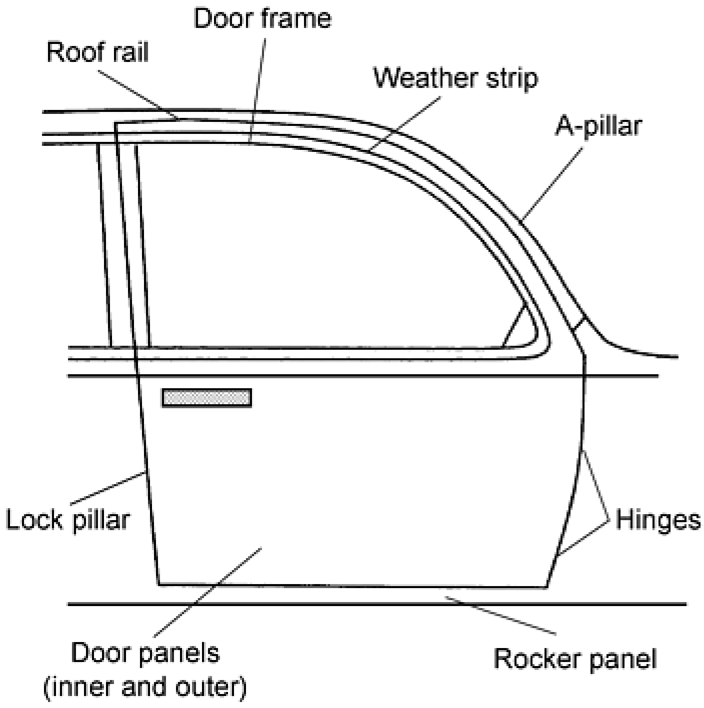

Fig. 2 Automobile door components that can contribute to tolerance stackup. Tolerance stackup may require reworking of parts to achieve proper fit.

In the not too distant past, doors on American cars required a greater effort to close than the doors on Japanese cars, because of tolerance stackup. Customers apparently want a door that closes at a certain number of pounds of pressure because it "feels" right to close the door at that level of force. When American engineers pulled apart Japanese cars to see how they were built, they discovered that, virtually without fail, doors on these cars closed at or around that ideal pressure, about 8 lb of force. The typical closing pressure for an American car was higher, about 12 to 16 lb of force, or varied from car to car. Why? Because all of the tolerances that met at the door were not at or near a target specification, but instead ranged from the specification limit's high to low ends. The result was doors that closed too lightly and thus didn't have watertight fits, or doors that had to be slammed shut.

On many older domestic automobile assembly lines, there are door fit "specialists" who shim hinges and seals or bend metal to make sure the recently attached doors have a watertight and nonbinding fit. As a rule, Japanese automakers don't have many door fit repair personnel on their assembly lines. Some of the latest vehicles from the "Big Three" American manufacturers are following the Japanese model, in which variation-causing tolerance stackup is designed out.

Example 2: Two Approaches to Quality in the Manufacture of Automobile Transmissions.

A well-known case pitting conformance to specification against target specification involved an American auto company and a Japanese auto company. The American company asked the Japanese company to build transmissions for a car to be sold in the United States. The American company was building identical transmissions for the same car at an American plant. Both companies were supposed to build the transmissions to identical specifications. The American company, however, was using conformance to specification as its quality standard, while the Japanese company was building every transmission as close to the target specification as it possibly could.

After the transmissions had been on the road for a while, it became apparent that the American-built transmissions were generating higher warranty costs and customer complaints about noise than the Japanese gearboxes. So, the American company disassembled and measured samples of transmissions made by both companies. At first, the American company thought its gages were malfunctioning--it couldn't find any variability from transmission to transmission among the Japanese gearboxes. Instead of using the go/no go conformance to specification approach, the Japanese company had consistently built its transmissions to target specifications.

The American manufacturer discovered that by working to continuously reduce variability around targets, the Japanese manufacturer incurred lower production costs. The American company, on the other hand, was paying for inspection, scrap, rework, and, ultimately, warranty costs. Indeed, the Japanese manufacturer's bid for the work indicated that it planned a total investment two-thirds less than that planned for the American plant. Because the Japanese company worked lean, with very little inventory, it was saving nearly $10 million in its transmission plant, just in material handling equipment. The American company learned this lesson well and has since implemented a very successful policy of continuous improvement around target values as its company-wide goal. In recent years this goal has spread to the company's suppliers through its supplier certification program. In fact, the company's manufacturing productivity today is among the highest in the global auto industry, Japan included.

Cost and Quality. American racing engine builders have always considered uniformity around target specifications to be a higher level of quality than simply staying within specification limits. The whole notion of the desirability of a "blueprinted" engine supports this claim. An engine builder meticulously measures every critical dimension of an engine--bearing clearance, piston fit, and so forth--and removes those parts that aren't at the target specification. The builder then substitutes parts that are built exactly to the target specification and rebuilds the engine. Why? To ensure optimum performance and reliability--that's quality, isn't it? Yes, but inspecting every part and scrapping those that don't measure up is expensive quality.

To a lesser degree, this is the method that American companies have traditionally used to ensure quality, because they did not attach a cost to quality. The Japanese quality surge was keyed to cost reduction, and thus the two terms became interchangeable. This interchangeability is the reason the Japanese are fanatical about quality: not because they care more about their customers than American manufacturers do, but because they care more about cutting costs. This idea is the driving force behind the concept of uniformity at a target specification.

Robust Design*

Lance A. Ealey, McKinsey & Company

The On-Target Key

Uniformity in and of itself is not the entire answer to having the same quality level from the first part produced to the 10 millionth. The tolerances of those 10 million products must be grouped close to a target specification in order to fulfill the designer's intent, which must be based on customer requirements.

Example 3: Target Specifications for Vinyl Sheet.

On many Japanese farms, neat rows of vinyl sheeting are positioned umbrella-like over certain easily damaged crops. These are a low-cost type of greenhouse. The vinyl is used by farmers to protect crops from the elements, thus extending the growing season. Typically, the thickness of the vinyl sheeting is, say, 1.0 mm, and acceptable tolerance limits for the thickness are ±0.2 mm. In other words, sheet that ranges in thickness from 0.8 to 1.2 mm is considered acceptable for use by farmers, according to the Vinyl Sheet Manufacturing Association.

One vinyl sheet manufacturer, through a series of quality improvement efforts, was able to reduce the variation in its processes to a remarkable degree. This manufacturer could hold tolerances of ±0.02 mm, quite an achievement. This new ability to create vinyl sheeting of extremely uniform thickness got the company managers thinking along these lines: If the company could make all its sheeting on the target specification's thin side, say at 0.82 ± 0.02 mm, it could save a considerable amount of money by using less material per square meter of vinyl sheeting. And, it would still be within the association's tolerance limits. Once in the field, however, this uniformly thin vinyl sheet tore easily, and farmers had to constantly repair or replace it. Sheeting that had a manufactured thickness that was uniform around the target thickness of 1.0 mm was thick enough by design to withstand the elements. Because of the increased number of complaints from the field, the association specified that the *average* thickness of the steel must be 1.0 mm and that the thickness variation could range ±0.2 mm.

Despite the fact that the company's sheeting was incredibly uniform in thickness, the technology that made that uniformity possible was not used to gain a quality-driven market advantage. Such an advantage--a sales point--would be increased toughness due to higher uniformity in sheeting thickness, and there would be a resulting increase in the

company's reputation among consumers. Instead, the company used its technology to uniformly reduce the robustness of the sheeting, with subsequent unfortunate results for crops, farmers, and, ultimately, consumers.

Robust Design*

Lance A. Ealey, McKinsey & Company

A Philosophy of Loss

The concept of tying quality to degrees of loss is an important one. Dr. Taguchi defines product and process quality in just those terms. Quality, Taguchi says, is the loss that a product imposes on society after it is shipped. The philosophy behind that statement is elegantly subtle. All products ultimately cause loss: they wear out or break and need to be repaired or replaced. The sign of quality is how much service a product provides before wearing out. A high-quality product causes little loss, because it fulfills its intended function for a period of time that customers consider adequate. A low-quality product, on the other hand, causes loss at every turn.

There are no absolutes in the realm of quality: a superb-quality product of one era may be deemed merely adequate in the next. This is why it is so important for companies to base quality specifications on the end-customer's requirements, not on internal guesses or competitor performance. And customer requirements change constantly. In 1979 in the American automotive market, for example, the American companies were averaging five to eight defects per car produced, while Japanese offerings averaged from two to three. At the time, the Japanese quality levels were considered extraordinary. Today, those 1979 Japanese cars would be considered worse than all but the lowest-quality cars, showing how customer expectations have continued to evolve.

The amount of service a product gives before creating loss has to at least equal the consumer's dollar-value expectation. Ideally, it should exceed this expectation. The only way a manufacturer can ensure this type of quality is by producing products that closely match the original design's blueprint, which in turn must closely match the end-customer's expectations. The manufacturer does this by designing desirable and buildable products and then producing them to these customer-focused target values, rather than by producing them within relatively broad specification limits and then sorting out defective products (which adds cost). This idea represents a dramatic departure from traditional quality/cost thinking, in which quality and cost are thought to be in conflict (the higher the quality, the higher the cost). Taguchi argues that lower cost is the driving force behind higher quality. In a quote from 1984 he noted, "American industry is amazed that Japan can produce high-quality products at such low costs; they're not amazed at Japanese quality. If Japanese automobiles cost two times more, most Americans would stop buying them."

Robust Design*

Lance A. Ealey, McKinsey & Company

The Quality Loss Function

Taguchi's quality loss function (QLF) allows an engineer to put a dollar value on quality. It provides an evaluation of quality in financial terms--that is, quality loss due to deviation from the target as well as quality improvement. The QLF is perhaps most effective as a way to choose among competing designs for the best, most cost-effective solution, which, in fact, is the primary way many Japanese companies apply it. It can be used both to evaluate loss at the earliest stage of product/process development and to incorporate improvements in quality into management planning. It provides a common language understood by both managers and engineers.

The QLF curve is quadratic in nature: Loss increases by the square of the distance from the target value (Fig. 1b). Thus, if a deviation of 0.02 mm from the target value generates a $0.20 loss, then a deviation of 0.04 mm would cost $0.80, a deviation of 0.06 mm, $1.80, and so forth. In other words, if deviation is doubled, the loss is quadrupled. If deviation is tripled, the loss increases nine times.

The QLF allows a manufacturer to economically justify a practice that has long been a black art in American engineering: the setting of product tolerances. Much traditional tolerancing is done mainly by experience. After designing a product and assigning target specifications for all dimensions, the engineer checks the specifications on the last product the company designed and sets the tolerances accordingly. This method of setting tolerances is usually expensive, because the conscientious engineer will typically set tolerances tighter than probably necessary to reduce the risk of premature failure in the field. Traditionally, tight tolerance limits have been considered more expensive to maintain than looser limits, because they usually require better materials or high-quality manufacturing equipment.

But do these engineering specifications realistically relate to the way customers see quality? Once again, we've come back to the notion of paying for quality. The problem here is that the only real-world feedback comes when warranty costs skyrocket. The engineer then knows that the tolerances weren't correct, but the damage has already been done. On the other hand, if warranty costs do not go up, the engineer has no idea whether the tolerance levels are set too tightly, which could mean the product is overdesigned and thus more expensive than necessary to meet or exceed customer requirements.

By using the QLF, the engineer can set tolerances according to customer sensitivity to loss. Ideally, the manufacturer should set tolerance limits at the breakeven point between the cost to rework a product and the cost of the consumer-absorbed loss.

Example 4: Using QLF to Determine Voltage Tolerances for a Television Set.

A television manufacturer builds TVs with a target voltage specification of 115 V. The manufacturer knows from customer research that the consumer will, worst case, tolerate a deviation of ±20 V from this target specification. If the voltage of a TV remains at 115, the consumer experiences very little loss: the TV works fine. If the voltage drops to 95 or less or climbs to 135 or more, most consumers will be dissatisfied with the performance of their TV and will take action. This action will come in the form of demands for the manufacturer to repair or replace the TV, which will cost, say, $100. This tolerance is the absolute limit of acceptance for consumers--many will become dissatisfied long before this limit is reached. In real-world terms, this tolerance usually represents the highest amount of loss possible. Obviously, a manufacturer would not set production tolerances this wide.

This limit of ±20 V is called the functional tolerance, or LD-50 (at least 50% of the consumers are unhappy), in Taguchi terminology. It is not a specification limit; rather, it is a functional limit. Taguchi uses this information and the QLF to develop actual production tolerance limits for the product. Loss projections can be developed for any other deviation from the target voltage if the cost of the loss at the LD-50 has been determined (in this case, $100 ± 20 V).

Now suppose that it is possible to rework the TV at the end of the assembly line so that its voltage is within limits at a cost of $2 per TV. It is now possible to use the QLF to discover at what voltage level the loss to the customer (and possibly to the manufacturer) will be equal to the cost of rework, or $2. In this case, this voltage is ±2.83 V (rounded to ±3.0 V). So, only if the voltage is less than 112 or greater than 118 should the manufacturer spend $2 to fix the TV.

The engineer has economically justified the specification limits: within the range of 115 ±3.0 V, the loss generated by variation equals or is less than the cost of reworking the TV. Had the engineer set the specification limits tighter than ±3 V, the manufacturer would be spending more money than is justifiable to meet the customer's quality needs. If, on the other hand, the engineer had set the tolerance wider than ±3 V, the manufacturer would save money in rework costs, but the cost to the consumer would be a great deal more, due to the nature of the quadratic curve of the QLF. For this reason, Taguchi says a manufacturer who betrays customers in such a fashion is worse than a thief: The manufacturer saves $2 but robs the customer of much more.

In figuring the loss caused by variation, a company can use only concrete dollar items such as warranty or scrap costs or include intangibles such as goodwill or customer inconvenience. If intangibles are included, one must look for a median versus a worst-case example, which could skewer subsequent loss computations.

Justifying Costs

QLF, aside from pegging tolerance limits to real-world effects, also helps a manufacturer in another way. The go/no go approach of conformance to specification makes it impossible for a manager to justify spending money to improve a process if that process is already building parts that conform to specification. Under the company's definition of quality, every part that conforms to specification is perfect.

The manager whose company is instead striving for continuous process improvement realizes that while perfect production (e.g., products that are built exactly to target specification) is impossible to achieve, the philosophy behind the concept provides benefits long after production quality is at world-class levels. Why? Because workers and management have a common goal: continuous improvement. The manager at this company can easily justify the expense by showing that output isn't uniformly grouped close to the target specification but rather is scattered widely across the specification range.

The concept of conformance to specification was an important first step in bringing manufacturing operations into control. But quality is relative. So while traditional American companies continue to measure quality performance in terms of defects per 100 products, world-class western and Japanese companies long ago began thinking in terms of defects per million or even per billion products. The enlightened manager will realize that the competition has moved its manufacturing performance far beyond conformance to specification.

There comes a point of diminishing returns in the quest to build all parts exactly to target specification: Quality becomes so uniformly high that one can't justify spending additional capital to improve it further. Under the concept of continuous improvement, however, workers continue to strive to improve quality through low-cost methods: by developing foolproof tools, refining parts bin positioning, and so forth.

Many American managers have problems with the idea of continuous improvement, in knowing exactly when the point of diminished returns is met. In other words, how do you know when to stop spending cash to improve quality? For the answer to that question, we turn once again to the QLF.

As described earlier, the QLF can be used to set tolerance limits for a product. Knowing the product or process deviation, and the loss due to scrap and rework and current tolerances, the manufacturer can determine the loss per unit for a given performance level of a process. It can then calculate the loss due to variation and decide whether further expenditures for improvements in quality are justified.

It is important to remember that according to the QLF, loss is quadratic, not linear, depending on how far the product is from the target specification. Loss increases dramatically the further the product strays from its target specification. This loss can include everything from the effects of tolerance stackup to the consumer inconvenience caused by products that must be returned for repair. It can also be rooted in strictly accountable costs, such as warranty claims and rework.

Robust Design*

Lance A. Ealey, McKinsey & Company

Parameter Design

Taguchi defines the development of a product or a process as a three-stage operation: system design, parameter design, and tolerance design. System design is the primary development stage in which the basic architecture of a product or a process is determined. During system design, the design engineer seeks to create a product or a process with distinct capabilities that will later serve as sales points. The system designer calls upon his or her expertise in the design of similar

systems to generate a new system that is superior in some way to previous designs. Robust design usually isn't applied to system design. It's estimated that American engineers focus 70% of their efforts on system design (compared to Japanese engineers' 40%), and only 2% on parameter design. Japanese engineers, on the other hand, apply 40% of their efforts to parameter design, the stage where costs can be most efficiently controlled.

Quality Characteristics. During parameter design, the design or process engineer seeks to optimize system design performance through experimentation that minimizes variation in the face of uncontrollable user and environmental factors. The engineer begins by identifying the quality characteristics that most affect system design performance, especially as it affects the customer. For example, a quality characteristic for a car might be that it starts easily and quickly every time, no matter what the external conditions are (e.g., a temperature range of -30 to +130 °F). Most products will have more than one quality characteristic, and it is important for the engineer to discover which quality characteristics consumers value most highly.

Noise Factors. During parameter design, the engineer seeks out all factors that will have a negative effect on the quality characteristic. In the case of the starting car, the list of factors would include outside temperature, humidity levels, the altitude range at which the car may operate during its lifetime, the fuel grades available in the regions the car may be used in, and so forth.

Notice that the engineer really has no control over these factors. For example, the car company can't tell the car buyer that the car shouldn't be operated when the temperature dips below or climbs above a certain temperature. So the engineer's goal must be to make the car resistant to these uncontrollable factors or, in Taguchi's words, "robust against noise." Taguchi calls these uncontrollable factors *noise factors.* Noise factors usually cause quality characteristics to deviate from target values, which subsequently causes quality loss.

Temperature, altitude, and fuel grade are considered *external noise factors* because they affect the product but are outside the control of the product designer. Two other types of noise factors also exist: *internal* (e.g., deterioration over time as the car battery wears down or as critical engine parts wear out) and *product-to-product* (e.g., one car assembled to target specification always starts while another, plagued by inconsistently made parts, does not).

Once the engineer has identified the various sources of noise that affect the quality characteristic, he or she sets about to create a system design that will allow it to operate consistently over time, regardless of noise. The engineer doesn't attempt to control the noise factors, but instead designs around them: Attempts to control noise usually prove impossible or add cost.

Establishing Design Parameters. The engineer then identifies design elements that need to be robust against the various noise factors. In the case of the car, these would include the drain placed on the battery, the primary ignition voltage, the efficiency of the starter, and the effectiveness of the fuel and air delivery systems. These factors are called parameters: factors that will be optimized to create a robust product (in this case, a car that starts easily, quickly and consistently under all conditions).

Once noise factors and parameters have been identified, the engineer determines multiple settings for each parameter in conjunction with others who have special knowledge regarding the various parameters. For example, starter settings might include turning the engine at three different speeds (i.e., the current speed and two alternatives that the engineers believe, due to their experience, might produce better results).

Experimentation to Determine Optimum Parameter Levels. Once the various settings or levels of operation for each parameter have been determined, the engineer begins to design the series of experiments that will ultimately reveal the optimum level of each parameter. The selection of these various levels is far from random; the engineer must use deep knowledge of the product or process to discover the best alternatives to the current level. With Taguchi's approach to experimental design, the engineer typically needs to run only a portion of the total experiments possible for various factors at their various levels. Rather than focus on the "trivial many," robust design focuses on the "vital few": A large number of factors with different operating levels can be easily assigned with a small number of experiments using orthogonal arrays (described below). However, the objective isn't simply to minimize the number of experiments, but to find reproducible results.

Analyzing Results Using Orthogonal Arrays. The engineer always begins experimentation using the lowest-cost parts and components, with the goal of optimizing them so that the product or process is on target, with little variability, and provides the most stable and reliable performance at the lowest manufacturing cost. At this point, the engineer will

use a linear graph to assign the control factors to an *orthogonal array* (Fig. 3). (An *orthogonal array* is a matrix of numbers arranged in rows and columns--each row represents the state of the factors; each column, a specific factor that can be changed from experiment to experiment. The word orthogonal comes from the Latin for "at right angles." Additional information is provided later in this article in the section "Orthogonal Arrays.")

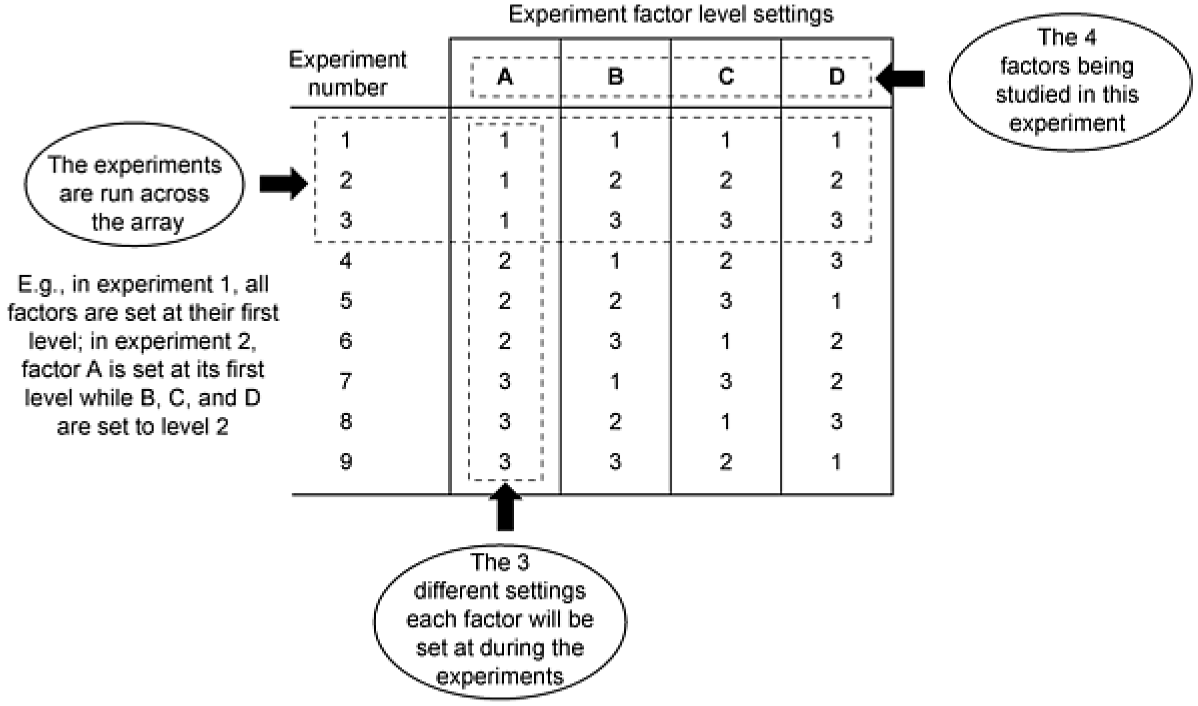

Fig. 3 Example of an orthogonal array. This L9 orthogonal array allows the experimenter to study the effects that four different factors at three different level settings have on the product or process under development. Because all factor levels are exposed to all other factor levels an equal number of times, it becomes possible to isolate the effect that each factor level has on the experiment. This allows the experimenter to identify the combination of factors that should provide optimum performance.

The orthogonal array for the control factors is called the *inner array*. The inner array varies the combinations of the control factors in a systematic fashion: Each factor setting or level of operation is exposed to every other factor level under experimentation the same number of times. This allows the engineer to make a balanced comparison between factor levels under a variety of conditions. A factor that exhibits a consistent effect with various conditions of the other factors will be more likely to reproduce this effect in the field.

Once the inner array is established, the engineer can create an orthogonal array for the noise factors, which is called the *outer array*. Each noise factor is also assigned several levels. The engineer is now ready to begin the series of experiments. Each experiment in the inner array is run several times against the combination of noise factors in the outer array, and each time an experiment is run, the engineer varies the levels of the noise factors. Thus, the engineer exposes the control factors of each experiment to the effects of various combinations of noise factors, which allows the evaluation of the product or process with respect to robustness against noise and the related costs.

The engineer will typically only run a fraction of the total experiments possible for the various parameters at their various levels. Factors that exhibit consistent effects, no matter how many different noise and parameter factors are changed around them, will be significant in increasing the mean result of the experiments or in reducing the deviation from the target specification.

Once all the experiments have been randomly run, the engineer begins to analyze the generated data. Because each experiment was run several times, the engineer has a performance range that shows the average result of the experiment and the performance variation around that average. The engineer must also verify the predicted results of the experimentation by performing a confirmation experiment. If the predicted results are not confirmed, the engineer should redevelop the experiment.

Signal-to-Noise Ratio. The information generated by the experiments is used to calculate a value for the signal-to-noise (S/N) ratio for each experiment. The S/N ratio is in reality a data transformation that expresses the variability and ideal function of the quality characteristic better than the actual data would. The S/N ratio indicates how much variation around the average or mean performance each experiment has generated, projecting field quality performance from the experimental data. The S/N ratio is the operational way of incorporating Taguchi's QLF into experimental design. The larger the S/N ratio, the less variability around the mean, and the smaller the quality loss.

The S/N ratio shows the engineer exactly how robust the product developed from each experiment will be when exposed to a wide range of noise factors. For example, one engine may start well under cold temperatures and at low altitudes but suffer from vapor lock at high temperatures and high altitudes. The engineer is seeking the combination of parameter settings that allows the engine to start easily no matter what the altitude, temperature, and other conditions.

At this point, the engineer could simply choose the experiment that produced the highest S/N ratio as the optimum engine-starting condition. However, the result would probably be far from optimum. Because the experiments were using orthogonal arrays, however, the engineer can go one step further. He or she can conduct other analyses to find the effect of each factor on the average or mean performance of the quality characteristic in the experiment. The engineer is now ready to sort control factors into those that have a strong effect on reducing variability, those that have a strong effect on mean performance, and those that have little effect on either.

Thus, the parameters are classified according to the effect they have on the S/N ratio. Those factors that affect the S/N ratio are used to reduce variability. Those with a strong effect on the mean but little effect on variability are used to adjust the mean performance closer to the target. They are called *adjustment factors.* Those with little effect on either are also important. Here the engineer can select the cheapest levels to reduce cost. They are referred to as *cost-adjustment factors.*

The engineer is thus able to create a product with those factors that can give, in the starting car example, the fastest starting time, those that can reduce the variation in starting time, and those that allow cost to be minimized. The engineer can thus improve quality while reducing cost. From the experimental data, it is possible to choose the parameter settings that will give the fastest starting time with the least amount of variation at the lowest possible cost.

Finally, the engineer combines all of the selected signal, control, and unimportant factors into yet another experiment to check the reproducibility of the results. If the results of this experiment don't come close to yielding the performance specified by the quality characteristic, the engineer must rethink the experiment. Either an important parameter has been missed that directly or indirectly affects starting performance, or the various parameters may have combined to create an interaction that cancels out their combined efficiency, which results when a poor quality characteristic is picked for experimentation. In either case, the engineer will have to redesign the experiment.

If the results of the confirmation experiment do yield an optimum combination that allows consistently fast starts, the engineer checks the results against the desired performance of the original characteristic. If the performance of the optimum combination of factors shows enough improvement in starting-speed consistency, the engineer has successfully completed the experimental-design work.

But what if the improvements in quality and cost still aren't great enough to meet the competition? Suppose, for example, that the starting speed consistency still doesn't meet the quality-characteristic specification. The engineer could try another experiment, or proceed to tolerance design. Improvements made during tolerance design usually require more expensive materials or components and therefore add cost.

Robust Design*

Lance A. Ealey, McKinsey & Company

Tolerance Design

During tolerance design, the engineer will systematically identify how much the performance levels of certain parameters will have to be increased in order to meet the quality characteristic. The engineer calculates the percentage contribution that each of the factors makes toward achieving the required performance for the quality characteristic. From this information, the engineer decides how much to reduce the tolerance levels of each factor in order to achieve the objective.

Tightening the tolerances of the factors almost always involves upgrading with higher-cost parts or components. The QLF is used during tolerance design to find the most cost-effective way of determining which tolerances must be tightened, and which can be left in place or opened up, in order to reduce cost.

For example, if the automobile starter is drawing too much power from the battery, the engineer will upgrade it with a more efficient and expensive unit. By using the QLF, the engineer can calculate just how much better the starter has to be to meet the quality characteristic. Hence, he or she will not upgrade a parameter beyond actual need, which would be more costly than necessary.

At this point, the experimenter can perform another experimental design run to select the most appropriate upgrades for the various factors. The engineer has now completed optimization and can be assured that the starter will perform as intended and under all foreseen conditions. As a final step, the loss function can be used to calculate the savings generated by the optimization.

Robust Design*

Technology Development

As Taguchi began to visit more large American companies in the 1980s, he realized that there was a fundamental difference between the ways that American and Japanese companies developed technology. The Americans, he found, do much more "far-upstream" development in technology, which is focused on creating new technologies, whereas the Japanese tend to concentrate much more on "mid-stream" development work, which is typically focused on applying technology at the product and process level. In other words, whereas many American companies develop proprietary technology based on pure research, Japanese companies tend to concentrate their efforts much more on developing technology for specific applications in products and processes.

Because of this, the Japanese company ensures robustness only after the product planning stage, which usually means that every product derived from a specific technology has to be made robust. This can require significant resources and can take up quite a bit of time, even for companies as efficient at product development as the Japanese.

While many American companies apparently do quite a bit of basic technology research, few ensure robustness at the technology level. Instead, the typical reaction that Taguchi found when talking to research engineers and scientists in American laboratories was that quality assurance was not part of their job: their job was to develop the raw technology itself and pass it on to the product and process development engineers, who would make it work for specific applications.

Thus, both Japanese and American companies have shortcomings in terms of technology development: the Americans do a lot of basic research but do not attempt to make the technology robust, while the Japanese typically work to make technology robust only at the product and process development stage, which tends to be an inefficient use of resources.

Taguchi has said that he considers the western method of research and development to be superior to the traditional Japanese way, but that western companies have to begin to ensure robustness in technology during research and development in order to be successful.

The problem with the Japanese method is simple: when technology is made robust in the context of a specific product application, many times the same technology transferred to another product application will fail miserably, because the robustness achieved earlier was linked directly to the original product application. Instead of this, argues Taguchi, why not make the technology used in the products robust before product planning takes place? By doing this, the company would only have to "tune" the technology to apply it across many different product or process situations. The technology itself would be robust against noise, which in this case could include the product application itself!

In technology development, the engineer works to make the *basic function* of the technology robust, which Taguchi defines as an engineering issue, as opposed to the technology's *objective function,* which is typically a quality characteristic requested by the customer. The basic function can be thought of as the main input/output relationship of a technology. This relationship involves energy transformation. For example, in an automobile engine, the basic function of

the engine is to transfer the energy stored in gasoline or diesel fuel into motive power. Objective functions, on the other hand, could include the specific quality characteristics of a specific engine: high miles per gallon, low noise or exhaust emissions, and so forth. But the basic function of the engine remains the same: how efficiently does it transform energy into movement? Taguchi says that once you solve this basic energy transformation question at the technology level, developing the technology for a specific application simply means identifying those factors that will allow you to tune the technology to a specific application.

The engineer has thus made the engine technology itself robust: Developing entire families of engines may be as simple as using the tuning factors to make the technology work across many different applications. The brilliance of technology development is that it removes much of the uncertainty that inevitably surrounds a new technology introduction. Once the technology itself is made robust, application engineering becomes simply a matter of tuning, potentially cutting millions of personnel hours out of product development cycles, allowing a company fast response times to market forces, and cutting development costs at the product level by millions of dollars.

Example 5: Technology Development of a Machining Process.

A major Japanese automaker has used technology development to make process technologies robust. The automaker's use of a new heat treatment process raised the hardness of the steel to be machined to such a level that it became very difficult to cut using regular machining technology. The engineering team decided that the energy transformation in this case had to do with the relationship between the dimensions that were programmed into the numerical-control (NC) machine as far as how the steel was to be cut and the actual dimensions of the steel piece after it was cut. The notion was that this should be a perfect proportional relationship.

The goal was to develop the technology itself (i.e., a generic NC machine technology) to such an extent that no matter what hardness of steel, type of part, cutting tool conditions, etc. were involved, the technology would always give this perfectly proportional output to any dimensional programming input. As a result of the study, the standard deviation of the NC machining process was reduced to one-tenth that of prior performance, and this was achieved regardless of what kind of part was to be machined.

The implications of this experiment are enormous. Now, when the company's engineers need to develop a process for machining a part, they can simply tune the NC machining technology that was made robust in the above experiment, cutting the time and effort that have to be expended to a mere fraction of former levels.

Robust Design*

Orthogonal Arrays

The concept of the orthogonal array isn't new: The Swiss mathematician Leonhard Euler did considerable research on them in the 1700s. However, orthogonal arrays were little more than academic curiosities until the early to mid-20th century, when researchers led by R.A. Fisher began to exploit their inherent balance when laying out and conducting experimentation. What is new regarding Taguchi's use of orthogonal arrays involves the kinds of information he is looking for when he employs them in experimentation.

Designing Experiments without Using OAs. A typical way of performing industrial research in the United States is known as the "one factor at a time" method (Fig. 4a). An engineer identifies each of the design factors (also known as variables) and its different performance values. During the first experiment, all factors are held at their current values and the result is recorded. In the second experiment, one of the factors is changed to its low or high value. If this causes an improved result compared with the initial experiment, that factor value is adopted and in the next experiment one other factor is changed. The experimenter continues in this manner until the system has been nudged as close as possible to its performance target.

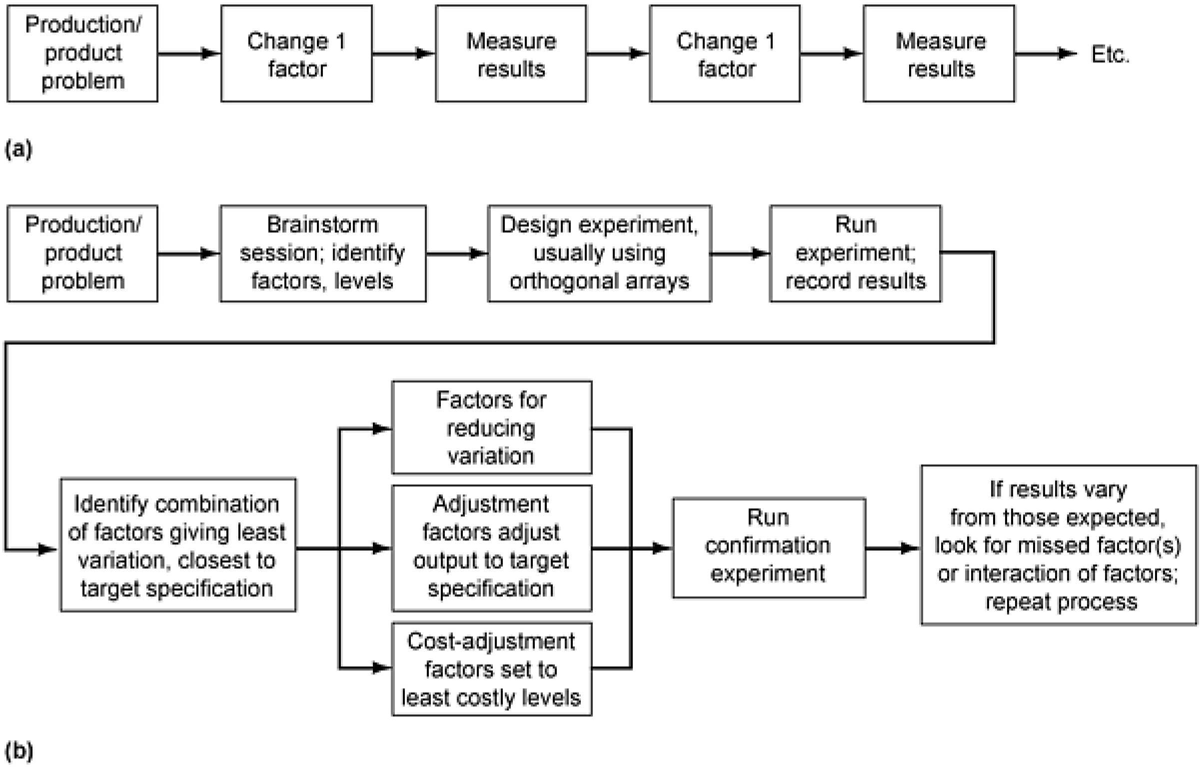

Fig. 4 Two approaches to problem solving during engineering design. (a) Traditional one-factor-at-a-time approach. (b) Taguchi parameter design approach

The trouble with results obtained in this manner is that they often have little in common with what happens in real life. In reality, rarely does one variable change while the rest remain fixed. Let's say an engineer is trying to optimize an automobile steering system. The engineer has decided that some 13 factors will be useful in attempting to optimize the steering (e.g., spring stiffness, steering geometry, etc.), and that each factor will be tested at three different settings or levels. The problem with using one factor at a time analysis becomes clear when you realize that, for example, while a certain spring stiffness provides ample performance when the road is dry, it may not work as well if the road is wet or icy, or if tire pressures are too low or too high. Thus, results obtained with the one-factor-at-a-time method may perform brilliantly in the controlled environment of the laboratory, yet fail miserably under the ever-changing conditions of the open road.

What this engineer needs, then, is some way to efficiently compare each of the three performance levels of any given steering factor with all the performance levels of all the other steering factors under test. If the engineer could do this in such a way as to separate, for example, the effect of spring stiffness at its high, low, and current settings on the experimentation as a whole, he or she could select the spring stiffness setting that consistently has the strongest positive effect. Since that spring stiffness setting has performed well, despite being tested in conjunction with every other setting of all 12 other suspension factors, it stands a very good chance of reproducing these positive results in the real world.

One way of doing this would be to perform all 1,594,323 experiments (3 to the 13th power). This would not be very efficient, to say the least. Our engineer needs a method that delivers reproducible results with a minimum of cost and in the shortest time possible. That's where the orthogonal array comes in.

Benefits of Using Orthogonal Arrays. The great power of the orthogonal array lies in its ability to separate the effect of each factor on the average and on the dispersion of the experiment as a whole. By exploiting this ability to sort out individual effects, large numbers of factors can be tracked simultaneously in each experimental run without confusion, thereby obviating the need to perform nearly 1.6 million possible combinations.

The ability to separate these effects is critical to Taguchi's technique (Fig. 4b). As noted above, when factors exhibit a consistent, positive influence on the experiment, no matter how many other factors are changed in the course of experimental runs, the results stand an excellent chance of working effectively under real-world conditions, thus

producing a robust product. The ability to generate such reproducible results is the primary reason that Taguchi uses orthogonal arrays in his quality engineering techniques.

The arrays used by Taguchi are balanced, pair-wise, across columns. This means that in any pair of orthogonal columns, all combinations of different factor levels occur, and they occur the same number of times.

In the L27 orthogonal array used by our car steering engineer, for example, any column may be compared to any other column, and nine different combinations, (1,1), (1,2), (1,3), (2,1), (2,2), (2,3), (3,1), (3,2), and (3,3), will appear three times each. This means that all three levels of spring stiffness will be exposed to all three levels of bushing stiffness, steering geometry, and so on an equal number of times by the time the final experiment is completed. This systematic exposure of every factor level to every other factor level is what's known as the "balancing" aspect of the orthogonal array.

The orthogonal array thus becomes the framework across which the steering engineer conducts the experimentation. Each of the rows in the array constitutes one experiment, and each column in the array represents a test factor. Column one, for example, could represent spring stiffness. Each of the 13 steering factors in our example will be tested at three different settings (for spring stiffness, these would be the current setting and a stiffer and softer setting, notated 1, 2, and 3 in the array). The engineer would then perform all 27 experiments, adhering to the arrangement of factor levels shown in the OA, and drawing lots to introduce an element of randomness to the experimentation.

It is important to note that the engineer isn't primarily interested in the end results of the 27 experiments in and of themselves. These may not produce large improvements over pre-experiment performance. (In this case, with almost 1.6 million potential combinations, there's a good chance they won't!) Instead, the engineer is mainly interested in exploiting the column-wise orthogonality of the array in order to separate the effect that each of the three spring stiffness settings, for example, has on the outcome.

In Taguchi's system, the orthogonal array allows the experimenter to identify those variables that will reduce performance variation, as well as those that will guide the product back to its performance target once robustness has been achieved. The orthogonal array is also used to find variables that have little effect on robustness or target values. These can and should be set to their least costly levels.

Taguchi often combines a second orthogonal array with the original to introduce "noise" into the experimentation. (The term *noise* in this sense refers to the error-causing factors that are either too expensive or impossible to control. Noise for the steering engineer could include ambient temperature, weather conditions, etc.) This practice can increase the potential robustness of the product to truly formidable levels.

One important final use Taguchi makes of the orthogonal array is as a screen for interactions among the control variables. Such interactions can compromise the reproducibility of the results during the confirmation experiment. If, on running the confirmation experiment, the steering engineer's results fall far short of those anticipated, strong interactions have probably been encountered. The engineer must then rethink the experimentation to find factors or quality characteristics that either do not interact or are robust enough to overcome interactions. In essence, Taguchi harnesses the power of the orthogonal array to provide a "design review" for the product before scale production is begun.

Risk and Hazard Analysis in Design

G. Kardos, Carleton University

Introduction

NO SYSTEM devised or used can be 100% safe or error-free. The objective of risk and hazard analysis is to identify the level of risk and to pinpoint the parts of the system that represent the greatest risk for failure. Then, if the analysis is used properly, steps can be taken to eliminate the cause or reduce the risk to an acceptable minimum. It has been demonstrated that hardware systems approaching a "failure-free" condition can be produced when actions are taken at all levels that are based on:

- Attention to past experiences with similar systems
- Availability of risk information for all project personnel
- A sound, aggressive risk and hazard analysis during all phases
- Development of suitable corrective action and safety programs based on the analysis
- A continuous and searching review of all phases of the program efforts

Rigorous applications of risk and hazard analysis have made difficult technological feats such as landing on the moon relatively accident-free.

The various analysis techniques have grown out of the search for system reliability. Consequently the approach is hardware oriented, with the emphasis on ensuring that hardware is able to perform its intended function. Backup systems and redundancies are used to reduce such risks. Through cost/benefit analysis, the performance of the system will have a computable value that can be compared to the cost of accomplishing the mission.

Risk and hazard analysis tools have been developed to ensure system reliability in critical applications. With the increased emphasis on safety, reliability, and achieving mission objectives, design teams must incorporate risk/hazard considerations in their designs. Figure 1 is a flow chart that shows the integration of risk and hazard analysis in the overall design process. Even if designers or design managers are not directly responsible for carrying out these analyses, they must be familiar with the methodology, so that they understand how they are carried out and how they can respond in terms of design or system changes. Most efforts are best carried out during early design phases, and they can be effectively used during design reviews to provide valuable feedback to the design to avoid failures.

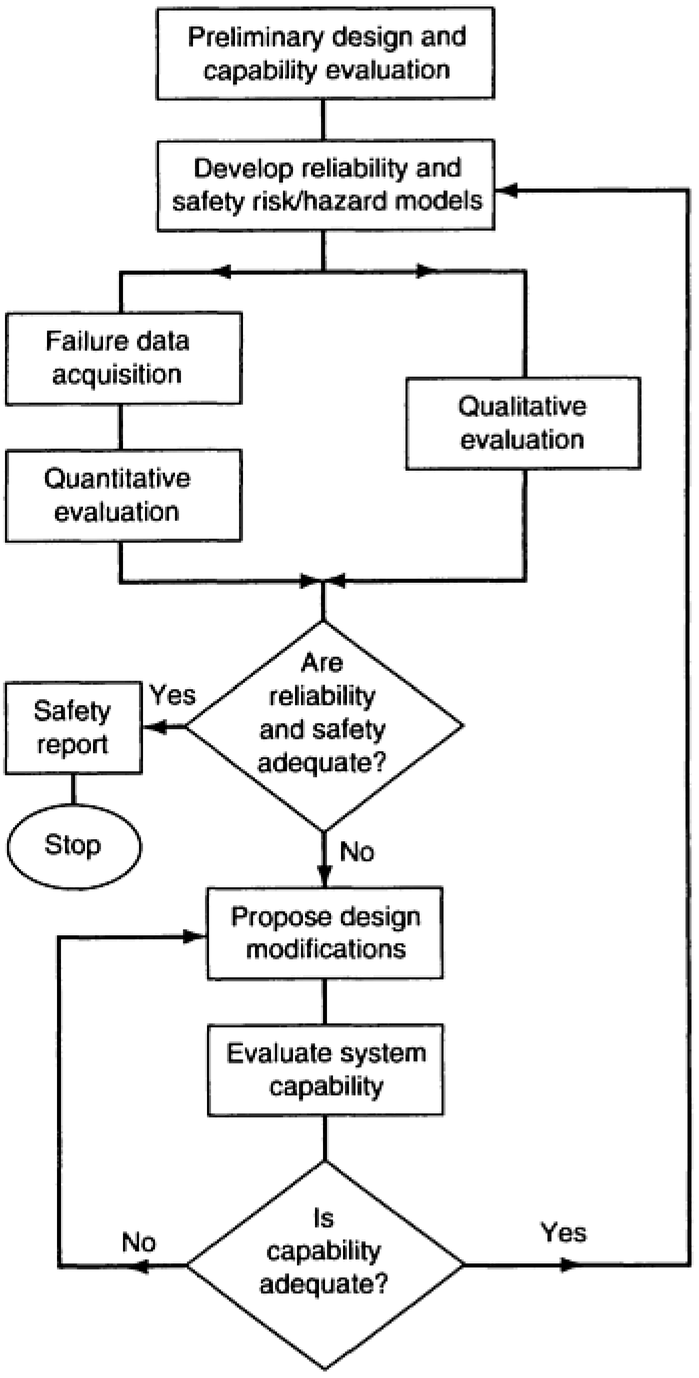

Fig. 1 Flow chart showing the integration of risk and hazard analysis into the design process. Source: adapted from Ref 1

This article outlines the principle methods of risk/hazard analysis as presented in the literature and as practiced by industry. It is intended to provide an appreciation for each method and an insight as to what can and cannot be accomplished with risk/hazard technologies. Related information is provided in the articles "Reliability in Design" and "Safety in Design" in this Volume.

Risk and Hazard Analysis in Design

G. Kardos, Carleton University

The Nature of Risk

All industrial and human activity involves risk and risk taking. Usually this risk is undertaken unconsciously or with only a vague notion as to the kind and magnitude of the risk. Here, the nature or philosophical basis of risk is explored because all hazard/risk analysis implies the acceptance of some level of risk. All risk analysis methods have as their prime objective the prediction of future risks.

The literature on the prediction of alternate futures is mixed with biases based on personal value systems and assessment of present trends. In truth, most predicted futures tell more about the person making the prediction than about any expected future. Decision makers, such as designers, cannot simply accept the validity of the predictions of the various experts, but must examine the logic, the assumptions and presumptions, to make their own evaluation and conclusions.

To clarify what is acceptable risk, Starr et al. (Ref 2) suggest it is useful to recognize the existence of four different definitions of "risk":

- *Real risk* is determined by actual circumstances as the future unfolds.
- *Statistical risk* is determined from currently available data, based on assumptions that a large number of future systems will, on the average, act the same way as a large number of similar past systems.
- *Predicted risk* is based on analysis of system, models, and historical data.
- *Perceived risk* is risk seen intuitively by individuals or society.

It should be noted that only the "real risk" is a property of the hardware. The other three represent the conception of the risk represented by the system. This conceptual risk can change and the other three forms of risk can change without changing the real risk in any way, simply by a better understanding of the system.

Because of the conceptual nature of risk, any careful analysis, experiment, or historical study may not correspond well with an individual's or society's perception of the risk. Statistical risk and predicted risk are generally analytical and quantitative, whereas perceived risk is qualitative. Because quantitative evaluations can only deal with those parameters that can be counted or computed, it is bound not to include *all* the parameters that concern an individual.

Perhaps the most important factor not accounted for in analytical methods is risk manageability or controllability. Individuals feel less threatened when they feel they have control over the time, place, and extent of the risk they are exposed to. The same statistical risk may be perceived to be less when individuals have a free choice over whether they will undertake that risk than when they are faced with having to simply "live with it."

Another important factor in the perception of risk is the probable severity of the consequences if an accident were to occur. A complete assessment of risk requires that the potential effects of an accident be somehow integrated with a probability of its occurrence. Unfortunately, the integrating function is not known and must be left to judgment.

Linked closely to severity of consequences in the perception of risk is the episodic nature of consequences. It seems that the size of a potential accident is more important than the probability of occurrence. This truly represents society's value system to a great degree. Activities capable of producing catastrophic accidents, therefore, are seen as a great risk and must be more stringently controlled than high-frequency individual risks.

As with risks, benefits may differ in perception from assessed value. Benefits are surely assessed more positively by those who benefit most directly. As with risks, the more directly the benefit impinges on us personally the more important it is.

It is in this region where gaps between perceived and assessed risks and benefits exist that government agencies are called upon to resolve the conflicts. When there is agreement between public and institutions, unanimity is easily achieved. But when differences in perception occur the resolution becomes difficult.

No general method of dealing with difference exists. The resolution cannot be made by application of technological, probabilistic, or statistical rules. It must be accepted that these differences are real and must be resolved in terms of humanistic and political concepts. The technical methodologies described in this article can identify possible hazards and possibly identify the resources that are necessary to avoid or reduce the risks; however, whether the resources *should* be expended to alleviate the perceived risk remains a political-humanistic-management decision. The justification for undertaking these technological studies is that they give a clearer picture of decisions that must be made. They cannot be expected to provide an automatic decision process.

One method often used for deciding on whether to undertake a project is the risk/benefit analysis (see the section "Risk/Benefit Analysis" in this article). Such an analysis involves two simplifying assumptions: first that risks and benefits can be stated in the same terms (dollars, for example) and second that both the risks and benefits are shared equally by all affected. Both these requirements can easily be satisfied when dealing with acquisition of a piece of hardware to perform a specific narrowly defined function (e.g., military hardware), but in instances of environmental hazards, neither assumption is likely to be satisfied.

The technological methodologies can quantify the inputs independent of the decision process. The value system that establishes the worth of alternatives must be added by all interested parties. In such a situation, clear distinction must be drawn between the scientific estimates of risk and perception of risk.

Generally the scientific-technological community advocates the use of quantitative analysis and risk/benefit assessments as the sole measure of whether to undertake a project. This is attractive because it makes the decision process simpler. But an opposite point of view is advocated by Kletz (Ref 3), who says that if risks exceed a certain level, they should be removed as a matter of priority, even though removal may be expensive; otherwise there is no incentive to look for less expensive solutions.

Risk and Hazard Analysis in Design

G. Kardos, Carleton University

Failure Mode and Effect Analysis

Failure mode and effect analysis (FMEA) was originally developed as a tool to review the reliability of systems and components. It has been modified over the years to include criticality analysis (CrA) and failure hazard analysis (FHA) to help determine equipment safety requirements. Its intent is still to ensure reliable system function. The objective of FMEA is to expose all potential element failure modes to scrutiny, to classify and quantify their possible causes with their associated probability of occurrence, and to evaluate their impact on the overall system performance.

Failure mode and effect analysis normally is carried out as part of a comprehensive reliability program. The analysis is performed at increasing levels of complexity as the design progresses, so that the recommendations resulting from the analysis can be implemented early at minimum cost. The results are to be used to guide other activities such as design, purchasing, manufacturing, and quality control.

Failure mode and effect analysis is a systematic, organized procedure for determining, evaluating, and analyzing all potential failures in an operating system; it is used to supplement and support other reliability or safety activities. The FMEA process involves examining each potential failure mode to assess if the system elements support reliability and to ascertain the consequences of the failure on the entire system. The general process involves the following steps:

1. The probable failure modes of the system are identified, evaluated, assessed, and documented.
2. The documentation of possible failure modes is used to check and verify the safety of the design.
3. Corrective actions are formulated to eliminate or reduce to an acceptable level the consequences of the failure.

To undertake an FMEA, it is essential at the outset to have well-defined and documented criteria for judging performance or safety. What constitutes hazard and at what level must be established at the performance definition stage. To be meaningful, the definition must classify failures in a clear and consistent manner. The *measure of acceptability* must be established before FMEA is undertaken. Similarly, the *conditions* under which the equipment must function throughout its entire life must be specified because the failures have to be analyzed under various operating modes and the transition periods between them.

Failure mode and effect analysis can be carried out at various levels of detail. Failures can be postulated at the component-part level or at subsequent higher subsystem levels. The level of detail at which the analysis is carried out is usually determined by cost constraints and the reliability required of the system. The more detailed the analysis, the greater will be the number of hazards considered, and the greater will be the cost and time required to carry out the analysis. Sometimes a less detailed analysis carried out in time to change the design may, in the long run, be more useful than an in-depth analysis available after completion of the design. The level of detail to which an analysis should be carried can only be based on experience.

Carrying out the FMEA is greatly enhanced by the use of standardized documentation. Failure mode and effect analysis requires an organized systematic approach; standardized documentation is a visible forcing technique that ensures that none of the steps are overlooked. The documentation also provides a historical record of what was considered. The format of the documentation should be arranged to "tell the story" of what happens when an assumed failure occurs.

The formal procedure (Fig. 2) for preparing an FMEA constitutes the following steps:

1. A functional block diagram or logic diagrams are developed for the system or subsystem (Fig. 3). Copies of these diagrams become part of the FMEA documentation. Individual items to be considered are identified by number.
2. All realistic probable failure modes of each element on the diagram are postulated and entered on the FMEA documentation item by item (Fig. 4).
3. The probable causes associated with each failure mode are listed beside each failure mode.
4. The immediate consequences of each assumed failure are described and listed beside the failure mode. Also listed are symptoms that would affect the function.
5. Any internal compensating provisions, within the system, that either circumvents or mitigates the effect of the failure, are evaluated and noted.
6. The effect of the failure on other components or systems is evaluated and documented.
7. The level of severity of each mode of failure is evaluated in terms of importance and documented as "critical," "major," or "minor."
8. A quantitative probability of occurrence of the failure mode is made. Where possible the probability should be expressed numerically (Ref 5). In some cases, categorizing may be more meaningful if commonly defined categories are used.
9. Finally, remarks and recommendations are documented. Here the analyst provides any additional data he feels would be meaningful.

Fig. 4 Completed FMEA form for a torpedo steering subassembly. Source: Ref 4

An abbreviated example of FMEA documentation is illustrated in Fig. 3 and 4. Figure 3 shows a block diagram for a torpedo system. This system is required to carry out its mission without posing a hazard to its operators or to other equipment. The torpedo must function satisfactorily in an operational environment of 10 to 1000 ft depth of sea water, at -55 to 105 °C, and subject to a launch shock of 10 g. The FMEA is carried out at component subassembly level. The FMEA of steering a hydraulic actuator subassembly is reproduced in Fig. 4. Similar analysis would be generated for each subassembly.

Failure mode and effect analysis procedures may vary in detail from company to company. In fact, it is important to tailor FMEA to the specific needs of the project. However, because of the emphasis on an organized approach, care must be taken that FMEA does not become simply a ritualistic exercise where the form is more important than the content.

The principle benefit achieved through FMEA is the qualitative one of having to scrutinize each item individually with respect to failure. Therefore, FMEA is best carried out as a cooperative effort between the design and the application engineer. The design engineer is best qualified to identify failure modes and effects. The application engineer usually is in the best position to evaluate the consequences and make beneficial recommendations.

When properly carried out, FMEA produces an orderly documentation of possible hazards. This becomes the basis for program planning and a source for design improvements or contingency plans aimed at eliminating or reducing the effects of failure.

Risk and Hazard Analysis in Design

G. Kardos, Carleton University

Fault Tree Analysis

Fault tree analysis (FTA) is intended to provide a deductive technique of probabilistic safety analysis. Fault trees are a diagram of the Boolean logic that relates the output event (called the TOP event) based on the state of the primary event. The fault tree itself is a graphical representation of the Boolean logic equations.

Boolean logic is made up of a series of simple logic statements called gates, which define the output based on the inputs. Usually, Boolean algebra deals with simple binary statements, true-false, go-no go, and so forth. The most common gates are the AND gate, requiring all inputs to be true for the output to be true, and the OR gate, requiring at least one input to be true for the output to be true. Typical fault tree symbols and organization are shown in Fig. 5.

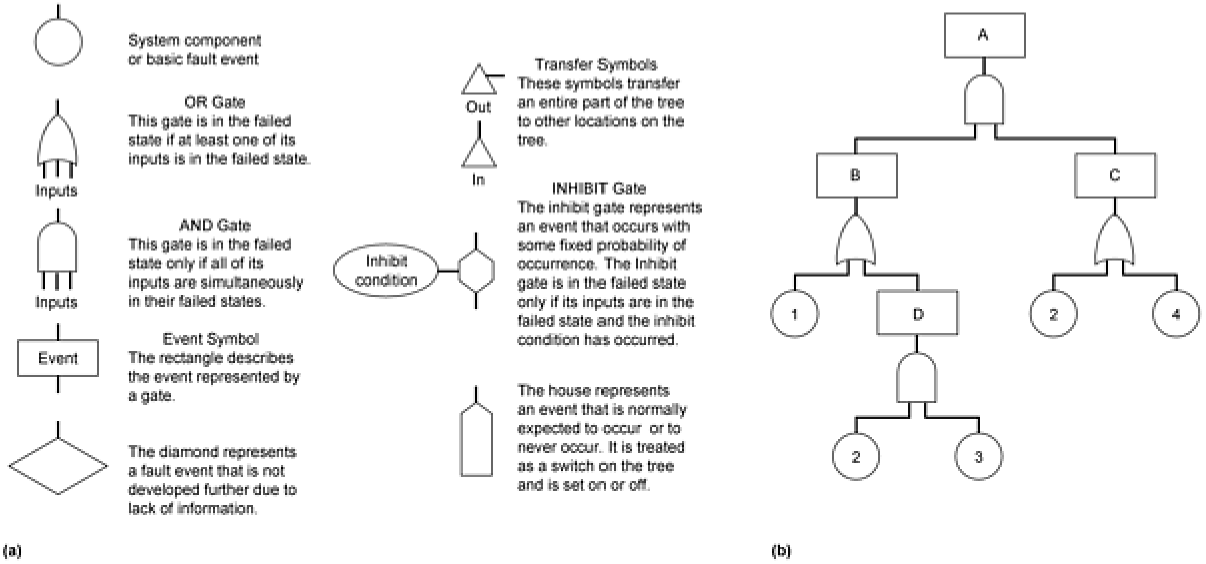

Fig. 5 Fault tree analysis. (a) Symbols. (b) Typical fault tree construction. Source: Ref 1

The versatility in the degree of detail that is reflected in an FTA is a main feature of the fault tree technique. The analyst has options for qualitative or quantitative analysis. The technique provides a basis for analyzing system design, justifying system changes, performing trade-off studies, analyzing common mode failures, and demonstrating compliances with requirements.

The point of view of the FTA is from the TOP event down. Each TOP event failure is analyzed to show what inputs or combinations of inputs from the next level down are necessary to cause the failure. As the fault tree construction proceeds, each fault is developed until basic events are reached. The failed TOP event is thus demonstrated to be a failure situation resulting from the logical interaction of specific basic events. In any one branch the event being developed is

called the base event of that branch. A branch of the fault tree is complete only when all events in the branch are developed to basic events. Figure 6 shows a fault tree developed for an automobile braking system. The TOP event is the fault that the brakes fail to operate.

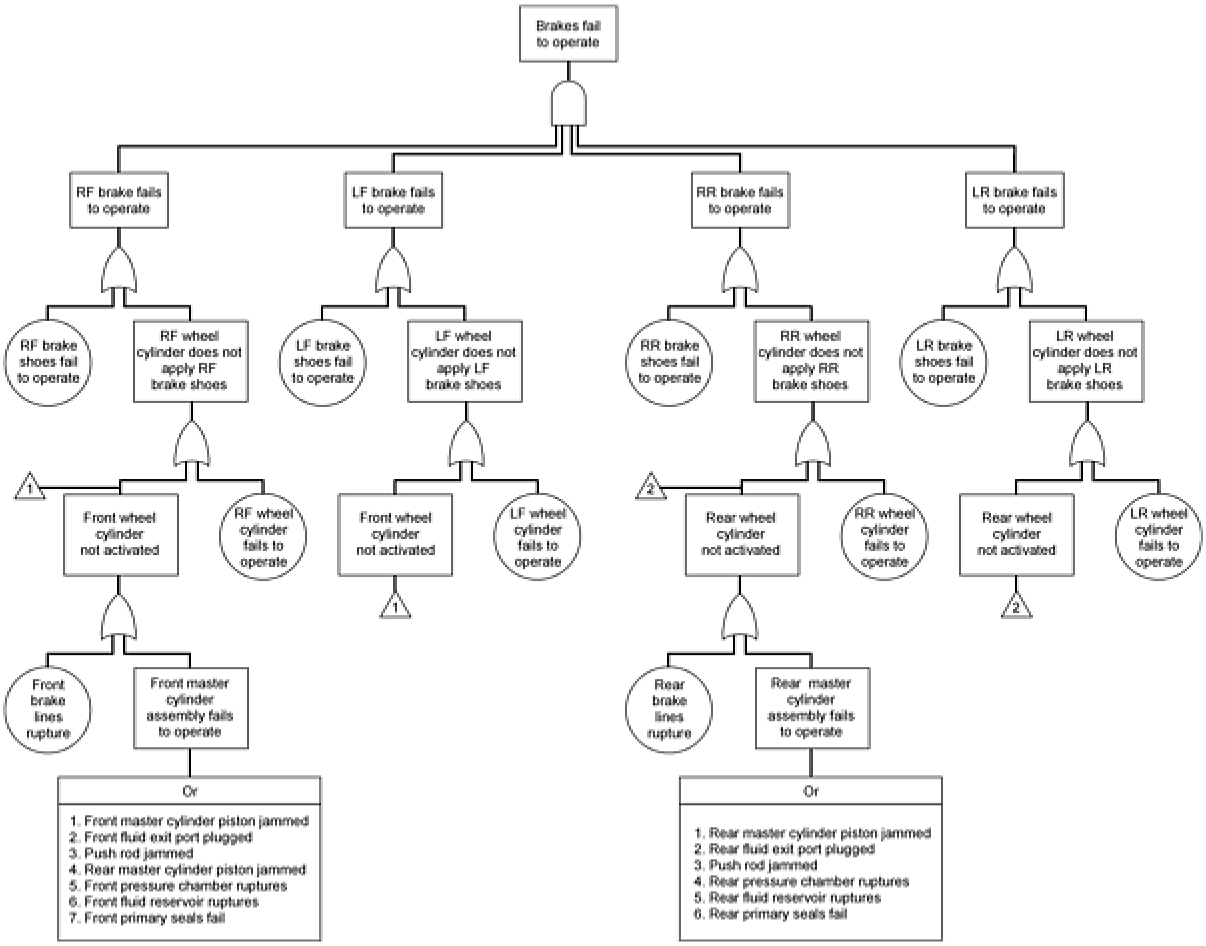

Fig. 6 Fault tree for vehicle braking system. RF, right front; LF, left front; RR, right rear; LR, left rear. Source: Ref 1

Events that can cause a TOP event are classified as primary faults, secondary faults, primary failures, and secondary failures. A failure is a change in a component that requires repair action; a fault is a change that does not require repair action. Secondary faults and failures are those for which the components are not directly responsible.

The fault tree is constructed from symbols to represent logical outcomes and events that constitute inputs and outputs. A selection of typical symbols used is shown in Fig. 5.

The objective of FTA is to determine the conditions (basic events) that could cause a specific final undesired event (TOP event). Therefore, in constructing the fault tree, only failure-related events are considered. The construction technique involves five steps:

1. The undesired events (TOP events) that will be used to assess system performance are defined. Emphasis is on those overall undesired events that are of primary concern.
2. A functional analysis of the system is drawn up. The functional diagram defines the system elements and the interconnections; it represents the physical system.
3. Starting from the TOP event, the system is analyzed to determine the events that can cause the defined system fault.
4. The fault event analysis is continued to the next lower order events that could cause fault. This is done until all events are primary events.

5. Using logical symbols, the logical relationships among fault events are developed. These events are defined in such a manner that probability values can be assigned.

The fault tree presents a logical picture of all the sequences of events that can cause the TOP event fault. This tree is amenable to qualitative and quantitative analysis.

Qualitative analysis includes determining the modes of failure and the components that are responsible for a failure due to a common cause failure. A "minimum cut set" is any mode of failure containing a group of basic events that alone are collectively sufficient to cause the TOP event to occur. A "common cause failure" is a secondary cause of failure that is responsible for more than one component malfunction.

Because the undesired event is the consequence of those basic independent events that singly or in combination terminate direct paths to the top of the tree, often even a qualitative evaluation can identify what corrective actions are necessary to reduce the hazard. Anything that reduces the possibility of the basic events will reduce the hazard.

Quantitative Analysis. It is with respect to quantitative analysis that FTA has received the most attention. By introducing numerical probabilities of the basic events occurring, a probabilistic evaluation of the TOP event occurring can be derived. Considerable effort has been put into developing means of manipulating the probabilistic data with the associated Boolean algebra.

The quantitative analysis is of value for analyzing system design, in demonstrating compliance with safety requirements, and in justifying system changes. If quantitative reliability data are available for individual components and inputs, or can be accurately estimated, the reliability of the system can be calculated.

In systems justifying a thorough component reliability testing program or where extensive reliability history has been documented, quantitative evaluation of the system reliability can be established. However, where such reliability data do not exist the final results can be highly suspect.

Considerable effort has been put into programs for generating and analyzing fault trees by computer. For large systems, this is extremely helpful because otherwise the manpower requirements are excessive. However, much of the benefit derived from FTA is due to the understanding and insight gained while constructing the fault trees. If generation of fault trees is done completely automatically, much of this benefit could be lost.

Advantages and Limitations of FTA. The versatility in the degree of detail that can be reflected in an FTA is a principle feature of the technique. The fault tree is useful in:

- Directing the analyst to ferret out possible failure modes deductively
- Highlighting aspects of the system that are important with respect to the failure of interest
- Providing a graphical aid to those in system management who are removed from system design
- Providing options for qualitative or quantitative system analysis
- Allowing the analyst to concentrate on one mode of failure at a time
- Providing the analyst with insight into the system behavior

Limitations of FTA include:

- In spite of the use of computers, minimum cut sets cannot always be found for large systems because of the large storage required.
- Because all decision equations are binary, some conditions of interest cannot be handled, such as degrading of performance, and standby systems cannot be handled quantitatively without use of Monte Carlo methods (requiring a large number of computer runs).
- Methods for quantitatively dealing with secondary failures do not exist. Nor can the use of repairable systems be dealt with quantitatively.
- Fault tree analysis is severely limited by the shortage of meaningful component reliability data.

- Fault tree analysis is expensive, especially if quantitative results are expected on large systems. The costs of generating suitable and meaningful fault trees for first-time application to a system may be in the same order as the engineering to design the system.

Event Tree Analysis

Event tree analysis (ETA), like FTA, is a binary logic tree. However, it is the reverse of FTA in that it starts with an initiating event (a basic event) and traces all the possible consequences of the event. Possible failure sequences are defined that consist of the initiating event and specific succeeding systems failures. All consequent system states (failure or success) are connected through a branching logic that represents all the specific accident sequences that can arise.

Event tree analysis is an inductive logic approach and is similar to the FMEA. The possible outcome of specific failures are enumerated in the form of sequences of failures that may occur. Physical consequences are determined and associated with each sequence of failures.

Figure 7 is an ETA diagram for a loss-of-coolant accident at a nuclear reactor. In this simplified event tree, the initiating event is assumed to be a pipe break, the probability of which is signified by P_A. The subsequent events depend on whether the break occurs at a time when the electric power is on or off, and a probability P_B is assigned to the failure of electric power at the time of the break. (Because the probability of such a failure is generally less than 0.1, the probability of success, or 1 - P_B, is always close to 1. Therefore, the probability associated with the upper branches in the tree is assumed to be 1.) One then follows each of the two branches, asking next what the probability of failure of the emergency core-cooling system is, which in turn will depend on the availability or nonavailability of electric power. In the example shown, the probability of failure of the emergency core-cooling system in the absence of electric power is P_{C_2}, and that branch leads farther down the tree. The worst possible case is that given at the bottom, in which the electric power, the emergency core-cooling system, the fission-product removal system and the containment system have all failed, resulting in a very serious accident. The topmost branch illustrates the situation in which the pipe does indeed break, but all the other systems perform flawlessly, so that no risk to the public ensues. The task of ETA is to estimate the probabilities of all intermediate chains of events in such a way that an overall assessment of the risk can be made.

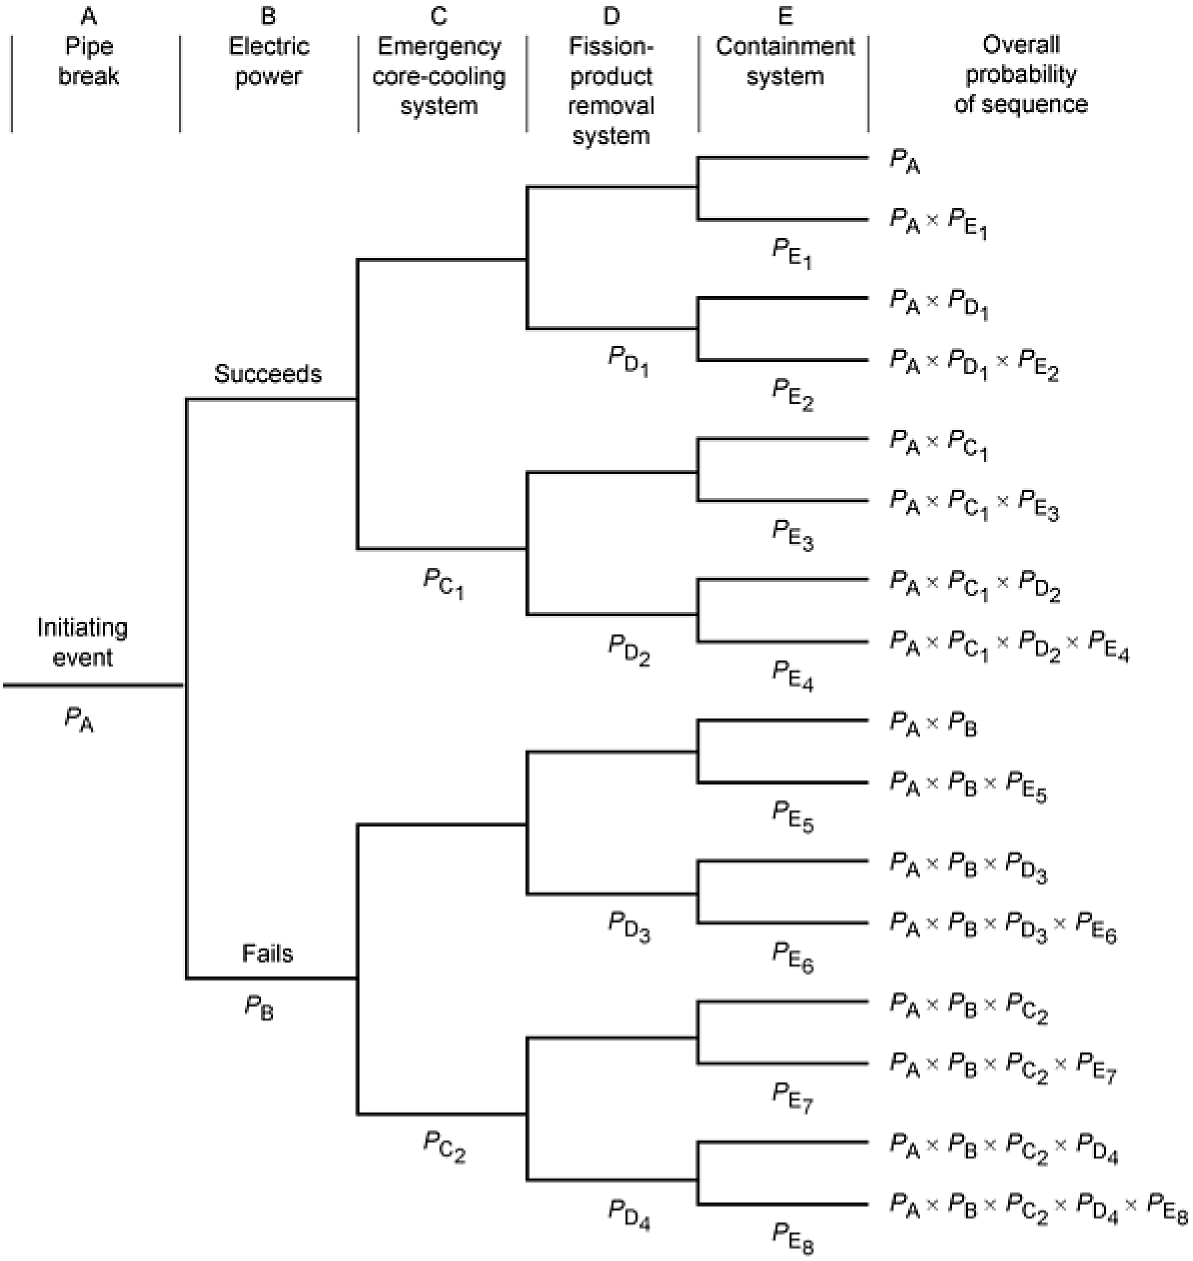

Fig. 7 Event tree analysis for a loss-of-coolant accident at a nuclear reactor. See text for discussion. Source: Ref 6

The logic of ETA is quite general and can be used whenever events occur in sequence of logical combination. By superposition of reliability data on the event occurrence and its consequence, a quantitative probabilistic assessment of the likelihood of the system failure can be computed. The initiating event occurrence can usually be derived from historical data. The probability of alternatives occurring can be derived from FTA or FMEA. The mathematical methods developed for FTA can usually be applied to ETA.

Event tree analysis is often used to complement FTA. Whereas most other hazard analysis methods emphasize the inherent reliability of the components and the system, ETA focuses on the consequences of unusual events; such an event could be an input that is out of specification or an unusually large environmental load.

Risk / Benefit Analysis

Risk/benefit analysis is a management technique to aid in decision making. It is based on the assumption that a *common value scale* can be found for expressing the risks and benefits inherent in a decision. If the common value scale is in dollars, the expected loss index (ELI) is defined as the total dollars being risked times the probability of failure, this is the dollar value of the risk. Then, if an acceptable dollar level of risk can be established, a potential tool for accepting or rejecting any decision can be generated.

By using the dollars at risk as one axis of a graph and the probability of failure as the other axis, a field is defined in which each point represents some specific combination of risk and dollars at risk (Fig. 8). Points with the same expected loss index lie on a straight line at an angle to both axes. By locating the risk versus dollars at risk for any event as a point on the graph it can easily be seen whether the risk is acceptable or not, based on a previously established ELI.

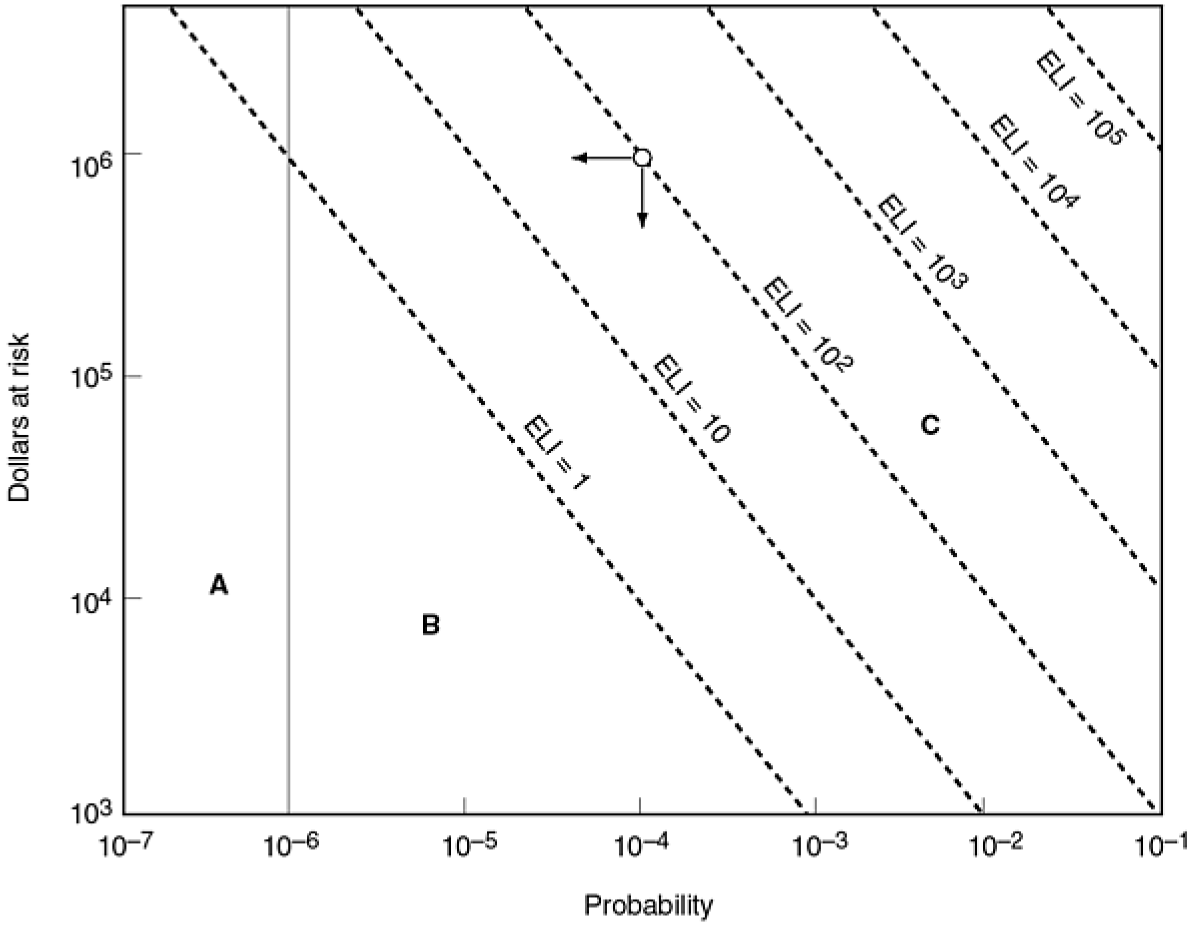

Fig. 8 Typical risk analysis graph. If target ELI is 100, ELI in region C are unacceptable, ELI in regions A and B are acceptable. Source: Ref 7

Although this approach is valid for financial considerations, when dealing with safety, it has some serious shortcomings:

- Safety often involves dealing with lives or irreversible damage, which cannot be readily equated to dollars, but has a highly emotional content (see the article "Safety in Design" in this Volume).

- Dollars at risk include elements difficult to isolate or determine: user costs, training costs, cleanup costs, and so forth.
- Reliable event probabilities should be estimates that are based on tests, but in many cases are simply a "best guess" of an expert.

Generally risk/benefit analysis makes sense when dealing with a closed system where only dollars are at stake. Elsewhere risk/benefit analysis must be viewed with caution.

Risk and Hazard Analysis in Design

G. Kardos, Carleton University

Safety Analysis

Safety analysis is the synthesis of other risk/hazard analysis techniques to produce a qualitative systematic analysis throughout all phases of the project design, development, and implementation, with the objective of preventing accidents. This includes preventing personnel injuries, damage to equipment, and so forth. The techniques are simple but rigorous and time consuming, and to be effective must be continued throughout the life of the system from conception to shutdown and disposal. The method can be applied to any system but from a different point of view than system analysis. The focus of safety analysis is the prevention of hazardous failure.

The primary tools of safety analysis are worksheets, a hazard log book, a checklist of hazards, and a system description. A basic requirement is that the practitioners have a willingness to challenge the status quo; they cannot be the same as those committed to the design and implementation of the hardware system.

Safety analysis should be started at the same time as the design, by using historical information and knowledge of the system; possible hazards and hazard--causing situations or scenarios should be identified as the design develops. The hazards are categorized according to their potential severity (e.g., catastrophic, critical, controlled, etc.). Worksheets are generated (Fig. 9) that allow each element of the system to be considered and challenged with respect to each potential hazard. The results of these challenges are entered onto the worksheet identifying which components are affected critically and the possible extent of the resultant problem. After the complete system has been challenged with respect to the hazards, the results are simplified by sorting out the "essential hazardous situation" (EHS), that is, the fundamental safety problems to be dealt with. A logbook is established for the system with files to keep track of each essential hazardous situation considered throughout the life of the system. This logbook is used to ensure that all system history from conception to closeout is available for reexamination to anticipate and prevent the essential hazardous situation from occurring.

Worksheet

(System elements identified)			
Hazard	Components possibly affected	Critical operation segments	Remarks
1. Acceleration			
2. Contamination			
3. Corrosion			
4. Dislocation, chemical			
5. Electrical			
6. Explosion			
7. Fire			
8. Heat and temperature			

(21 categories of hazards)

Fig. 9 Hazard worksheet for safety analysis. Source: Ref 7

The identification of the hazards is an initial and continuous activity. Identification initiates an iterative process--the preliminary hazard analysis (Fig. 10) that undertakes to eliminate or reduce the essential hazardous situations to an acceptable minimum. Design changes, safety devices, warning systems, crew procedures, emergency measures, and so forth, are all recommended. These are carried out to control or resolve the hazard situation. This often requires compromises between the designer and the safety analyst, or even changes in the specification governing the functions and use of the system. In any reasonable project, at some logical point before completion, a design review takes place. The safety analyst should become a part of the design review to assess whether the designer has been cognizant of the essential hazard situations. At this stage, the design has reached a degree of maturity and new hazards may be identified, which may require further action. At the completion of the preliminary hazard analysis:

- The general hazards of concern are identified.
- Additional design and operation requirements have been established to forestall or alleviate anticipated hazards.
- Areas where further improvements with respect to safety are necessary have been identified.
- A databank has been started that can be used to follow and document potentially hazardous situations.

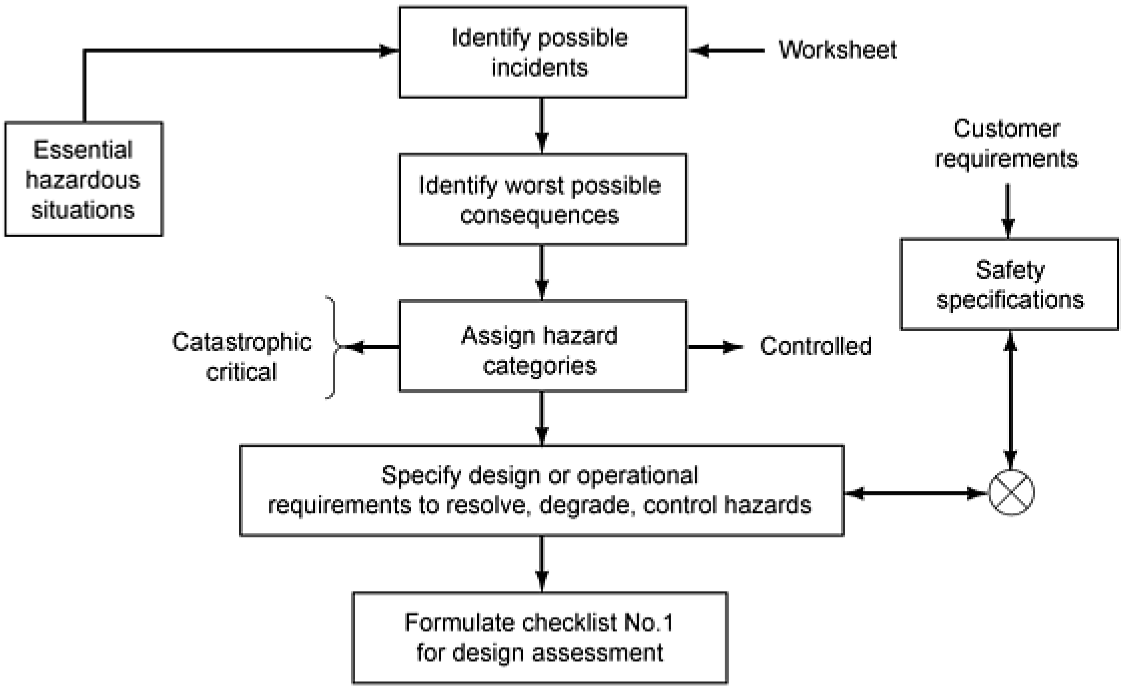

Fig. 10 Safety analysis flow chart for preliminary hazard analysis. Source: Ref 7

The log book on hazard data is expanded and embellished as the design is refined and as more detailed information becomes available. From this, at any specific point throughout the design, the safety analyst should be able to say what hazards are still possible due to any part of the design and what action is contemplated or necessary to reduce the hazard to an acceptable level. After the system has been completed, has been in service, and is retired, the log book then becomes a valuable historical record on which additional or new systems can draw.

For large complex systems, each part of the system (system, subsystem, assembly, component) is broken down into its basic elements and subjected to its own system hazard analysis (Fig. 11). The complete system hazard analysis is best carried out before commitment to hardware so that the results of its deliberations can be incorporated into the hardware. The techniques used in system hazard analysis are the same as used in the preliminary analysis, but are carried out in greater detail.

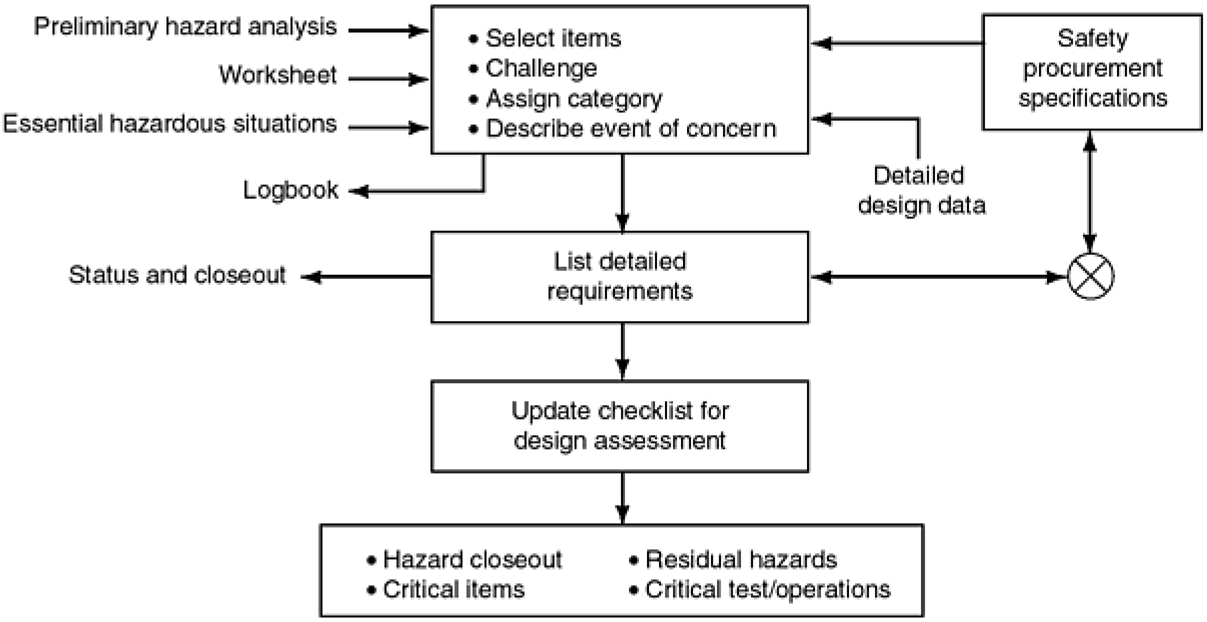

Fig. 11 Safety analysis flow chart for system hazard analysis. Source: Ref 7

Before the design is finalized, a safety review should be held. The purpose is to review all known safety problems and to establish a schedule, budget, and approach to their elimination.

When the design is completed, the data collected on the system safety during the design phase become a source used to determine test requirements, quality control, and operational procedures. Similarly, problems that appear during testing or early operation are fed back into the log book to help formulate future design and safety requirements.

Because no system is perfect, safety analysis cannot stop with the design and production of hardware. The safety analysis evolves into the next stage, operating hazard analysis (OHA) (Fig. 12). This serves to identify solutions where failure that is attributable to operator performance is likely to occur. Human factors studies at this stage are a useful input (see the article "Human Factors in Design" in this Volume). The techniques of carrying out OHA are the same as for system hazard analysis except that the human operator and his limitations must be considered. The outputs from OHA are operational requirements that compensate for or correct a human limitation. The procedures have to either prevent the hazard or confine and minimize its impact.

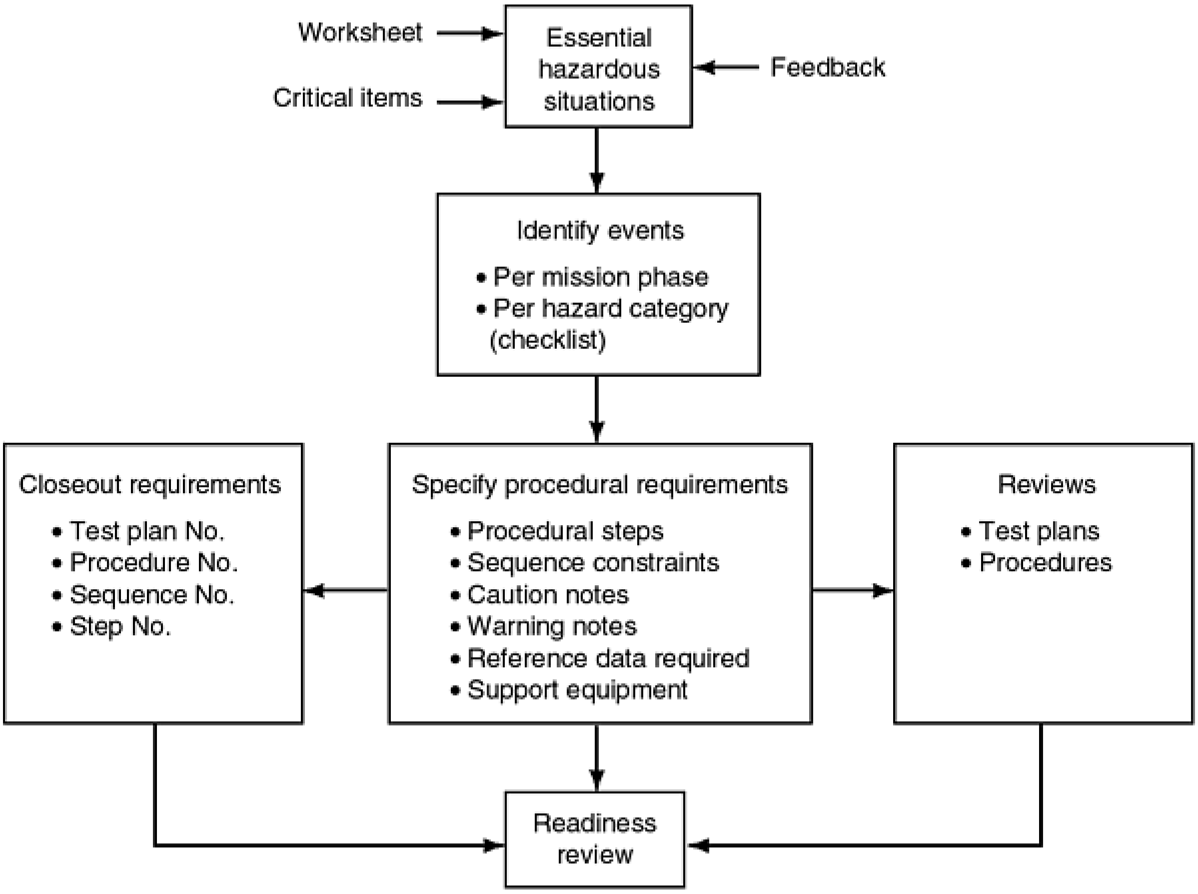

Fig. 12 Safety analysis flow chart for operating hazard analysis. Source: Ref 7

The outputs from OHA can be in the form of:

- Procedural steps
- Sequence constraints
- Caution or warning notes
- Reference data
- Support or standby equipment

With these various hazard analyses, the equipment and the operating system should be as safe as possible. However, before starting up the facility the system should be subjected to one more review, a readiness review. At this point, all critical personnel are brought together and all safety hazards are reexamined to see whether they have been adequately taken care of. Crew procedures are assessed to ensure that personnel are properly trained, not only for normal operation, but for emergency situations as well. Only when this readiness review panel is satisfied that all necessary actions have been taken should the system be put into service.

The previous discussion presents a description of an ideal safety analysis program. It is doubtful that such an idealized program can be instituted except in the case of small hardware items completely within the control of one firm. However, it is an ideal that can be strived for, especially in the case of large complex systems where the impact of failure can be catastrophic. The institution of a safety analysis program does not exclude the use of other risk/hazard analysis techniques, but instead provides a framework wherein these other techniques can be integrated into design and operating considerations.

Probabilistic Estimates

Most risk/hazard analysis techniques rely on statistical or probabilistic techniques to quantify their results. It should be emphasized that such probabilistic reliability quantities are not properties of the hardware; they represent the state of one's understanding of the potential life of the hardware. By increasing the information one has about the system it is possible to change the expressed probability of failure. This will, in no way, affect whether a specific system will fail or not. Probabilistic quantities only deal with one's perception of the world.

Second, statistical and probabilistic quantities, no matter how accurate, do not reflect knowledge about a single specific system. Statistical or probabilistic quantities describe what will happen to a large number of identical systems if they are all asked to perform identical functions under identical circumstances.

Finally, no matter how small the probability of an event may be, there is always a possibility of that event occurring. In fact, a probability specifically predicts that if enough systems are tried, the event *will* occur. Moreover, if probabilistic evaluation shows that an engineered system would only fail catastrophically once in 10^6 years, that does not mean that failure will occur after 10^6 years, it could fail in the next hour. Probabilistic evaluations cannot predict *when* failure will occur.

Consequently, reliance on statistical and probabilistic data for decision making must always be tempered with understanding.

G. Kardos, Carleton University

Conclusions

Those who are involved in using risk/hazard analysis methodologies advocate their use, but always with a note of caution. Those who are involved in developing the details of algorithms for manipulating the quantitative aspects of risk/hazard analysis are much more enthusiastic about the methodologies than individuals responsible for applying the methods to hardware.

For the designer, the chief benefits to be gained from risk/hazard analysis are qualitative ones. Because the analyst is required to consider all possible failures and to focus on details, there is less likelihood of anything being overlooked or taken for granted. Corrective action can be taken, because someone has been made responsible for safety.

Although there is great promise in quantified probabilistic hazard assessment, more is in the promise than in the fact. The state-of-the art is not sufficiently developed so that one can realistically expect to specify a number and state that systems that come below that number are satisfactory and systems above that number are unsatisfactory. The only way to eliminate or reduce safety hazards is through a continuous monitoring of the system design and eliminating those problems that may contribute to the hazard.

In spite of the fact that no analysis can produce a simple quantifiable specification requirement, the risk/hazard analysis techniques developed can be used by designers and operators of systems to reduce the hazards inherent in any system.

It is apparent that the various techniques have much in common and that any really effective safety program should use several of the techniques so that they complement one another. There is no doubt that risk/hazard analysis is still an art and not a science. It is expected that two analysts looking at the same problem may generate quite different but equally valid hazard assessments.

To be effective in reducing ultimate hazards, the analysis must be done early and before the design is fixed. Consequently, the risk/hazard analysis must be instituted and carried out by the agency responsible for the design.

Human Factors in Design

Charles O. Smith, Engineering Consultant

Introduction

THE TERMS *human factors, ergonomics,* and *human engineering* are often used interchangeably despite some significant differences in the basic meanings of the terms. While one tends to think of human factors as the process of designing products and systems for human use, this is too limited. Human factors also include operational methods and procedures, testing and evaluating these methods and procedures, job design, development of job aids and training materials, and selection and training of people who will be users. This article is primarily concerned with the design of equipment, although work environment and work methods also have significant effects. The central approach of human factors engineering is the systemic application of relevant information about human characteristics and behavior to the design of human-made objects, facilities, and environments that people use. For an acceptable level of human performance, the designer must focus on each of the following elements:

- The state or condition of the *human being*
- The *activity,* including equipment and required tools
- The *context* in which the activity is performed

Human Factors in Design

Charles O. Smith, Engineering Consultant

The Human

The human being is the most complex of the three required elements. Human performance can be affected by a range of conditions that are internal to the individual and have no reference to the activity or context. The designer must understand potential areas of deficiencies in people and account for them when making design decisions.

The major aspects of the human are sensors (vision, hearing, touch, smell, and taste), brain (cognitive) processing (ability to think, reason, and decide), and responders (properly functioning fingers, arms, feet, mouth, etc.). The designer must have a good understanding of how humans function in each of these aspects.

Degraded performance can result if any of the basic capabilities to perform an activity are reduced or lacking. Other factors such as sleep (or lack thereof), fatigue, biological rhythms, illness, drug reactions, lack of basic (or advanced) skills, and/or lack of motivation can influence human performance, usually negatively.

Designers commonly assume that potential users have skills of perception, problem solving, decision making, and movement control. If any of these skills, or any other important skills, is lacking, the designer must provide an efficient way for the user to learn or develop it. This implies an unspoken assumption that the user has the ability to learn the necessary skills in a reasonable time. Some potential users may not have the necessary learning skills, and some of these people will be unable to develop the required skills within an acceptable time. There is a further assumption that potential users are mentally healthy. Designers often assume that all people are much alike and that an individual does not change over time, especially in a very short period. These latter assumptions are seldom justified.

Human beings exhibit a multitude of variations: variations in height, weight, physical strength, visual acuity, hearing, computational capability, intelligence, education, and so on. Designers must consider all these variables, and their ranges, because they recognize that their product will ultimately be used by humans.

Designers seldom have control over the people selected to use the system being designed. The best approach for a designer is to have a clear understanding of the characteristics of the potential user population so that the most appropriate design decisions can be made. Because most products and systems are designed for groups of people, rather than one specific individual, it is necessary to deal with the extremes of strengths and weaknesses of the potential user population. In addition, the designer should document the assumptions about the user population for those who *do* select the users.

Charles O. Smith, Engineering Consultant

The Activity

Cazamian (Ref 1) says: "For a period measured in millennia, work was carried out in the form of crafts. The craftsman or artist was at one and the same time the organizer and executor of his own works. . . . Today, we live in a situation where the craftsman's function has, so to speak, split into two parts: those of the organizer (system designer) and those of the executor (systems users). In many, many cases the designer is no longer a user and a user has limited or no input to a designer."

The designer is concerned with the technical and economic aspects of products and systems. The user is much more oriented toward getting through the day, since for many users work is simply a means of existence. Success at work, however, may determine other successes or failures of an individual. A good designer will thoughtfully create the activity to be performed rather than let it evolve.

The designer can control some conditions relating to performance of an activity, so the designer must know what kinds of work people do best, what is best done by machines, how (and what) tasks are best combined into a work module, and what training is required to develop necessary skills for an acceptable level of performance. In many situations, interface requirements must be considered.

Human Factors in Design

Charles O. Smith, Engineering Consultant

The Context

There are two aspects to consider with regard to the context in which a human performs an activity: the *physical context* and the *social context.* In the physical context, noise, lighting, temperature, humidity, vibration, and so on may all have significant effects on the user. In the social context, crowding versus isolation is an example of a factor that may have a significant effect on user performance. The so-called "home court advantage" in athletic events suggests that social context can make a difference in human performance.

Human Factors in Design

Charles O. Smith, Engineering Consultant

Human-Machine Systems

Most systems have some common characteristics. Every system has some purpose or objective that must be clearly understood, including a statement of performance specifications. For the system to fulfill its purpose, specific operational functions must be performed, usually in a definite sequence. Each function must be performed by a person or by a physical component. If the system is a *flow* system, a block diagram can be used for help in allocating each function to a human or to a physical component. In other systems, however, such as driving a motor vehicle, there is no unambiguous way of representing the constantly changing interactions among the driver, the vehicle, and the environment. Execution of any operational function involves a number of basic functions, as indicated schematically in Fig. 1. The basic elements of a human-machine system are shown in Fig. 2.

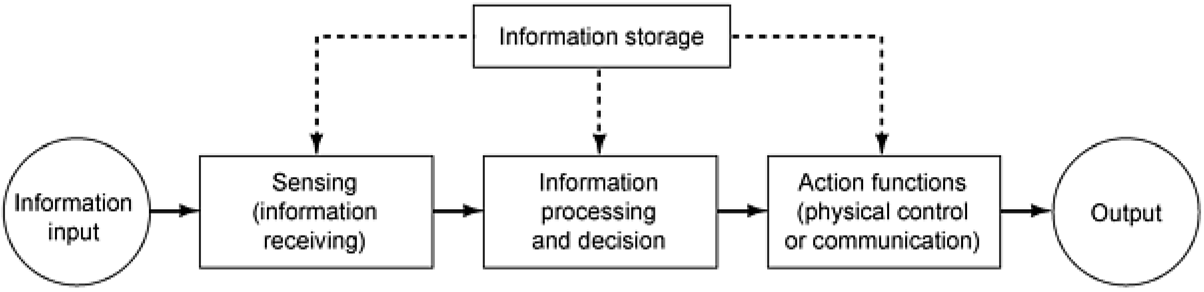

Fig. 1 Schematic representation of basic functions performed by human or machine components of human-machine systems. Source: Ref 2

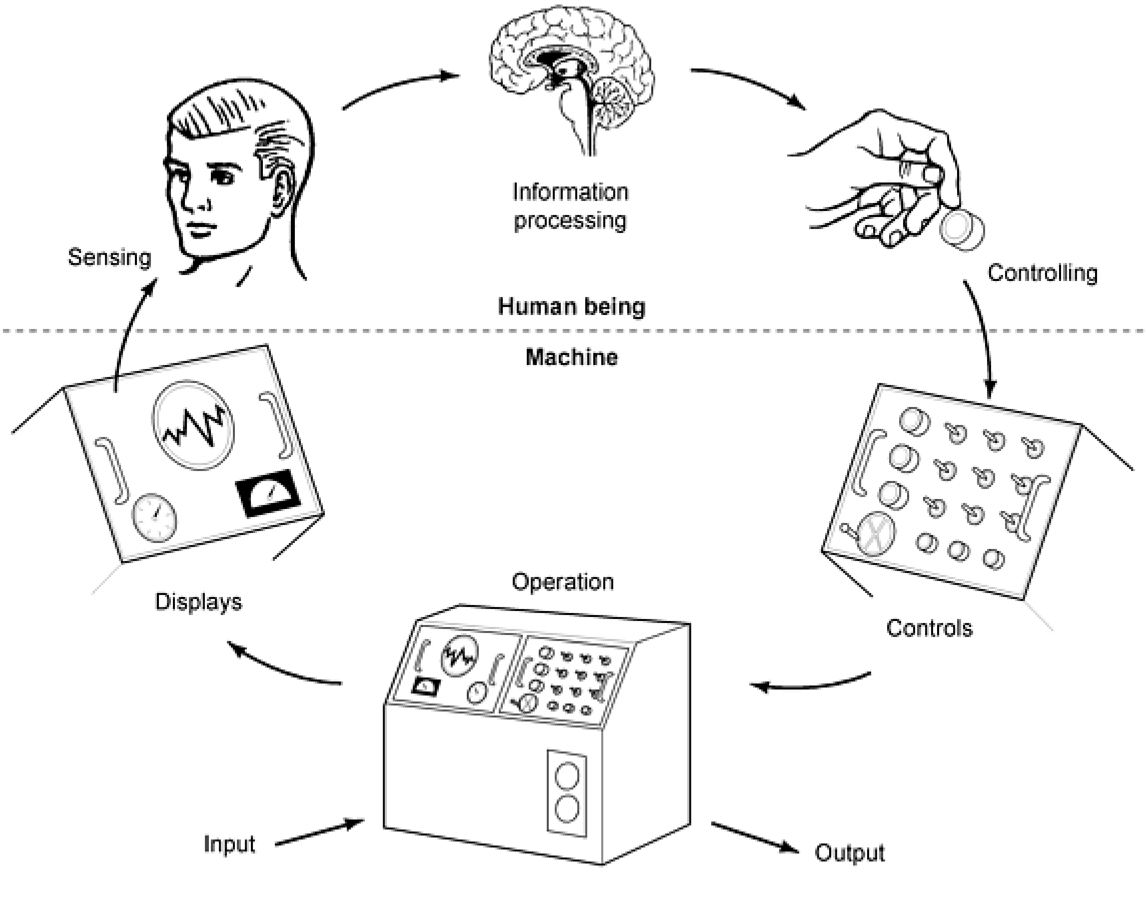

Fig. 2 Schematic representation of a human-machine system showing basic elements and modes of function. Source: Ref 3

Human-machine systems can be classified by the degree of human versus machine control:

- *Manual systems* primarily consist of hand tools and other devices that are used together by the human operator, who controls the operation. Examples are a cook plus utensils or a singer plus amplifier.
- *Semiautomatic systems* consist of well-integrated physical components (e.g., powered machine tools) that are generally designed to perform the desired functions with little variation. The machine normally supplies the power, and the human function is primarily one of control, usually through control devices. A motor vehicle is one example.
- *Fully automatic systems* perform all operational functions, including sensing, information processing, decision making, and action. Examples are automatic telephone systems and digital computers.

Distinctions among these three systems are not always readily apparent. Even within any one system, the degree of manual versus automatic aspects can vary among the different components (or subsystems).

In design and development of a new product or system, the majority of the most critical decisions to be made are related to human performance. Informed decisions require the designer to have a good understanding of human engineering, human factors, and ergonomics. Problems are highly likely to develop when humans and machines interact. Human factors engineering attempts to minimize these problems and obtain maximum effectiveness in any human-machine operation by integrating the best capabilities of both.

The designer must avoid any design that expects, or requires, individual operators to exceed their available physical strength, perform too many functions simultaneously, perceive (or detect) and process more information than is possible, perform meticulous tasks under difficult environment conditions, work at peak performance (or capability) for long periods, work with tools in cramped spaces, and so on. Insofar as possible, ***the designer should adapt the machine to the human.***

The designer may think in terms of the "typical" or "average" human. This view is much too simple:

- People come in assorted sizes, shapes, capabilities, and varieties. Even when it may be appropriate to design for the average, the designer must remember there is a range of differences from that average.
- Some products are designed for limited groups such as infants, children, teenagers, the elderly, or the infirm. The characteristics of the specific group must be emphasized.
- When designing for the public the designer needs to provide for the entire range of characteristics of people, from babes-in-arms to nonagenarians. For example, doors, ramps, escalators, entries, and so on must be appropriate for the baby in a perambulator, a healthy and active man or woman, and a handicapped or elderly person with a walker or in a wheelchair. The task is not easy.

Human Factors in Design

Charles O. Smith, Engineering Consultant

Broad Design Considerations

The starting point of human factors design is the allocation of functions to the equipment and the operator. Whether a given function should be performed by the equipment, by the operator, or jointly by both depends on which arrangement

will give the most effective function in the operational situation. This requires a comparison of the strengths and weaknesses of both. There is no simple answer to the question of best allocation. It has been suggested, however, that if the content of all inputs and outputs of a given function cannot be fully specified, that function should be assigned to the operator, because only humans have the capability and flexibility to make decisions about unexpected events.

If we visualize three stages of system design development (i.e., conceptual, preliminary, and detailed), there are special considerations at each stage.

Conceptual Design. The designer should consider such aspects as:

- *Potential user characteristics* such as size, intelligence, age, reaction time, health, sex, training, and physiological tolerance
- *System features* such as task, operational, and environmental stresses; hazards; and task instructions and procedures
- *Preliminary task descriptions* for users, operators, and maintenance personnel

Preliminary Design. The designer reviews the previous results. In addition, the designer studies or analyzes such things as:

- Human-machine simulations and mockup studies
- Time line analysis (i.e., is the planned use of the operators or maintenance personnel feasible?)
- Task analysis
- Task description
- Link analysis (i.e., is the grouping and sequencing of human tasks logical and manageable?)

Detailed Design. The designer reviews the previous results. In addition, the designer studies such things as:

- Hazard and safety analyses
- Refined time line and link analyses
- Personnel requirements (i.e., how many and what type of people are needed for field operation?)
- Task and training requirements
- Technical literature publications, which must be prepared carefully so that the user can use them effectively

Human Factors in Design

Charles O. Smith, Engineering Consultant

Human-Machine Function Allocation

As noted above, there are some things at which humans are better than machines, but there are also some things at which machines are better than humans. The human factor designer must know which is which. Table 1, while not necessarily complete, gives a substantial number of comparisons of human and machine capability for various functions.

Table 1 Human-machine function comparison

Function	Humans	Machines

Flexibility	Able to handle low-probability alternatives, unexpected events. High flexibility.	Flexibility limited; unexpected events cannot be adequately handled.
Ability to generalize	Able to recognize events as belonging to a given class, to abstract similarities, and to disregard conflicting characteristics.	Zero, or very limited abilities. Can react only to physical properties set up.
Ability to learn	Previous experience can be used to change subsequent behavior.	No change unless equipment configuration is changed.
Sensitivity	Sensitive to wide range of kinds of inputs. Can transduce many kinds of physical stimuli simultaneously. Small amounts of physical energy can be detected.	A given instrument is sensitive to only one kind of input. Thresholds not generally as low as human's. However, can sense energies beyond human spectrum.
Cost	Inexpensive and in good supply. Amount of training required depends on complexity of task.	Cost rises rapidly as complexity increases. Supply limited.
Weight	Light.	To reproduce human functions, would have to be immensely heavy.
Originality	Able to sense and report events and observations not of immediate concern.	No originality in discovering incidental intelligence or the relationships between functions.
Monitoring capacity	Poor.	Good.
Expendability	Nonexpendable; safety considerations have to be imposed.	Expendable.
Manipulability	Ability to perform precise manipulations required in maintenance.	To perform same tasks, machine would be extremely costly and complex.
Reliability	Subject to errors. However, reliability of manual equipment is higher than that of more complex automatic equipment because of smaller number of components.	Makes no errors, but reliability of automatic equipment is lower than that of manual equipment because of increased number of components.
Fluctuation in performance efficiency	Highly variable from day to day.	Minimal variability.
Reaction time	Relatively slow. Shortest human response about 200 ms.	Usually as fast as relay operating time, microsecond lags.
Physical force	Relatively weak unless aided by machinery.	Practically limitless in power.
Boredom or fatigue	A repetitive task results in error. Rest period required. 8 to 10 h maximum efficient work expected.	Capable of many operations without decrement. Only physical limitations, such as heat, corrosion, or wearout, need be considered.

Environmental requirements	Can exist only in a very narrow band of environmental conditions. Physiological maintenance requirements are extensive.	Can tolerate many fluctuations in environment. Restricted only by design specifications.
Tracking ability	Comparatively poor tracking characteristics, although satisfactory in wide range of situations. Can change performance constants to produce best attainable system performance in any situation.	Good tracking characteristics. Considerable complexity needed, however, to track well in all conditions.
Channel capacity	Limited. Has maximum amount of information that can be handled at a given time.	Can be made arbitrarily large. Capacity limited only by design.
Overload operation	May be able to perform better in certain cases of overload than machines; can tolerate temporary overloads without complete disruption.	May break down completely if overloaded; with information-handling capacity fixed, overload leads to system disruption.
Survival	Interested in survival. Situations with possibility of danger are "stress-inducing," resulting in behavior degradation.	Not "conscious" of danger. No behavior decrement in the face of destruction.
Computational ability	Comparatively slow and poor computers.	Excellent and very rapid computers.
Memory storage	Poor short-term storage. Excellent long-term storage.	Excellent short-term storage. Long-term storage very expensive.
Deductive logic	Cannot always be expected to follow optimum strategy. The right premises sometimes lead to wrong conclusions.	Excellent in deductive logic; can exhaust all theorems from a set of postulates. Can store and use optimum strategy for high-probability situations.
Inductive logic	Can go from specific cases to general rules or laws.	No good at inductive logic.
Distraction	Easily distracted by competing stimuli.	Cannot be distracted by competing stimuli.

Further Design Guidelines

The designer certainly must consider the hazards in the design when it is used or operated in the intended manner. A hazard is any aspect of technology or activity that produces risk or danger of injury. The designer must also recognize that

the product may be used in unintended but foreseeable ways. Protection must be provided against hazards in all uses that can be foreseen by the designer. Unfortunately, even the most diligent search for foreseeable uses may still leave a mode of use undiscovered. In litigation, a key issue often revolves around the question of whether the specific use was foreseeable by a reasonably diligent designer.

Example 1: A Snowmobile.

A female teenager and her boyfriend rented a snowmobile for a few hours to ride around on a lake. He was driving; she was a passenger. They collided with another snowmobile rented from the same rental agency. She was thrown on the ice, injuring her left knee. Surgery was performed but left her with permanent injury.

The owner of the agency admitted that the brakes had been disconnected by the previous owner of the agency (while he was an employee) and that he had left them disconnected. The reason given was that renters became confused about the operation of the throttle and the brakes, with the result that they "tore up the equipment." Without brakes, the only mechanism for slowing the snowmobile was to release the throttle and let the engine provide braking. The owner claimed that the throttle had been adjusted to limit the speed to between 20 and 25 mph.

The owner's manual said: "The squeeze-type throttle lever, conveniently located on the right side of the steering handle, enables the operator to control the sled and the engine RPM at the same time." The manual further said: "The hand-operated brake lever is located on the left side of the steering handle. By mounting the brake and throttle levers on the steering handle, the operator is able to maintain complete control of his snowmobile using his hands only."

The throttle was opened (to increase speed) by closing (i.e., squeezing) the right-hand lever. The brakes were applied (to decrease speed) by closing (i.e., squeezing) the left-hand lever. When the throttle was released, the engine slowed. At some lower (undetermined) speed the clutch disengaged and the tracks stopped moving, thereby generating significant drag.

As an exercise, this design is analyzed from the human factors viewpoint. If changes would improve the design, what changes would be made?

Most people immediately see this design as very poor from the viewpoint of human factors. Most operators will never see the owner's manual, but in this context that is minor. The natural (automatic) thing for people is that both the left and right hands will do the same thing simultaneously (i.e., both will open or both will squeeze), unless deliberate thought is given to doing otherwise. When a collision is imminent, there is no time for conscious thought, only conditioned reflex. Only well-experienced operators might be expected to have the left hand squeeze while the right hand opens.

It is not necessary, moreover, to have the design that was used. Reversing the action of the brake lever would be a better design (i.e., both hands squeeze to move forward; both hands release to stop). This "deadman" arrangement is common in railway locomotives, power movers, snow-blowers, and so on. This arrangement is technically and economically feasible. The argument that keeping the left hand closed is undesirable is weak, because the right hand must be kept closed while the snowmobile is operating.

Another, perhaps superior, alternative is found on many motorcycles and would be familiar to many people. The throttle is operated by rotating a grip on the steering handle. The brake is operated by a squeeze lever on the same side of the steering handle. The two cannot be operated simultaneously. This alternative is technically and economically feasible with no foreseeable adverse effects. Additional information can be found in the section on "Definition of Defects" in the article "Products Liability and Design" in this Volume.

Example 2: A Ladder Label.

Figure 3 shows a full-scale copy of a label "permanently attached" (by some sort of adhesive) to the inside of a rail on a fiberglass ladder. The text of the original label had black lettering on a yellow background in keeping with ANSI Z535.1 (Ref 6). The three-line heading was yellow on black. The text print size was 6 points. ("Point" is a printer's measure equivalent to 0.01384 in. or essentially 72 points per in.) ANSI Z535.4 (Ref 7) specifies type (in the text) of 1.5 mm high (minimum), or 5 points. Presumably this label was intended to serve for warnings, directions, or both. *Directions* are intended to *ensure a proper and effective use* of a product. *Warnings* are intended to *ensure a safe use.*

FIBERGLASS
SINGLE & EXTENSION LADDER
FOR SAFETY, READ CAREFULLY

INSPECTION

1. Inspect upon receipt and before use.
2. Never climb a damaged ladder. Return for repair or discard.
3. Check all working parts, rivets, bolts, rope and cable for good working order.
4. Never use ladder with missing parts.
5. Discard if exposed to fire or chemicals.

SELECTION

1. Use 300 lb., and 200 lb. Duty-Rated Ladder for maintenance and heavy-duty work. Never use ladder jacks on 200 lb. or 225 lb. Duty-Rated Ladders.
2. Use ladder with correct duty rating to support combined weight of the user and material. Ladders are available with duty ratings of 200, 225, 250, 300 lb.

SET-UP AND USE

1. Set up ladder at 75½° by placing bottom ¼ of length being used out from vertical resting point.
2. Set ladder on firm level ground. Never lean sideways and never use on ice or snow.
3. Use proper size ladder. Never use temporary supports to increase length or to adjust for uneven surfaces.
4. Keep rungs free from wet paint, mud, snow, grease, or other slippery material.
5. Extend only from ground. Never extend from top or by bouncing.
6. Never walk or jog ladder while on it.
7. Securely engage ladder locks before climbing.
8. Erect ladder with fly (upper) section above and resting on base (lower) section.
9. Each section of a multi-section ladder shall overlap the adjacent section by 3 ft. up to and including 36 ft.; by 4 ft. over 36 ft., up to and including 48 ft.; by 5 ft. over 48 ft., up to and including 60 ft.
10. Always have the four ends of the ladder rails firmly supported.
11. Always tie top and base to building.
12. Project ladder minimum of 3 feet above roof edge.
13. Tie down ladder before stepping onto roof.
14. Never over-reach. Move ladder instead. Keep belt buckle inside ladder side rails.
15. Never use in high winds.
16. Never overload. Ladder designed to support one person when properly used.
17. Never use as a horizontal platform, plank or material hoist.
18. Never use on a scaffold.
19. Never fasten different ladders together to increase length.
20. Never apply a side load to ladder to push or pull anything while on ladder.
21. Never drop or apply impact load to ladder.
22. Never sit on end of ladder rails.
23. When reassembling, properly engage all guide brackets and lock prior to use.
24. Never use in front of unlocked doors.
25. Fly section must have safety shoes if used as a single ladder.
26. Hooks may be attached at or near top for added security.
27. To support the top of a ladder at a window opening, a stabilizer should be attached to span the window.
28. Never use ladder when you are in poor health.
29. Never use if taking drugs or alcoholic beverages.
30. Recommend never using if over 65 years of age.

CLIMBING INSTRUCTIONS

1. Never climb onto ladder from the side or from one ladder to another.
2. Face ladder when ascending or descending. Maintain a firm grip and stand on middle of rung.
3. Never stand above 3rd rung from top.
4. Never climb above support point.

STORAGE

1. Support ladder on racks when stored.
2. Never store material on ladder.
3. Properly support ladder in transit.

FOR ADDITIONAL INSTRUCTIONS, SEE ANSI A14.5

Fig. 3 A black-and-white reproduction of a decalcomania label to be placed on the inside of the side rail of a fiberglass ladder. The heading was yellow lettering on black. The text lettering was black on yellow. Reproduction is 100% of original size.

As an exercise, critique this label from the viewpoint of human factors, keeping in mind information given in the articles "Products Liability and Design" and "Safety in Design" in this Volume.

At least two problems deserve comment. One is the content of the text on the label. There are 44 items under five different headings, and many of these items are somewhat ambiguous. For example, in the first three items under "INSPECTION," it is not clear just what one looks for (i.e., there is no definition of terms). Under "SET-UP AND USE," the first item is poorly stated. Engineers have no difficulty in understanding what is intended, but many people besides engineers use ladders. In addition, does any user ever actually measure $75\frac{1}{2}°$, or even "$\frac{1}{4}$ of length being used"? Item 10 seems to conflict with Item 12. Item 11 says: "Always tie top and base to building." Are ladders used only on buildings? Does anyone ever tie a ladder to a building? If so, how? Item 30 says: "Recommend never using if over 65 years of age." Is this the age of the ladder or of the user? And why 65 rather than some other age? One could go on at length about other items. At the bottom the label says: "For additional instructions, see ANSI A14.5." Will the average user have any concept of what this means or where to find a copy? Will any user, even the intelligent engineer, obtain and read ANSI A14.5?

The second problem is the type size. It does conform to ANSI Z535.4. Did you have any difficulty in reading it? Bailey (Ref 8) notes that "type size in books and magazines usually ranges from 7 to 14 points with the majority being about 10 to 11 points. Probably the optimum size is from 9 to 11 points--sizes smaller or larger can slow reading speed."

There was no indication of the location of the label on the ladder rail. If this were an extension ladder, one should find the label at about eye height (5 to 6 ft, 1.52 to 1.83 m) on the base (lower) section. If this were a single ladder, one should find it at the same height on both ends.

How good is this label? How effective is it? Assuming that users do indeed see the label, how many will read it? Of those who read it, how many will really comprehend what the manufacturer is trying to say? It appears that the label was not well thought out, either in content or in phrasing, which is unclear or ambiguous in many places. The label does not provide clear instructions on use or explicitly warn of the dangers. Thus the label is clearly inferior and essentially ineffective. One infers that the manufacturer was trying to cover all possibilities to provide "protection" against products liability suits. It is ineffective in that respect as well.

Anticipating Errors. When humans are involved in the use of a product or system, there will be errors. Some errors are extremely difficult, if not impossible, to anticipate. Also, in many situations, people will abuse equipment. This is commonly a result of poor operating practices or lack of maintenance. In other situations, there may be deliberate action by the user (e.g., trying to fit two components together in a manner that is not intended, such as installing thread adapters on pressurized gas containers). There is no question that the designer cannot anticipate all these possibilities and provide protection. Nevertheless, the designer is not relieved of a substantial effort to anticipate such actions and try to thwart them.

How does one proceed? The designer must be well informed on anthropometrics (physical characteristics), how people tend to behave or perform, and how to combine such data to achieve a suitable, effective, and safe design. A wealth of literature is available.

Hunter (Ref 9) includes enough anthropometric data to give insight into the kind of data to expect. He also provides many examples of sources of information. He comments on Department of Defense documents that provide substantial and significant information. The objectives of these various documents can be applied with equal validity to both civilian and military products.

Human behavior is largely a question of psychology, a topic about which most engineers know little. Little information focused for use by engineers seems to be readily available. Possible sources are Ref 10, 11, 12, 13, 14, and 15.

Many publications provide varying degrees of insight and help in applying human factors information to design. Some that may be particularly useful are Ref 4, 16, and 17.

One of the many objectives of the designer is to minimize the probability of "human error," where human error is any personnel action inconsistent with established behavioral patterns considered to be normal, or that differs from prescribed procedures. Predictable errors are those that experience shows will occur repeatedly under similar circumstances. The designer must minimize the possibility of such errors.

People have a strong tendency to follow procedures that require minimum physical and mental effort, discomfort, and/or time. Any task that conflicts with this tendency is highly likely to be modified or ignored by the person who is expected to execute the task.

One of many important considerations in design is to follow common stereotypical expectations as much as possible. Consider a few examples:

- Clockwise rotation of a rotary control (knob) is expected to increase the output.
- Moving a lever forward, upward, or to the right is expected to increase the output.
- On a vertically numbered scale, the higher numbers are expected to be at the top.
- In vehicles, depressing the accelerator is expected to increase speed, and depressing the brake is expected to decrease speed. One expects the right foot to be used to apply force to the accelerator, then moved to the brake pedal. This is true whether one drives on the right or left side of the road.

Smith (Ref 5) tells of a forklift truck that violated the fourth item. The left foot was used to depress a pedal that increased speed, and a brake was applied when the foot was lifted.

Environmental Aspects of Design

Shirley T. Fleischmann, Seymour and Esther Padnos School of Engineering, Grand Valley State University

Introduction

ONE OF THE HALLMARKS of the late twentieth century has been a growing awareness of the harmful effects on the earth's environment caused by the manufacture and use of a wide variety of products and processes. Ranging from concerns about chlorofluorocarbons (CFCs) and possible destruction of the ozone layer to concerns about shrinking landfill capacity to concerns about pollution of air, water, and land, protection of the earth's environment has become a global issue and an enormous challenge to the engineering community. Engineers stand at the center of what has been called the paradox of technology, namely "that environmental disruption is brought about by the industrial economy, but that advancement of the industrial economy has also been and will be a main route to environmental quality" (Ref 1). This will come about through the development of specific tools that will be used by engineers in environmentally responsible design; it will also require cultural change: "Design should not merely meet environmental regulations; environmental elegance should be a part of the culture of engineering education and practice. Selection and design of manufacturing processes and products should incorporate environmental constraints and objectives at the outset, along with thermodynamic and economic factors" (Ref 1).

The topic of this article is so broad that it is difficult to organize the vast amount of available information into usable form; however, Allenby (Ref 2) has suggested a useful framework. He has identified two streams into which environmental concerns can be divided as engineers develop methodologies for environmentally sound design. Those two streams are generic concerns and specific concerns. While specific concerns often involve product- or process-specific guidelines and techniques intended for use by the design team, generic concerns involve the corporate or management structure that will support specific practices in design. In parallel to total quality management (TQM) methods, which recognize that quality comes only with total and "top-down" commitment, consistently good environmental practice will most likely occur if it is supported throughout a given company--from the top management on down to the hourly workers. The rest of this article follows the two streams suggested by Allenby, first the generic concerns or guidelines that provide the structure in which specific techniques can be developed and used are discussed, then specific tools that have been developed and specific information that engineers can use are presented.

Environmental Aspects of Design

Shirley T. Fleischmann, Seymour and Esther Padnos School of Engineering, Grand Valley State University

Generic (Structural) Concerns

Consistently good environmental practice will most likely occur within a structure or organization that supports such practice throughout the entire organization. In addition to the required support for the time and material resources that are needed for environmentally responsible design, the design team needs a tremendous flow of information about products and processes at a very detailed level. This information flow begins with those who work most closely with the process or product. Each person in the company has the potential to contribute a different type of information, based on where that person works in the company.

Generic concerns include ethical frameworks within which companies and individuals function. Most professional engineering societies include statements of ethics that place public health and welfare at the center of engineering practice. Many companies have developed mission and values statements as part of a TQM approach. Such statements set the tone for activities within the company, and the inclusion of environmental concerns are a first step to good environmental practice.

General guidelines aid companies in developing a plan for good environmental performance by outlining specific activities to which a company must commit. For example, the *Valdez* principles mandate:

- *Protection of the biosphere:* Companies will minimize the release of any pollutant that may endanger air, water, or earth.
- *Sustainable use of natural resources:* Companies will make sustainable use of renewable natural resources, including the protection of wildlife habitats, open spaces, and wilderness.
- *Reduction and disposal of waste:* Companies will minimize waste and recycle wherever possible.
- *Wise use of energy:* Companies will use environmentally safe energy sources and invest in energy conservation.
- *Risk reduction:* Companies will minimize environmental health risk to employees and local communities.
- *Marketing of safe products and services:* Companies will sell products or services that minimize adverse environmental impacts and are safe for consumer use.
- *Damage compensation:* Companies will take responsibility through cleanup and compensation for environmental harm.
- *Disclosure:* Companies will disclose to employee and community incidents that cause environmental harm or pose health or safety hazards.
- *Environmental directors:* At least one member of a company's board will be qualified to represent environmental interests, and a senior executive for environmental affairs will be appointed.
- *Annual audit:* Companies will conduct an annual self-evaluation of progress in implementing these principles and make results of an independent environmental audit available to the public.

The U.S. Environmental Protection Agency (EPA) certainly has many regulations about environmental performance as do state Departments of Natural Resources. These "command-and-control" guidelines are briefly discussed elsewhere in this article; however, the U.S. EPA also offers more generic EPA Environmental Design Strategies (Ref 3); these strategies emphasize:

- Product system life extension
- Material life extension
- Material selection
- Reduced material intensiveness
- Process management

- Efficient distribution
- Improved management practices

Steps that can be used to standardize an approach to design for the environment (DFE) include (Ref 4):

1. *Initiation:* Define the scope, goal, and system boundaries of the study.
2. *Inventory:* Carry out a life cycle analysis study of the product system.
3. *Impact:* Classify all the relevant environmental data and calculate actual environmental effects.
4. *Improvement:* Having identified the areas for improvement, modify the system specification.

International Standards. ISO 14000, the international standard for Environmental Management Systems (EMS) within a company is another powerful generic guideline. The ISO (International Organization for Standardization) standards are voluntary; however, in a globally competitive marketplace such standards can serve to level the field by defining certain threads that are common to all successful companies. ISO had historically developed specific environmental standards that were oriented toward procedures or specific processes. ISO 14000 is different in that it is a generic standard for environmental management systems, as is discussed later. It is also different from previous standards in that it traces its roots to activities from the United Nations. From the beginning, it has been supported by the international business community as well as by the United Nations. A spirit of cooperation has guided the activities of the ISO Technical Committee 207 (TC 207), which has been charged with the development of this standard. The charge to the committee was to develop a generic standard for the development of environmental management systems that involve good environmental practice, but which also enhance the economic status of the company and encourage trade. Critical organizational performance issues that must be addressed by globally successful companies center on the following five areas: economic, quality, occupational safety and health, environment, and social responsibility.

Registration under ISO 9000 is widely recognized as a core strategic business issue related to quality. It is a generic quality standard that transcends national and cultural boundaries and has, in the past 10 years, swept through the global economic community in a way that any legal or regulatory action could not. ISO 14000 parallels ISO 9000 in that it is a generic standard for environmental management systems rather than quality systems (as for ISO 9000). Like ISO 9000, it will involve third-party registration with regular audits required for renewal of that registration. Because the ISO 14000 standards are voluntary, they provide a mechanism for environmental protection and management that are alternatives to the traditional command-and-control model without infringing on national sovereignty or inhibiting the ability of any company to compete. Environmental responsibility is once again placed within the realm of public trust. Since January of 1993, when the ISO Technical Management Board decided to establish TC 207, and March of that year when Canada was awarded the TC 207 secretariat position, more than 80 countries have participated in numerous working groups on a voluntary basis in order to develop the ISO standards, which are briefly summarized as:

- ISO 14000, environmental management system (EMS)--general guidelines on principles, systems, and supporting techniques
- ISO 14001, EMS--specifications with guidance for use
- ISO 14010, environmental auditing (EA)--general principles
- ISO 14011.1, EA--audit procedures (Part 1): auditing of EMS
- ISO 14012, EA--qualification criteria for environmental auditors
- ISO 14020, environmental labeling (EL)--basic principles
- ISO 14021, EL--self declaration, environmental claims, terms and definitions
- ISO 14022, EL--symbols
- ISO 14023, EL--testing and verification methodologies
- ISO 14024, EL--practitioner programs--guiding principles, practices, and certification procedures of multiple criteria (type 1) programs
- ISO 14031, environmental performance evaluation
- ISO 14040, life-cycle assessment (LCA)--general principles and practices
- ISO 14041, LCA--goal and definition scope and inventory assessment
- ISO 14042, LCA--impact assessment
- ISO 14043, LCA--improvement assessment

- ISO 14050, terms and definitions
- ISO 14060, guide for the inclusion of environmental aspects in product standards

The Regulatory Framework. Environmental regulations often contain elements that are unique to the country or region for which those regulations have been developed. The U.S. EPA oversees environmental regulation. The regulatory framework provided by the EPA is most often the "command-and-control" type of framework, but it offers additional guidance in the development of environmentally responsible design. Major legislation by the EPA is summarized in Table 1. Enforcement of this legislation by the EPA falls under the criminal code of law. States that file a State Implementation Plan (SIP) retain enforcement rights for their own State Department of Natural Resources or Department of Environmental Quality. In addition to EPA regulations, each state has its own regulations and industries in a given state are subject to both the Federal and the State regulations. In either case, violation of environmental law is a violation of criminal law--which is a powerful command and control-driven incentive.

Table 1 Major environmental legislation in the United States

Resource Conservation and Recovery Act, 1976 (RCRA)	**Clarified waste disposal issues and established cradle-to-grave control of hazardous waste**
Comprehensive Environmental Response, Compensation, and Liability, 1980 (CERCLA)	Reauthorized and amended RCRA, clarified responsibility and liability of parties involved in hazardous material management, established Superfund to pay for remediation (by 1984 the EPA identifies 378,000 sites requiring corrective action)
Hazardous and Solid Waste Amendments, 1984 (HSWA)	Step up national efforts to improve hazardous waste management
Emergency Planning and Community Right to Know Act, 1986 (EPCRA), Also known as Superfund Amendments and Reauthorization Act (SARA)	Section 313 of Title III of this act includes the Toxics Release Inventory (TRI), which makes hazardous waste and toxins a matter of public record. This act sets fines for violations.
Pollution Prevention Act, 1990 (PPA)	Establishes hierarchy of Pollution Prevention (PP or P^2), places source reduction at the head of the list for pollution prevention; firms that must report under TRI must also report level of pollution prevention accomplishments
Clean Air Act, 1970 (CAA)	Controlled chemicals list, allowed EPA to assess risk and act to prevent harm; EPA allowed to enforce law without proof of harm; in 1990 establish Maximum Achievable Control Technology (MACT) instead of previous public health standards; emission levels set by EPA or states (Reauthorized 1996, amendments 1977, 1990, 1995)
Clean Water Act, 1972 (CWA)	Gave EPA authority to control industrial discharge to water by imposing discharge requirements on industry, placing special controls on toxic discharge and requiring a variety of safety and construction measures to reduce spills to waterways
Toxic Substances Control Act, 1976 (TSCA)	All new (toxic) substances or new uses of substances entering the marketplace evaluated for health and environmental effects
Examples of Non-Legislative EPA Measures/Actions	
Environmental auditing, 1986	The EPA attempts to formalize procedures for environmental auditing by developing a generic protocol for environmental auditing.

Industrial Toxics Project (33/50 Program), 1991	Companies with large releases of the 17 chemicals of the TRI (Toxic Release Inventory) reported with largest volume releases asked to target 33% reduction by 1992, 50% reduction by 1995. This is a voluntary measure. There are hopes to foster a pollution prevention ethic in business.

For companies considering new processes or new designs, certain parts of this legislation provide lists of controlled chemicals. Every effort should be made to avoid these chemicals because releases require reporting and legal accountability. For example, the Toxic Release Inventory (TRI), which is a part of the Emergency Planning and Community Right to Know Act (EPCRA) (also known as Superfund Amendments and Reauthorization Act, SARA, Title III, section 313) is a list of restricted toxic chemicals, and under the Clean Air Act (CAA) the National Ambient Air Quality Standards (NAAQS) (section 109 under section 40 of the CAA) and the National Emission Standard for Hazardous Air Pollutants (NESHAPS) (section 112 under section 40 of the CAA) both involve lists of chemicals with standards for discharge. Toxic chemicals with the highest volume releases to the environment, according to the TRI were chosen by the EPA for the 33/50 Program. It was called the 33/50 Program because it sought a 33% voluntary reduction in the emission of these chemicals by 1992 and a 50% reduction by 1995. The 17 toxic chemicals targeted by the program are:

- Benzene
- Cadmium and compounds
- Carbon tetrachloride
- Chloroform
- Chromium and compounds
- Cyanides
- Dichloromethane (methylene chloride)
- Lead and compounds
- Mercury and compounds
- Methyl ethyl ketone
- Methyl isobutyl ketone
- Nickel and compounds
- Tetrachloroethylene
- Toluene
- Trichloroethane
- Trichloroethylene
- Xylene(s)

The chemicals and substances covered by NAAQS include:

- Carbon dioxide
- Hydrocarbons
- Nitrogen oxides
- Suspended particulates
- Photochemical oxidants
- Sulfur oxides
- Lead

NESHAPS is a system of point source air discharge standards, which regulates the amount of chemical that can be emitted, the controls required for managing these emissions, and the reporting of any facility modifications that would effect air emissions. Chemicals included under NESHAPS are:

- Asbestos
- Benzene

- Beryllium
- Coke oven emissions
- Mercury
- Vinyl chloride
- Inorganic arsenic
- Rn-222
- Radionuclides
- Copper
- Nickel
- Phenol
- Zinc and zinc oxide

Lists such as these give the designer specific information about chemicals that are known to be harmful.

In addition to its command-and-control approach, the U.S. EPA has also attempted to foster pollution prevention (PP) as a business ethic through various voluntary efforts. The 33/50 Program is one example of these efforts. Pollution prevention roundtables on a national as well as the state level provide forums for the exchange of information. In 1986, the EPA developed a generic protocol for environmental auditing; the use of protocol was/is voluntary, but it does provide a place to begin.

Compliance with environmental regulations on both federal and state level is required and noncompliance can involve substantial fines. The details of the regulatory framework can be overwhelming, and for this reason many companies hire environmental consultants or they designate certain employees to be responsible for environmental compliance. New designs or new processes will have new environmental consequences. For this reason, it is an excellent idea to include someone with knowledge about relevant environmental regulations as part of a design team from the very beginning of the design process. In addition to this designated person(s), it is a good idea to acquaint every engineer involved in design with the basics of the regulatory framework. Note that a company that hopes to be certified under ISO 14000 will most likely undertake these steps as part of its EMS.

Tools for Environmentally Responsible Design

Specific concerns include specific design methods and tools as well as information that is helpful to engineers who hope to complete environmentally sound designs. The various design for "X" (DFX) methodologies, including DFE are discussed in this section. Lists of materials that are frequently recycled and lists of problem materials and products are helpful resources. Organizations such as the Air and Waste Management Association (One Gateway Center, 3rd Floor, Pittsburgh, PA 15222) provide technical manuals and other information exchange. Additionally, trade organizations such as the Institute for Scrap Recycling Industries, Inc. (ISRI) (Suite 1000, 1325 G Street, N.W., Washington, D.C. 20005-3104) can provide specific information. Samples of such information are included. Many professional engineering societies provide journal articles as well as manuals and handbooks--this Volume is just one example--with specific information of value to design engineers. A partial list of software resources is also included.

Life cycle assessment (LCA) is a "cradle-to-grave" assessment of the environmental as well as the energy impacts of a given product design. The article "Life Cycle Engineering and Design" in this Volume provides details about this type of analysis. A full LCA involves a considerable commitment of time and other resources; however, the framework of LCA thinking can be used to prompt the designer to ask questions about the entire product life cycle that might not be asked in a more traditional approach to design. In many cases the primary design focus is on functionality, and environmental performance has not been a significant enough part of the design culture to be considered as part of functionality.

A small example serves to illustrate this point. One company reported providing every employee with a ceramic coffee mug as part of an effort to reduce total discarded paper. (Note that coatings on paper hot beverage containers make them difficult to recycle, so disposal is often the only option.) A narrow concentration on the discarded paper cup waste stream showed a significant decrease in volume; however, life cycle thinking prompted the company to examine the upstream and downstream impacts of this change. They found that many of their employees washed their cups after each use and dried them with paper towels. Not only did they use extra energy by using hot water (which, in turn impacts the environment through discharges from the production of energy), but they also significantly increased the discarded paper towel waste stream. A formal LCA was never done; however, the framework of LCA thinking prompted a much broader and more complete view of the impacts of this change. The habits of the mind that are developed through LCA thinking and that broaden the system boundaries to include cradle-to-grave considerations at the beginning of a design may be the greatest contribution of this type of analysis.

It should also be noted that LCA is a significant part of ISO 14000. There are already examples of standards driving a given design approach; for example, QS 9000 requires failure modes and effects analysis (FMEA). As a result, many automotive suppliers are now including FMEAs as a part of their design process. The same thing may very well happen with LCAs within ISO 14000.

Environmental impact assessment (EIA) can be considered as part of an LCA study; however, it is a separate step that involves its own discipline or approach. Figure 1 shows how an EIA study structures an approach to study the impact of emissions in such a way that major potential problems are identified.

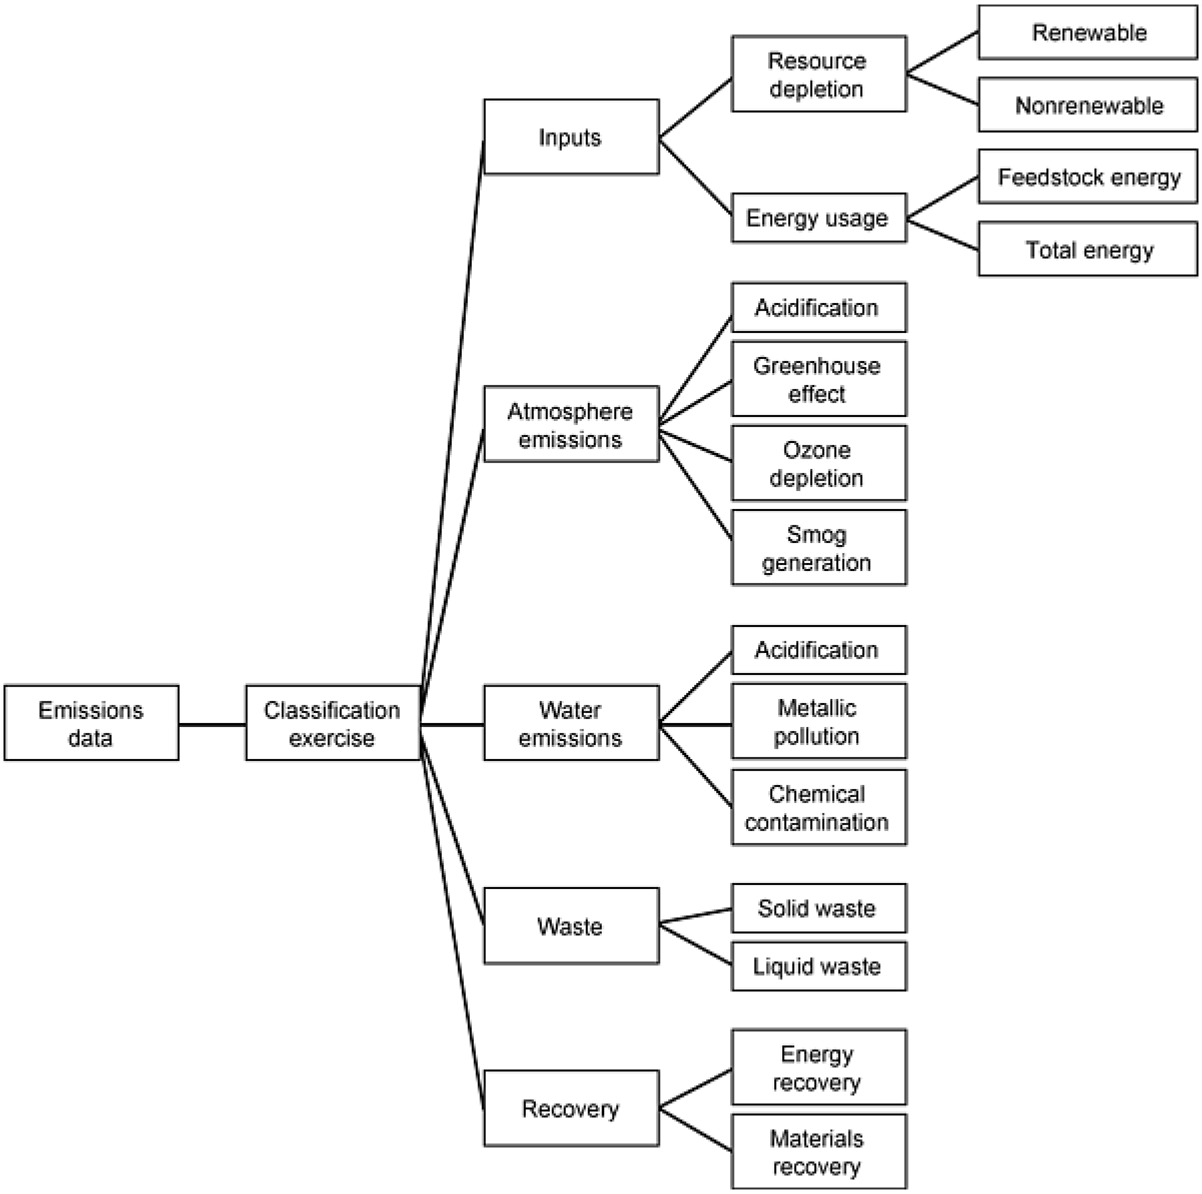

Fig. 1 Schematic showing an environmental impact assessment (EIA) study of emissions data. Source: Ref 5

Quality function deployment (QFD) is a structured approach to design that begins with customer requirements ("needs and wants") and deploys those requirements throughout the entire design through production control. QFD consists of four phases: production planning, design deployment, process planning, and production control. The output for each phase feeds into the next phase as shown in Fig. 2. One of the strengths of this approach to design is that environmental requirements can be explicitly entered into phase 1 as customer requirements. Figure 3 shows one way to enter environmental concerns or requirements as a separate environmental block. Another strength of this approach to design is that phase 1 planning requires explicit measures by which the design team will assess the extent to which the design actually meets customer requirements. Designers may enter the design process with good intentions of being environmentally responsible, but unless measures of good environmental performance are specified at the beginning, it may be difficult to ensure that intentions alone will sustain the commitment to environmental performance. By requiring specification of measures at the beginning of this type of a cascaded process, it is far more likely that good environmental practice goals will be met.

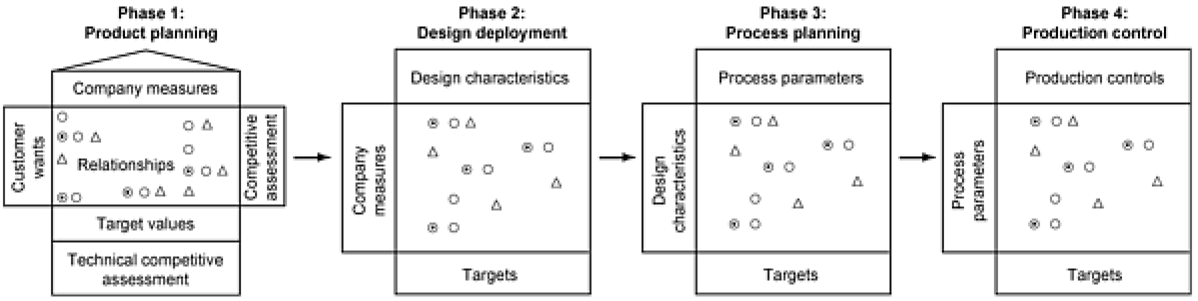

Fig. 2 The four phases of quality function deployment (QFD). Courtesy of the American Supplier Institute

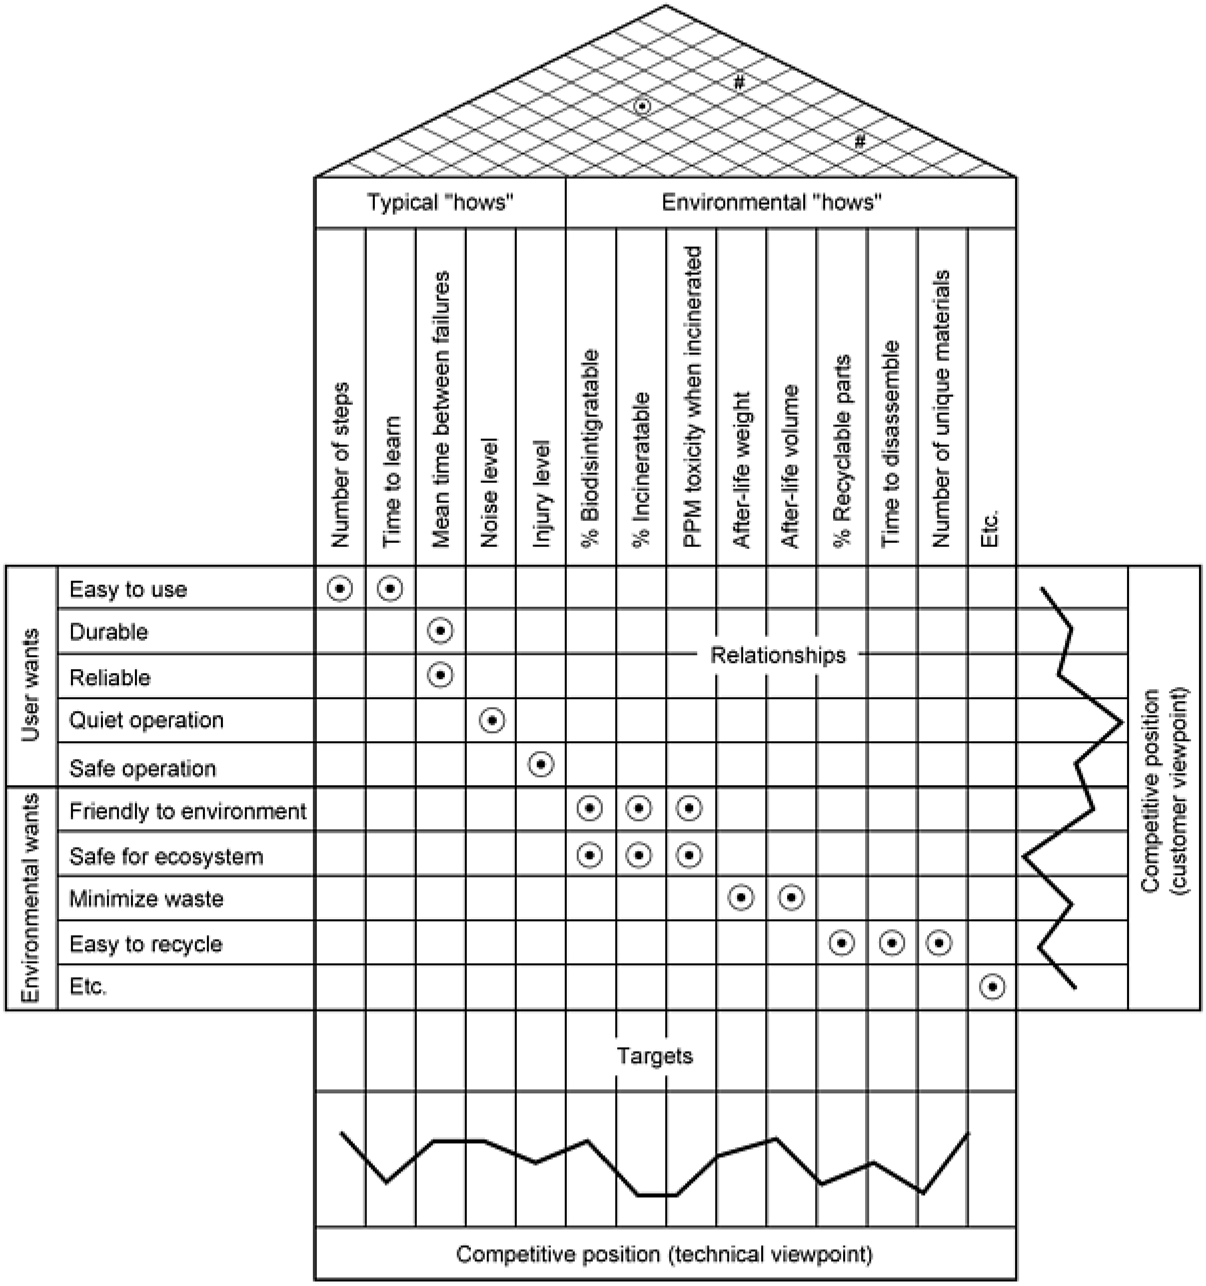

Fig. 3 An example of how environmental concerns can be added to phase 1 of a QFD analysis. Courtesy of the American Supplier Institute

The phase 1 chart includes two competitive assessments. On the bottom of the chart, the proposed design can be compared to a benchmark design or a competitive design based on the measures proposed directly above on top of the chart. On the right-hand side, a similar competitive assessment based on customer requirements is included. The competitive assessments presented in this highly visual form make it far easier to determine if improvements must be made from a technical performance or a customer satisfaction point of view. A product with an excellent technical performance and poor customer performance might indicate a need for the marketing department to step in; a product with good customer performance and poor technical performance shows a potential for problems if technical measures are brought into focus.

The "house of quality" at the top of the chart provides a structured approach to identify the trade-offs involved in optimizing the design. Strongly negative interactions in meeting test requirements indicate the areas in which research might be required and in which potential breakthroughs may occur. Outcomes from phase 1 are inputs to phase 2 and so on through the four phases as noted earlier. This structured method provides a way to include and also to track environmental performance throughout the design. Further information about the QFD approach is provided in the articles "Conceptual and Configuration Design of Products and Assemblies" and "Concurrent Engineering" in this Volume.

Design for "X" (DFX) approaches include design for assembly (DFA), design for disassembly (DFD), and so forth. Each approach seeks to optimize design performance with respect to a given variable such as ease of assembly, ease of disassembly, manufacturability, and so forth. While these approaches are discussed in other articles in this Volume, DFD and DFE are appropriate to discuss here. Design for the environment might involve QFD as a design method; it would most likely involve LCA and EIA; that is, it might involve many of the tools discussed to this point. However, the primary focus of the design effort is to optimize environmental performance while also meeting all other requirements.

Failure modes and effects analysis (FMEA) is currently required of many automotive suppliers as part of a QS 9000 (a version of ISO 9000 developed cooperatively by the automotive "Big 3" for automotive supply) quality plan. Like QFD it is a structured approach in which product or process failure modes are identified and ranked. The tool guides the design team to develop methods to avoid these failure modes. While functional failures are often the focus of such an analysis, environmental failure modes such as accidental releases of dangerous chemicals to the environment or inability to recycle and reuse material at the end of the product life and so forth could be included. Additional information about FMEA is provided in the article "Risk and Hazard Analysis in Design" in this Volume.

Software for Environmentally Responsible Design. Boothroyd and Dewhurst, Inc. has developed software to facilitate a number of the DFX approaches. In particular, the company has a DFE product that enables designers to estimate the type of environmental impact that a design will have from the beginning to the end of its useful life. It can assist the designer in assessing costs and benefits directly attributed to disposal, recycling, and reuse of all or part of the product. It is particularly helpful when used in conjunction with another DFX program such as DFA (see the article "Design for Manufacture and Assembly" in this Volume). With little additional effort, the DFA spreadsheets can be imported into a DFE program for a more thorough product analysis.

The Boothroyd-Dewhurst Design for Service (DFS) software enables a designer to estimate ease of product disassembly as well as disassembly time. This is an important part of DFD. Recovery of parts and materials is often very labor intensive in both the disassembly and sorting phases.

AT&T Bell Laboratories is developing (Ref 6) a scoring system that allows the "greenness" of a design and its components to be quantified using factors such as ease of separation, environmental impacts of material choices, relative weight of recyclable to nonrecyclable material, and whether materials are clearly identified. The system advises designers where scoring points are lost so that areas for improvement can be quickly and clearly identified.

Carnegie-Mellon University has developed a computerized DFE tool called ReStar (Ref 7). This program aids the designer in assessing trade-offs between recycling cost and the benefits derived from reduced environmental distress. For most products, 100% recycling is not economically feasible; instead certain parts or subassemblies might be either recyclable as refurbished (remanufactured) parts or material recovery might be possible. This program serves to aid the designer in deciding how far to go in disassembly. It balances revenue or savings expected from recycling with the costs of recycling.

Design for Disassembly (DFD). If material is to be recovered and reused at the end of the useful life of a product, DFD may be the key to economically feasible recovery. An issue of *Business Week* magazine (Ref 8) featured DFD and a number of new products as well as the companies that led the DFD effort. For example, the BMW Z1 automobile has an

all-plastic exterior that is designed to be completely disassembled from the chassis in 20 min. Also, the Polymer Solutions U-Kettle (an electric water heating kettle) can be pulled apart into like-material components after removing a minimal number of screws. Use of two-way pop-in and pop-out fasteners rather than glues or screws and a dramatic decrease in the number of different types of plastic used in a given product are just two of the strategies that were discovered in these early efforts. As noted in the article, "This is not easy stuff. Designing durable goods for disassembly is something of an oxymoron" (David L. Calhoun, G.E. Plastics). For example, Polymer Solutions found that tolerances between parts that snap together had to be very fine in order to eliminate relative motion between parts in use. BMW discovered that they used on the order of 20 different types of plastics in a typical car, and many products are made from resins that are not clearly identified. Because the recovery of materials is typically very labor intensive, the extra time required for the positive identity of plastics when there are literally hundreds of differing formulations on the market can make it economically unfeasible to recycle the product. Guidelines for DFE where many of the suggestions are clearly linked to DFD include (Ref 9):

- Make sure that everyone involved in the product design fully understands DFE principles and design guidelines.
- Avoid the use of toxic materials (as much as possible) in the product and its manufacturing process.
- Design the product and its components to be reusable, refurbishable, or recyclable.
- Minimize the number of parts.
- Minimize the amount of material in the product.
- Avoid (if possible) the use of separate fasteners.
- Utilize the minimum number of screw head types and sizes used in fasteners in one product or portion of the product.
- Use the fewest number of fasteners so as to reduce disassembly time.
- Design parts so that fasteners are easily visible and accessible to aid in disassembly.
- Design the product to be easily disassembled, if possible, even if some parts are corroded.
- Minimize the number of different materials in the product.
- If the number of different materials cannot be reduced for reasons of manufacturing economics or other reasons, choose materials that are compatible and can be recycled together.
- Avoid the use of composite materials such as glass- or metal-reinforced plastics.
- Standardize components (and subassemblies) to aid in eventual refurbishing of products.
- Use molded-in nomenclature rather than labels or separate nameplates for product identification.
- Use modular designs.
- Wherever feasible (e.g., in molded and cast parts) identify the material from which the part is made right on the part.
- Make separation points between parts as clearly visible as possible.
- Avoid designs requiring spray-painted finishes.
- Provide predetermined break areas if needed.
- Use a woven metal mesh (more easily removable) instead of metal-filled material for welding thermoplastics.
- Design the product to use recycled material from other sources.

Recycling of plastics presents a special problem. To begin with, there are literally hundreds of different types (chemical formulations) of resins--clearly not compatible. Many consumers are familiar with the Society of the Plastics Industry (SPI) coding system found on consumer goods--the molded-in recycling symbol with a number from 1 to 7 in the center. Numbers 1 through 6 are plastics commonly used for packaging; number 7 is designated "other" for all other resins. The Society of Automotive Engineers (SAE) has developed SAE Specification J1344, which is a far more extensive coding system involving many engineering resins. Standards such as ISO 1043, DIN 6120, and VDA 260 are further examples of standards for marking and identification of plastics. Reference 10 contains more information about the identification of plastics.

In addition to the large number of different plastics, plastics are also often lightweight and initially inexpensive. Most secondary materials processors buy and sell material based on weight; a lightweight, high-volume material is more difficult to recycle economically. Because recovery and recycling involve costs of labor and processing and because properties of plastics are often degraded in the recycling process, it is difficult to make recycled material that is cost competitive with often low-cost virgin material. Plastics are also easily contaminated by common chemicals.

Additionally, colors that are added to plastics and that eliminate the need for painting in many cases are almost impossible to remove. In addition to sorting by type of plastic, secondary use may also require sorting by color unless the color is not critical. This generally represents more hand sorting and added handling costs. Overall, the market infrastructure for plastics recycling is not nearly as well developed as the secondary materials market for many metals, and partly because of the difficulties in identification and other problems listed above it will be difficult to develop those markets.

Example: Processes and Equipment Used by a Scrap Processor.

In order to design products that can be recycled, it is helpful to know how those products are treated in the recycling and material recovery process. This case study is a description of the scrap processing facility owned and operated by the Louis Padnos Iron & Metal Company. The company owns and operates several scrap yards; the Holland, MI (headquarters) yard was chosen because of the variety of processes in a single facility. The ability to move material quickly and efficiently into and out of the facility is extremely important to a scrap processing facility; this particular yard is also interesting because of access by truck, rail, and ship. While the variety of processes described in this study might not be found in a typical facility, the processes and equipment described are typical for the scrap-processing industry.

The Padnos Company processes both postconsumer products and industrial scrap from manufacturing plants. Postconsumer products generally involve mixed materials and possible contamination; separation is required. Industrial scrap is generally a single type of material, that is, turnings from machining operations or clip from stamping operations, which are identified by the company selling the scrap to the company. The metallurgical laboratory is used to verify the identity of incoming material and also to test samples of processed material that is about to be sold.

Materials enter and exit the yard by truck, railcar, or by ship. The latter is least frequent, but the yard is located on Lake Macatawa from which ships have access to the Great Lakes. Railcars and trucks are weighed upon entering and exiting the yard, and they are also scanned for radioactive materials. Such materials are not accepted for processing, and scanning prevents accidental mixing with other materials. Most materials are bought and sold on the basis of weight, so this is a critical operation. In fact, railcars are swept out before loading in order to avoid transportation costs for dirt--a material with no market value.

Briquetter. One of the first operations encountered in the yard is the briquetting machine. Turnings from machining operations are heated (below melting temperature) and pressed into small bars roughly 50 by 150 by 25 mm (2 by 6 by 1 in.) in size. This is a very valuable form of scrap because of its purity and its density. Turnings that arrive from the manufacturer are frequently coated with oil from the machining process. The entire area under the briquetting operation is covered by an underground geomembrane--a thick layer of plastic--which collects the oils that drain off the turnings. The oil and other runoff is pumped to a central collection tank from which oil is recovered. A baghouse air-filtering system traps airborne emissions from the heating and pressing process.

Shear. The 1100 metric ton shear prepares plate metal material for steel melting furnaces. Preprocessing of large products to a size and shape suitable to enter the shear is done by hand--usually using cutting torches. The plate material leaving the shear is then sorted, again by hand, according to size and surface finish. Paint causes problems mainly for furnaces without pollution-control equipment.

The shredder is perhaps the centerpiece of the postconsumer processing equipment in the yard. Automobiles, appliances, and a large number of largely metal consumer goods are processed here. Automobiles have most often been preprocessed by automotive salvagers who remove such valuable parts as radiators (copper), catalytic converters (platinum), working subassemblies such as steering columns, alternators, horns, and so forth, for reconditioning and resale. Airbag deployment is not required, in part because it is difficult to detect them, but it should be noted that undeployed airbags do pose a safety risk to scrap-processing workers. The Institute of Scrap and Recycling Industries (ISRI) has prepared a pamphlet that explains the industry position on this important safety issue. Fuel tanks must be removed because they are an explosion hazard. Batteries must be removed to avoid lead contamination, and it is preferable to also remove the tires because the tires have little or no value. Engine blocks are removed and treated in a separate part of the yard, and refrigerants must also be removed. The Holland yard does not have a refrigerant recovery facility; however, another scrap processing yard in Grand Rapids (also part of the same company) does have a recovery unit. This is an issue for appliances as well as automobiles.

Figure 4 is a schematic of a typical shredder. Crane-mounted electromagnets or claws lift material into the ripsteel where three slowly counter-rotating wheels literally rip the product apart. The material then enters the hammermill where 36 hammers weighing 350 lb each are attached to a drum which rotates at 893 rpm. The ripped materials are pounded and in

the process dissimilar materials are loosened from each other. Material leaving the hammermill drops through a 150 mm (6 in.) grate onto a shaker conveyor. From this point on, the material is separated into three streams: ferrous metals, nonferrous metals, and fluff. Ferrous metals are deposited onto a second conveyor that leads into a large cyclone blower. Light contaminants such as dirts or shreds of plastic are blown off the remaining scrap or "No. 2 frag" is deposited in a large pile. "No. 1 frag" comes from a uniform material source where contamination and mixed material is not a problem. The "No. 2 frag" is more common and comes from a mixed input stream such as has been described (cars, washing machines, etc.). Padnos holds a Q-1 Award from Ford Motor Company for the quality of the ferrous material from the shredder, which Ford uses as feedstock for its steel-making processes. This material can be reused with little or no detriment in its properties. Nonferrous metals are not picked up by the magnets. Large blowers blow the light material such as dirt, plastic, glass, foam, and so forth, away, leaving nonferrous metals for a second output stream. These metals are more difficult to separate and require specialized equipment or hand labor. They are sold to another scrap processor. The third stream, the fluff, which consists of plastic, glass, foam, wood, dirt, carpet, and so forth, is a mixed stream with little value. It is generally landfilled and is therefore a direct cost to the shredding operation.

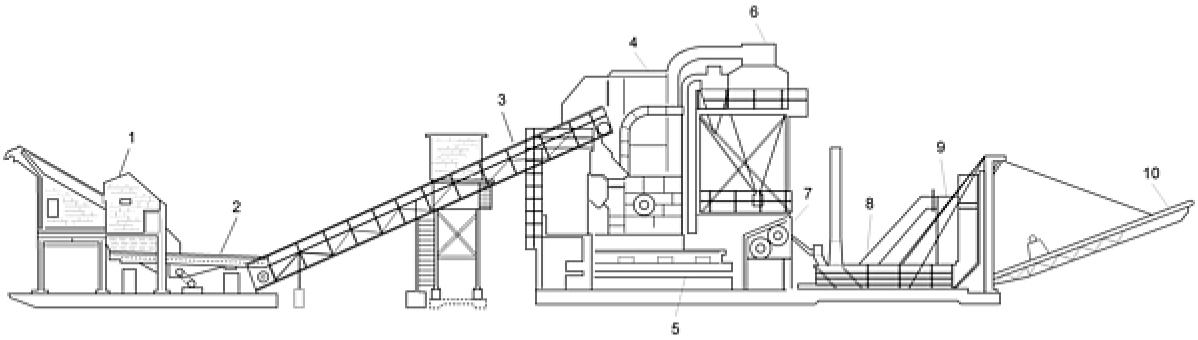

Fig. 4 Schematic of a typical shredder. 1, preshredder; 2, oscillating conveyor; 3, piano hinge conveyor; 4, shredder (ring mill); 5, oscillating conveyor; 6, dust collector unit; 7, magnetic separator; 8, incinerator; 9, smoke scrubber; 10, finished product conveyor

Note here that the metals (and mainly the ferrous metals) make the shredding operation profitable. As metals usage decreases and plastics and resins are substituted, shredding becomes less profitable. A labeling scheme for the plastics might be proposed, and plastics could be removed before shredding, but such removal and separation often involves hand labor and is both time consuming and costly. Recovery of such materials will occur if it is cost effective; however, consider that a typical American automobile can contain over 200 different resins. Parts not clearly marked or easily separable are most economically landfilled or sent to an incinerator. Finally, the markets for metals are well established, and infrastructure for recovery and reuse of metals exists. Markets for plastics are much more difficult to find, the material has less intrinsic value, and the infrastructure to handle such materials does not exist.

Engine Block Crusher. Engine blocks are placed into a special containment area where fluids are allowed to drain out. Again, this part of the yard has an underground containment system to keep oils and other fluids from draining into the soil and eventually into the watertable. After draining, engine blocks are crushed in a hammer-mill. The material is washed, and aluminum parts are removed by hand, and the remaining material is further hand sorted by size. Aluminum is melted into large "sows" and sold. Because of its low melting temperature, other metals commingled with aluminum in this process generally do not melt in the furnace and are easily removed in the pouring process. The crushed and cleaned block material is mostly cast iron and can be sold as feedstock to casting furnaces.

Baler. A crane-mounted electromagnet lifts stock into a chamber, and a plunger crushes the material. When the chamber is full of crushed material, metal bands are bound around the completed bale. The stock, which is baled by Padnos in the Holland yard, is typically flat stock that is the scrap from stamping operations. Like the turnings, this material typically comes from a manufacturing plant and is both uniform and the composition is known.

Nonferrous Metals Processing. Padnos also handles nonferrous metals in the Holland yard. Aluminum cans are crushed and baled. Plumbing fixtures, wire, brass stamping scrap, and so forth, are largely processed and sorted by hand.

Paper Processing. Paper is processed in the Holland yard, but Padnos does operate a separate paper-processing plant in Grand Rapids. Paper is separated by hand and baled for sale. The profit margin for paper is small, but with large

enough volume and with a ready market for this material it is cost effective to process it. Foil, plastic, nonwater soluble glues, spiral bindings, and so forth, are all contaminants for paper recycling and must be removed and separated in the hand-sorting process.

Conclusions. Understanding how secondary materials are processed is critical to design engineers who wish to design products from which materials will be recovered. It is evident that recovery processes involve a considerable amount of hand labor in the sorting of materials. Strategies such as clearly identifying materials, making a product from the smallest number of different materials possible, making it very easy to disassemble products into marketable parts, and using materials for which a secondary material market exists are all important strategies.

Additional information about recycling of metals is available in the articles "Recycling of Iron, Steel, and Superalloys" in *Properties and Selection: Irons, Steels, and High-Performance Alloys*, Volume 1 of *ASM Handbook* (Ref 11) and "Recycling of Nonferrous Alloys" in *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials*, Volume 2 of *ASM Handbook* (Ref 12). Recycling of plastics and recycling of ceramics and glasses are discussed in Ref 13 and 14, respectively.

Additional Environmental Guidelines. What makes a product environmentally unfriendly? Sources of environmentally unfriendliness (Ref 9) are:

- Noxious or poisonous fumes or gases
- Excessive noise
- Hazardous liquids including acids, alkalies, and solvents
- Hazardous solid materials including heavy metals such as mercury, lead, and arsenic
- Safety hazards such as sharp corners or mechanisms that can crush body members or cause electrical shock
- Radioactive materials
- Bacterial contamination of food, drink, or materials that will be used in their preparation/storage

Note that the lists of restricted chemicals from the EPA provide specific information about which materials are hazardous.

Chlorofluorocarbons (CFCs) have been recognized as being environmentally unfriendly due to their potential to destroy the earth's ozone layer. It is now illegal to vent such materials, and care must be taken to recover CFCs from appliances. Alternate materials have been found for decreasing and cleaning, and for many years foams have been made with non-CFC foaming agents. There may be some difficulty with older appliances such as refrigerators with foams that were made with CFC foaming agents. In that case, the CFCs released in crushing the foam may be comparable to the amount released by venting the cooling system. Newer appliances do not have this problem because of design changes made for environmental reasons.

Difficult-to-Recycle Materials. Some materials are simply not economical to recycle, including (Ref 9):

- Laminated materials such as plastics and glass, plastic foam material and vinyl, plastics and metals and dissimilar metals
- Galvanized (zinc-coated) steel
- Thermosetting plastics such as phenolic, urea, or melamine
- Ceramic materials
- Parts with glued or riveted or otherwise fastened identification labels made of a different material than the part (for example, glued paper labels impair the recyclability of glass and plastic containers)
- Subassemblies riveted or otherwise permanently joined dissimilar materials (for example, steel casters on plastic chair bases that cannot be easily extracted)

Difficulty in separation of differing materials and physical properties of materials are frequently the cause of making material recovery uneconomical. For example, thermosetting plastics cannot be melted; when they are formed they are generally made of two or more chemical parts that bond into an almost crystalline lattice structure that must be chemically dissociated. Tires are a thermoset material and also present a large-volume environmental problem, but they also can be

considered as a neglected resource (Ref 15). The Institute of Scrap Iron and Steel, Inc. (ISIS) has produced the list shown in Table 2 of problem products. They note that the list is not exhaustive, neither do they suggest that scrap processors refuse to handle these products. They have simply published this list to inform scrap processors about potential problems. The list should be tremendously valuable to designers also.

Table 2 Materials and products that should be evaluated in terms of environmental risk

Material product	Potential problems
Gas tanks	Explosion, lead from gasoline residue
Batteries	Lead, acid, nickel-cadmium residues
Closed containers and tanks	Explosion, chemical residues
Testing and laboratory equipment, hospital equipment, vials, bottles	Radioactivity, chemical residues, medical and human wastes
Gages and measuring devices	Radioactivity
Compressed gas cylinders	Explosions, hazardous gases
Turnings	Oil, chemical residues
Insulated/coated wire and cable	Asbestos, lead, other coatings or internal chemical residues
Pipe	Asbestos, lead, other coatings or internal chemical residues
Transformers and capacitors	PCBs, oil
Paint/paint thinner cans, buckets	Explosions, lead, cadmium, solvents
Metallic sludges, drosses	Chemical residues
Motor blocks	Oil, solvents, chemical residues
Undeployed automotive airbags	Explosion
Demolition scrap	Radioactivity, asbestos, lead
White goods, appliances	PCBs, CFCs, cadmium, asbestos
Military/government scrap	Explosions, chemical residues

Slag and pit scrap	Chemical residues
Aircraft material	Aluminum,/lithium explosions, chemical residues
Automotive or rail brakes/drums	Asbestos
Waste oil	"Free-flowing," polychlorinated biphenyl (PCB) residues
Plated, coated, painted scrap	Cadmium, lead, zinc

Environmental Aspects of Design

Shirley T. Fleischmann, Seymour and Esther Padnos School of Engineering, Grand Valley State University

Conclusions

Changes in the use of international standards, the global marketplace, and the pursuit of quality in manufacturing enterprises have all had a synergistic effect on environmental awareness and environmentally responsible design practice. The specific concerns described in this article can be viewed as the more vertical aspect of design--the specific methods or guidelines used by those designers directly involved in the design of a particular product or process. The generic concerns (organizational structures and guidelines) can be viewed as the horizontal dimension that links design practice

into the world in which designs must function. Both the vertical and the horizontal, the generic and the specific concerns, must be addressed if cultural changes are to occur in engineering education and practice.

Safety in Design*

Charles O. Smith, Engineering Consultant

Introduction

THE ASME CODE OF ETHICS says: "Engineers shall hold paramount the safety, health and welfare of the public in the performance of their professional duties." This consideration is not new. Tacitus (Ref 1), in about the first century A.D., said: "The desire for safety lies over and against every great and noble enterprise." Even some 2000 years earlier, the first known written law code (Ref 2), while not specifically mentioning safety, clearly implied a necessity for a builder to consider safety.

The National Safety Council (Ref 3) says: "Each year, accidental deaths and injuries cost our society in excess of $399 billion--in the United States alone. This figure includes lost wages, medical outlays, property damage and other expenses. The cost in human misery is incalculable. Accidents are the fifth leading cause of death. The Council believes that accidents are not just random occurrences, but instead result mostly from poor planning or adverse conditions of the environments in which people live, work, drive and play. In our view, `accidents' nearly always are preventable--as are many illnesses."

If for no other reason, one should emphasize safety as a matter of enlightened self-interest. Those who design machines and who have an interest in productivity and cost control serve their "customers" well if risks are at a minimum and thus interruptions called accidents are also at a minimum.

Safety in Design*

Charles O. Smith, Engineering Consultant

Definitions of Safety

One dictionary (Ref 4) definition of safety is: "The quality or condition of being safe; freedom from danger, injury or damage." Most other dictionary definitions are similar. Hammer (Ref 5) says: "Safety is frequently defined as `freedom from hazards.' However, it is practically impossible to completely eliminate all hazards. Safety is therefore a matter of relative protection from exposure to hazards: the antonym of danger." Lowrance (Ref 6) says: "A thing is safe if its risks are judged to be acceptable." This definition contrasts sharply with the Webster definition (which indicates "zero" risk) and, like Hammer's, implies that nothing is absolutely free of risk. Safety is a relative attribute that changes from time to time and is often judged differently in different contexts. For example, a power saw, lawnmower, or similar powered equipment that may be "safe" for an adult user may not be "safe" in the hands of a child.

Lowrance's definition (Ref 6) emphasizes the relativistic and subjective nature of the concept of safety. It further implies that two very different activities are required for determining how safe a thing is: *measuring risk,* an objective but probabilistic effort; and *judging the acceptability of that risk,* a matter of personal and/or societal value judgment. In addition, the level of acceptable risk involves moral, technical, economic, political, and legal issues.

Technical people are generally qualified to measure risks. The decision whether the general public, with all its individual variations of need, desire, taste, tolerance, and adventurousness, might be (or should be) willing to assume the estimated risks is a value judgment that technical people are no better qualified (and are perhaps less qualified) to make than anyone else.

This matter is explored further in the sections "Paramount Questions" and "Acceptable Level of Danger" of the article "Products Liability and Design" in this Volume.

Safety in Design*

Charles O. Smith, Engineering Consultant

Hazard, Risk, and Danger

Considerable confusion exists about the meaning of the words "hazard," "risk," and "danger." Products liability litigation in the United States has developed clear distinctions among these three words. See the sections "Hazard, Risk and Danger" and "Definitions of Defects" of the article "Products Liability and Design" in this Volume. "Danger" is the unreasonable or unacceptable combination of hazard and risk. The objective in safe design is to eliminate danger. (Lowrance's use of "risk" seems close to the legal definition of "danger.")

Charles O. Smith, Engineering Consultant

Designer's Obligation

The designer/manufacturer of any product (e.g., consumer product, industrial machinery, tool, system, etc.) has a major obligation to make the product safe (i.e., reduce the risks associated with the product to an acceptable level). In this context, "safe" means a product with an irreducible minimum of danger (as defined in the legal sense), that is, safe not only with regard to intended use (or uses) but also all unintended, but foreseeable, uses. For example, consider the common flat-tang screw driver. Its intended use is well known. Can anyone say that they have never used such a screwdriver for any other purpose? It must be designed and manufactured to be safe in all these uses. That can be done.

There are three aspects, or stages, in designing for safety:

1. Make the product safe (i.e., design all hazards out of the product).
2. If it is impossible to design out all hazards, provide guards that eliminate the danger.
3. If it is impossible to provide proper and complete guarding, provide appropriate directions and warnings.

Safety in Design*

Charles O. Smith, Engineering Consultant

Make It Safe

In designing any product, there are many considerations, such as function, safety, reliability, producibility, maintainability, environmental impact, quality, unit cost, and so on. In terms of safety, consideration of hazards and their elimination must start with the first concept of the design of the product and be carried through the entire life cycle. As Hunter (Ref 7) says: "This must include hazards which occur during the process of making the product, the hazards which occur during the expected use of the product, the hazards which occur during foreseeable misuse and abuse of the product, hazards occurring during the servicing of the product, and the hazards connected with the disposal of the product after it has worn out."

Because each design is unique, even a modification of an existing product, the designer needs to give full consideration to safety aspects of the product. Although no fixed, universal set of rules exists that tells the designer how to proceed, some general guidelines are available.

Hazard Recognition

Hazard recognition must start as early as possible in the design stage. Hazard recognition requires much background and experience in identifying accident causation. While academic training is very limited, the National Safety Council and many other organizations publish information on this topic. Any threat to personal safety should be regarded as a hazard and treated as such. These threats come from several sources.

Kinematic/Mechanical Hazards. Any location where moving components come together with resulting possible pinching, cutting, or crushing is a kinematic hazard. Examples are belts and pulleys, sets of gears, mating rollers, shearing operations, and stamping operations with closing forming dies. The author can remember working in a machine shop where individual machines (lathes, grinders, shapers, planers, etc.) were belt driven with power supplied by a large prime mover. Such shops had a great number of nip-point hazards where belts ran onto pulleys and a possible flying object

hazard if a belt came apart or slipped off the pulley. Development of low-cost, reliable electric motors for driving individual machines removed the belt-pulley hazards but introduced electrical hazards.

Electrical Hazards. Shock hazard, possibly causing an undesirable involuntary motion, and an electrocution hazard, causing loss of consciousness or death, are the principal electrical hazards for people. Electrical faults (i.e., "short circuits") are the major hazard to property. Massive arcing, cascading sparks, and molten metal often start fires in any nearby combustible material. Any person in the vicinity of a large electrical fault can be severely injured. The danger of electric shock can be reduced by ground fault devices.

Energy Hazards. A potential energy hazard exists if stored energy can be suddenly released in an unexpected manner. Compressed or stretched springs, compressed-gas containers, counterbalancing weights, and electrical capacitors are all energy hazards. Energy hazards are of major importance during servicing of equipment. A designer must develop methods and procedures for placing the product in a "zero energy state" while it is being serviced.

Flywheels, fan blades, loom shuttles, conveyor components, and, in general, any parts with substantial mass that move with significant velocity are kinematic energy hazards that can damage any objects or people who interfere with their motion.

Human Factors/Ergonomic Hazards. All consumer products and most industrial/commercial equipment is intended for use by humans. Ergonomics, defined as the art and science of designing work and products to fit the worker and product user, is a top-priority consideration in the design process.

In many ways a human's capability can exceed that of a machine. The human can adjust to unusual situations; the machine cannot. The human can decide to go over, under, or around an obstacle, and do it; the machine cannot. In an emergency situation, the human can outdo normal performance to a degree that would cause a machine to fail (blow a fuse, pop a gasket, etc.). Unfortunately, humans also make mistakes that can cause accidents.

For additional information, refer to the article "Human Factors in Design" in this Volume.

Environmental Hazards. Internal environmental hazards are things that can damage the product as a result of changes in the surrounding environment. For example, in a water-cooled engine, the water can freeze and rupture the cylinder block if the ambient temperature goes below the freezing point. This problem can be alleviated by using freeze plugs that are forced out of an engine block if the water freezes, adding antifreeze to the cooling water, or using an electrical heating coil that replaces the oil drain plug (standard winter equipment in cities such as Fairbanks, Alaska).

External environmental hazards are adverse effects the product may have on the surrounding environment. These include such effects as noise, vibrations (e.g., from forging and stamping operations), exhaust products from internal combustion engines, various chemicals such as chlorinated fluorocarbons ("Freon") and polychlorinated biphenyls (PCBs), electronic switching devices emitting electromagnetic disturbances, and hot surfaces that can burn a human or cause "thermal pollution."

Hazard Analysis

Hazard analysis is the investigation and evaluation of:

- The interrelationships of primary, initiating, and contributory hazards
- The circumstances, conditions, equipment, personnel, and other factors involved in the safety of a product or the safety of a system and its operation
- Avoiding or eliminating specific hazards by using suitable design, procedures, processes, or materials
- Controls for containing possible hazards and the best methods for incorporating these controls in the product or system
- Damaging effects resulting from lack, or loss, of control of any hazard that cannot be avoided or eliminated
- Safeguards for preventing injury or damage if control of the hazard is lost

References 8, 9, 10, 11, and 12 present typical approaches.

The Consumer Product Safety Commission (CPSC) publishes results of its accident data collections and analyses in the form of Hazard Analyses, Special Studies, and Data Summaries. These identify hazards and report accident patterns by types of products. Information is available from the National Injury Information Clearinghouse, CPSC, 5401 Westbard Avenue, Washington, DC 20207.

Consumer products, as the term implies, are those used by the general public. While service life can be relatively short, some products, such as household refrigerators, stoves, clothes washers, and dryers, often operate for many years, perhaps 20 or more.

In contrast to consumer products, industrial and commercial products are intended to provide revenue for their owners and normally have a relatively long service life. While long life is an advantage from the economic viewpoint, it tends to perpetuate safety design problems for years after safer designs have been developed and distributed in the marketplace. Long service life requires extra care in designing for safety.

Failure Modes and Effects Analysis. Failure modes and effects analysis (FMEA) is performed at the individual component level very early in the design phase to identify all possible ways that components can fail and to determine the effect of such failures on the system (i.e., what the user will experience). FMEA is an inductive process that asks: What if? Additional information can be found in the article "Risk and Hazard Analysis in Design" in this Volume.

Failure Modes and Criticality Analysis. Some components or assemblies in product are especially critical to the product's function and the safety of operators. These should be given special attention with more detailed analysis than others. These more critical components can be identified through experience, engineering judgment, or other analysis. Criticality is rated in more than one way and for more than one purpose. For example, the Society of Automotive Engineers has an Aerospace Recommended Practice (ARP) 926 that establishes four categories of criticality as a function of the seriousness of the consequences of failure. This type of analysis is essentially an extension of FMEA and is designated failure modes, effects, and criticality analysis (FMECA).

Fault Tree Analysis. Fault tree analysis (FTA) differs from FMEA in that it is deductive rather than inductive. FTA starts with what the user experiences and traces back through the system to determine possible alternative causes. The focus is on the product, system, or subsystem as a complete entity. Additional information can be found in the article "Risk and Hazard Analysis in Design" in this Volume.

Fault Hazard Analysis. FMEA and FTA consider only malfunctions. Fault hazard analysis (FHA) has been developed to assess the other categories of hazards. FHA was developed at about the same time as FTA, but it does not use the same logic principles as FTA or the quantitative aspects of FMEA. It was first used by analysts with no knowledge of FTA and by those desiring a tabulated output, which FTA does not provide. FHA is qualitative. It is used mainly as a detailed extension of a preliminary hazard analysis.

Operating Hazards Analysis. FMEA, FMECA, FTA, and FHA are primarily concerned with problems with hardware. In contrast, operating hazards analysis (OHA) investigates the actions of operators involved in activities such as operating, testing, maintaining, repairing, transporting, or handling a product. The primary emphasis is on personnel performing tasks, with secondary consideration of equipment. The end result is usually recommendations for design or operational changes to eliminate hazards or better control them. OHAs should be started early enough to allow time for consideration and incorporation of changes prior to release of a product for production.

Design Review

Design review is an effort, through group examination and discussion, to ensure that a product (and its components) will meet all requirements. In a design of any complexity, there must be a minimum of three reviews: conceptual, interim, and final. Conceptual design reviews have a major impact on the design. As the design becomes fixed, less time is available for major design changes, so interim and final reviews have less impact than the early reviews. It is much easier and much less expensive to design safety in at the beginning of the review process than to include it retroactively. This topic is discussed in greater detail in the section "Design Review" of the article "Products Liability and Design" in this Volume.

Standards

Once a design problem is formulated with the intended function clear, the designer should collect, review, and analyze all pertinent information relative to standards, codes, regulations, industry practices, and so on. From this study, the designer

can usually get assistance in hazards analysis and formulate the design constraints resulting from the known requirements. A clear distinction must be made as to those requirements that are voluntary and those that are mandatory. Additional information can be found in the article "Designing to Codes and Standards" in this Volume.

Occupational Safety and Health Administration. The Federal Occupational Safety and Health Act (OSHA) was passed in 1970. One of its goals was "to assure so far as possible every working man and woman in the nation safe and healthful working conditions." These regulations have the force of law, which means employers must provide a workplace with no recognized hazards. Thus employers cannot legally operate equipment that exposes workers to unprotected hazards. Consequently, designers must design hazards out of their products before these products reach the market. Additional information can be found in the article "Designing to Codes and Standards" in this Volume.

Maintenance

Maintenance safety problems can be separated into those that occur during maintenance, from lack of maintenance, or from improper maintenance. Improper maintenance, for example, might be a situation where electrical connections on a metal case were not installed correctly, thus giving a hazardous condition where none existed previously. There seems to be little the designer can do to prevent a lack of maintenance. Much improper maintenance can be avoided by designing products in such a way that incorrect reassembly is essentially impossible.

Equipment of all kinds requires periodic adjustment or replacement of parts. Designers sometimes fail to consider the hazards to which maintenance personnel will be exposed, even in routine maintenance. During maintenance, safety devices must often be disconnected and/or protective guards removed to permit necessary access. In this context, maintenance personnel may need to put parts of their bodies in hazardous locations that were protected by now-bypassed safety devices. It is the responsibility of the designer to provide protection in this situation.

Lockouts, Lockins, and Interlocks. Many injuries and fatalities have occurred when a worker unwittingly started equipment while a maintenance worker was in the equipment. It is necessary to make it impossible for machinery undergoing maintenance to be started by anyone other than the maintenance worker. CFR 1910.147(c)(2)(iii) [OSHA] requires the designer to provide lockout protection.

A lockout prevents an event from occurring or prevents an individual, an object, force, or other factor from entering a dangerous zone. A lockin maintains an event or prohibits an individual, an object, force, or other factor from leaving a safe zone. Locking a switch on a live circuit to prevent current from being shut off is a lockin; a similar lock on a switch on an open current to prevent it from being energized is a lockout. Both lockouts and lockins can be accomplished if each worker has a personal padlock and key (any duplicate key would be in a central office in a locked cabinet). This procedure can mean multiple locks placed on a lockout panel.

Interlocks are provided to ensure that an event does not occur inadvertently or where a sequence of operations is important or necessary and a wrong sequence could cause a mishap. The most common interlock is in the form of an electrical switch that must be in the closed position for power to be supplied to the equipment. If a guard, cover, or similar device is opened, or left open, the machine will not operate. Although interlocks are usually very effective, they can be rather easily bypassed by using some means to keep the switch closed.

Smith (Ref 13) comments on two accidents, one involving a screw auger for mixing core sand in a foundry, the other involving a large batch mixer. In both cases, maintenance workers suffered permanent disabling injuries when another worker negligently switched on the equipment. A lockout or an interlock that functioned when the cover was lifted would have prevented the injuries.

Zero Energy. Many products require storage of energy for operation. For example, energy is stored in any spring that is changed during assembly from its free, unstressed dimensions. This energy storage is also true of cables, cords, and chains that are loaded in tension. Some other sources of stored energy are compressed gases, energized electronic power sources, and lifted counterweights. The zero energy concept requires the designer to provide protection for any operator or maintainer of equipment against the consequences of unanticipated release of stored energy (i.e., neutralize these energy sources in an emergency situation or during maintenance work).

Fail-Safe Designs

A significant fraction of accidents are the result of product failure or malfunction. Fail-safe design seeks to ensure that a failure will either not affect the product or change it to a state in which no injury or damage will occur.

Fail-passive designs reduce the system to its lowest energy level. The product will not operate until corrective action is taken but there will be no further damage from the failure-initiating hazard. Circuit breakers are a good example of fail-passive devices.

Fail-active designs maintain an energized condition that keeps the system in a safe operating mode until corrective action can be taken or the system is replaced. Redundancy using standby equipment is an example of a fail-active system.

Fail-operational designs allow safe continuation of function until corrective action can be taken. Fail-operational is obviously the preferred form, if possible. The ASME requires fail-operational feed-water valves for boilers. Water must first flow under, rather than over, the valve disk. If the disk is detached from the valve stem, water will continue to flow and allow the boiler to function normally.

Designs should be made fail-safe to the greatest degree possible.

General Principles of Designing for Safety

Hunter (Ref 7) gives the following statements as general principles or guidelines for designing safe products:

- Recognize and identify actual or potential hazards, then design them out of the product.
- Thoroughly test and evaluate prototypes of the product to reveal any hazard overlooked in the preliminary design stages.
- Make certain that the product will actually perform its intended function in an acceptable manner so that the user will not be tempted to modify it or need to improvise possibly unsafe methods for using it.
- If field experience reveals a safety problem, determine the root cause, develop a corrective action to eliminate the hazard, and follow up to make certain that the corrective action is successful.
- Design equipment so that it is easier to use safely than unsafely.
- Realize that most product safety problems arise from improper product use rather than product defects.

Safety Checklists

Hammer (Ref 9, 10) and the National Safety Council (Ref 14) provide lists of basic safety requirements for use in developing safe designs. For example, at the top of his list, Hammer (Ref 9, 10) says: "Sharp corners, projections, edges, and rough surfaces which can cause cuts, scratches, or puncture wounds will be eliminated unless required for a specific function." There are 21 more items in the list.

Acceptable Conditions

Hammer (Ref 9, 10) notes that safety engineers (perhaps no one else?) generally consider the following conditions acceptable and indicative of good design.

- Any design that to cause an accident requires at least two *independent* malfunctions, two *independent* errors, or a malfunction and an error that are *independent*
- Any design that positively prevents an error in assembly, installation, connection, or operation that analysis indicates would be safety-critical
- Any design that positively prevents a malfunction of one component (or assembly) from causing other failures that could cause injury or damage (fail-safe)
- Any design that limits and controls the operation, interaction, or sequencing of components (or subassemblies) when an error or malfunction could cause an accident (e.g., when activating switch B before activating switch A could cause damage) (interlock)
- Any design that will safely withstand a release of greater energy than expected, or normally required
- Any design that positively controls buildup of energy to a level that could potentially cause damage

(e.g., use of a shear pin to protect a shaft)

Safety in Design*

Charles O. Smith, Engineering Consultant

Guarding

As indicated above, if it is impossible to design out all hazards, guards must be provided. The basic legal requirements are set forth in CFR 1910.212, *General requirements for all machines* (OSHA), which says:

> (a) Machine guarding. (1) Types of guarding. One or more methods of machine guarding shall be provided to protect the operator and other employees in the machine area from hazards such as those created by point of operation, ingoing nip points, rotating parts, flying chips and sparks. Examples of guarding methods are barrier guards, two-hand tripping devices, electronic safety devices, etc. (2) General requirements for machine guards. Guards shall be affixed to the machine where possible and secured elsewhere if for any reason attachment to the machine is not possible. The guard shall be such that it does not offer an accident hazard in itself.

One should note the key word "all" in the heading. Further, the use of "shall" makes the requirement for guards mandatory.

Most of the dangerous hazards from moving parts of machines occur in three areas:

- *Point of operation:* where the machine works on the workpiece to shape, cut, and so on
- *Power train:* the set of moving parts that delivers power to the point of operation (e.g., shafts, gears, chains, pulleys, cams)
- *Auxiliary components:* such items as feeding mechanisms and other components that move when the machine is in operation

All of these parts have obvious nip points. Less obvious nip points are between an auger screw conveyor and the trough, between a tool rest and a grinding wheel or part being turned on a lathe, between the spokes of a handwheel and the guide or support behind it, between a translating component and a fixed component close to it--in short, a shear of any kind (Ref 15). In general, a nip point occurs when two components are in close proximity with relative motion that reduces the separation between them. There are other hazards, such as potential pressure vessel explosions and bursting flywheels.

The general requirement for a guard is that the point of hazard be substantially enclosed, screened, barricaded, or otherwise protected so that persons, whether workers or bystanders, cannot inadvertently come in contact with the hazard.

Mechanical guards, the most common type, can be fixed, adjustable, or interlocked. Grimaldi and Simonds (Ref 16) give the basic requirements for a mechanical guard as:

- It must be sturdy to prevent damage to the guard from external sources or interference with the operation of the machine. Either of these possibilities would probably cause the operator to remove the guard and not arrange to have it repaired and replaced.
- It must permit maintenance operations without requiring excessive labor for dismantling and reassembling the guard, or else there will be a tendency to omit its installation.
- It must be properly mounted. The mounting must be rigid to prevent objectionable rattles or interference with working parts. The mountings should be strong enough so that they will not fail under use.
- It should be designed so that there are no detachable parts that would reduce its guarding effectiveness if removed and not replaced.
- It should be easy to inspect, and a periodic checkup program, as a part of the maintenance procedure for shop equipment, should be established in order to continue its effectiveness.

Fixed guards should be used wherever possible, because they provide permanent protection against hazardous machinery components. Adjustable guards are used when the mode of operation of the machine is expected to change and adjustment is necessary to accommodate a new set of dimensions. Once adjusted, the guard should then function as a fixed guard. Interlocked guards prevent operation of the machine until the guards have moved into positions that keep the worker out of the hazardous zone. It is essential that the guard put the machine in a safe mode if the guard should fail for any reason (fail-safe).

In using pullbacks, bands are strapped around the operator's wrists, and cords or cables run from the bands to a pulling mechanism synchronized with the down stroke of a power press. If the operator does not remove his or her hands from the hazard area, they are automatically pulled away, even if the press recycles on its own. Pullbacks, however, are not complete protection. The author knows of at least one situation where injury to the worker resulted from an unanticipated recycle. Pullbacks require adjustment to each operator, frequent inspection, and diligent maintenance. Pullbacks are often objectionable to the worker, who feels tied to the machine.

Barrier gates are simple mechanical devices that are opened and shut by machine motion during the operating cycle. This function allows the operator to approach the point of operation (e.g., to feed work stock) but keeps any part of the body from being in the hazard zone when the machine is activated. In most cases, an interlock interrupts power when the gate is open and prevents the operator from opening the gate when the machine is in motion.

Electromechanical Devices. Presence-sensing devices commonly use (a) a light beam and a photoelectric cell ("electric eye") to stop the machine if the light beam is interrupted or (b) a radio frequency electromagnetic field that is disturbed by the capacitance effect of the introducing body.

Distance/Separation Guarding. A logical and effective way of guarding is by separation or distance. The question of location must be considered by the designer. For example, tables of distances and the corresponding openings permitted are given in CFR 1910.217(c)(2)(vi) [OSHA] and in ANSI B11.1.

Input/Output Systems. Systems for feeding stock and ejecting workpieces can provide more safety by using semiautomatic or fully automatic systems. Perhaps the most desirable is a robotic system for mechanical feeding of stock and retrieval of parts. Although more expensive, robots can work where there is a high noise level, can work at a temperature higher than tolerable for most humans, and can perform repetitive monotonous functions indefinitely. One hazard is that the robot may strike a bystander. This hazard, however, can be avoided by barriers or presence sensors.

Auxiliary equipment is generally used in connection with other protective devices to give an additional measure of safety. For example, it is very difficult to provide complete point-of-operation guarding for a band saw, because the saw blade must be exposed in order to accomplish the desired function of cutting material. When small or narrow pieces are being cut, the operator's fingers can get too close unless a push stick or push block is used. The block allows control over the workpiece to get the desired result but keeps the operator's fingers away from the hazard zone. A great variety of

pliers, tongs, tweezers, magnetic lifters, suction cup lifters, and so forth are available for use as auxiliary equipment. Such equipment may need to be adjusted for use in different applications.

Controls. Operating controls can be designed to ensure that the operator is out of the hazard zone (point of operation). For example, if only one push button is provided, the other hand could be in the hazard zone. To prevent this, two buttons are provided, far enough apart to require use of both hands, and arranged in series so that both must be pushed to activate the machine. If the stroke time is long enough for the operator to push the buttons and still get a hand into the hazard zone, a requirement can be added that both buttons be held down until the stroke is completed. There is a temptation for workers to tie down one of the buttons, which obviously defeats the two-button safety feature. To circumvent this, a requirement can be added that both buttons must be pressed within a short time period. If the allowable delay is exceeded, the machine will not operate. While most machines should have a two-button control system, there are situations in which a single set of on-jog-off buttons is acceptable because the operator is physically distant from the hazard zone (e.g., control of an overhead crane).

Another aspect of control buttons is that the start, or operate, button (or buttons) should be recessed to reduce the possibility of inadvertent operation. These are also usually green in color. A stop button should have a large, mushroom-shape head that is not recessed and should be easily reached from the normal operating position for use in case of an emergency. The usual color for stop buttons is red.

In cases where a machine runs continuously while the operator is exposed to hazards in any manner, it is necessary to use a control that can immediately stop the machine. The stop button, noted above, is one possibility. In other cases, a trip wire is placed where a worker can easily reach it from any location of the workstation. Pulling on this wire will stop the operation. In one situation (Ref 15), the trip wire was not sufficiently close to be effective when a worker had a hand caught in a shear nip point. In other situations, a force- or pressure-sensitive bar has been used. When the bar is pushed (e.g., if the operator stumbles, loses balance, or is pulled into the machine), the machine will be deactivated. Location is critical. The bar must be located so it will be effective in an emergence but not be inadvertently activated by the material being processed. Presence-sensing devices, "electric eyes," infrared beams, and so forth can also be used to deactivate equipment. Machines that continue to run after power is cut off require a brake for quick stopping.

Data Sources. As noted above, OSHA regulations and ANSI standards are available and can provide much information on guarding. Pertinent data can be found in many other publications (e.g., Ref 7, 16). Information is also available from the National Safety Council (Ref 14, 17, 18), which has videos available for employee training.

Safety in Design*

Charles O. Smith, Engineering Consultant

Warnings

As noted above, where it is not possible to provide complete and effective guarding, or where such guarding would severely impair the intended function of the product, it is necessary to provide appropriate directions and warnings.

Obviously, eliminating all the potential hazards in a design and/or providing effective guarding is not a simple task. In some cases, it is impossible. Developing a proper, effective warning is generally even more difficult. In large measure, this is because there is hardly consensus, let alone anything approaching unanimity, on a truly adequate and acceptable warning for a given situation. Nonetheless, a full-scale effort must be made.

Directions are instructions intended to *ensure effective use* of a product. *Warnings*, in contrast, are intended to *ensure a safe use* (i.e., to inform of hazards, to inform of improper use, and to instruct how to guard against these, if possible). The distinction is clear in concept, but it is not always possible to tell whether a given statement is a direction or a warning. Lehto and Miller (Ref 19, 20) say: "Perhaps the best way to initially distinguish between warnings and other forms of safety-related information is to state that warnings are specific stimuli which alert a user to the presence of a hazard, thereby triggering the processing of additional information regarding the nature, probability, and magnitude of the hazard. This additional information may be within the user's memory or may be provided by other sources external to the user. Much of the current controversy regarding warnings is actually related to the need for this additional information."

Three criteria must be met for a warning to be fully effective:

- The message must be received.
- The message must be understood.
- The endangered person must act in accordance with the message.

A warning is not effective unless it changes the potential behavior of the endangered individual.

Types of Warnings

Injury or damage can often be avoided by a focus on the existence of a hazard and the need for careful action. Every method for calling attention to a hazard requires communication; each of the human senses, singly or sometimes in concert, have been used for this purpose.

Visual Warnings. It is widely recognized that most information on hazards, perhaps as much as 80%, is visually transmitted to personnel. There are more variations of visual methods than of the other senses. A hazardous area is often more brightly illuminated than other areas in order to focus attention. A piece of equipment can be painted in alternating stripes or in a bright, distinctive color (e.g., fire trucks are now being painted in greenish-yellow rather than red for better visibility). Signal lights are often used (e.g., on emergency vehicles and at railroad crossings). Flags and streamers can be used. Signs are common, such as highway signs.

Auditory warnings may have a shorter range of effectiveness than visual warnings, but their effectiveness may be greater in that short range. Auditory warnings are often coupled with visual warnings, such as on emergency vehicles. Typical devices are sirens, bells, buzzers, and horns (e.g., the intermittent sound of a horn on a truck that is backing up).

Olfactory Warnings. Odorants can be used in some limited, although effective, ways (e.g., addition of small amounts of a gaseous odorant to natural gas to warn of leaks).

Tactile Warnings. Vibration is the major tactile means of warning (e.g., rumble strips on highways). Vibration in machinery may mean the beginning of serious wear or lubrication failure. Temperature sensing, at least an indication of significant temperature change, can also be included in this category.

Tastable warnings have little use in machine applications but have been used with foods and medicines.

Written Warnings

Much confusion exists, especially within the legal system, as to the meaning of the term "warning" when applied to products and their uses. The major reason may be that "warnings" are usually considered synonymous with the explicit "warning labels" that are sometimes placed on products. One consequence is that sources of information that do not explicitly (in words) describe the hazard, specify its intensity, provide instructive countermeasures, and strongly advocate adherence may not be considered adequate warnings. Another reason for the confusion is that society seems to expect warnings to perform multiple functions.

Warnings should supplement the safety-related design features of a product by indicating how to avoid injury or damage from the hazards which could not be feasibly designed out of the product, designed out without seriously compromising utility, or protected against by providing adequate guards. In theory, providing such information will reduce danger by altering the user's behavior or by causing people to avoid using a product. However, from the litigation viewpoint, warnings often perform functions having little to do with either safety or transfer of safety-related information. A manufacturer may view warnings as a defense against litigation. One consequence is extensive use of "warning labels," which sometimes yields no increase in safety. Even more unfortunate is that some manufacturers may use warnings instead of careful design, which is absolutely unacceptable.

As indicated above, for a warning to be effective, the endangered person must receive the message, understand it, and act in accordance with it. The designer/manufacturer obviously has no control over the action, but does have substantial control over sending the warning and making it understandable. Failure on the part of the endangered person to meet any one of the above criteria makes the warning ineffective. The probability that a warning will be effective is certainly no higher than the percentage of users who read the warning. There is general agreement that many people who see a warning label do not read it. Many do not even see the label. This obviously can be discouraging to one trying to develop a proper, effective, warning label. Nonetheless, a major effort must be made.

Every warning, including labels, has an alerting function. The warning label must be prominently located (i.e., in a position such that the user will be virtually sure to see it). The warning label must also be distinctive (i.e., sufficiently different from other labels that there is no question of its identity). Shape has an influence; shapes with rounded or curved boundaries are not as effective in attracting attention as shapes with sharp corners. Rectangles seem to be more effective than squares or triangles. Labels with five or more sides are rarely used on industrial or consumer products.

Three signal words (in relatively large letters) and color combinations are normally used to attract attention:

- *Danger:* The hazard can immediately cause death or severe injury. Letters should be white on a red background.
- *Warning:* The hazard can immediately cause moderate injury or death, or severe injury may eventually result from contact with the source of the hazard. Letters should be black on an orange background.
- *Caution:* The hazard can immediately cause minor injury, or moderate injury may eventually result from contact with the source of the hazard. Letters should be black on a yellow background.

Every warning, especially a label, has a *message.* This message must be clear, simple (unambiguous), succinct, and convincing. Short words are preferred, and as few words as possible. Long sentences with technical terms should be avoided. There are indications in the literature that directions and warnings should be written at the sixth grade level. The use of indices such as the Flesch Reading Ease Formula, Gunning's Fog Index, or McElroy's Fog Count can be helpful. See also Ref 21. For products that will be used only within a country or region in which there is one common language, the choice of language is obvious. For products that will be used in regions with different languages, warning labels must be in those languages. Those who write labels in languages different from that of the manufacturer must be knowledgeable about the linguistic and cultural characteristics of those regions.

A partial alternative to the use of multiple languages is the increasing use of pictographs. A pictograph communicates an idea or concept in one symbol which is universally recognized. For example, there is general recognition that a 45° red diagonal line through an annulus forbids whatever is displayed within the annulus (e.g., a lighted cigarette within the annulus indicates that no smoking is permitted). General guidelines for pictographs are:

- Use a simple design for the symbol.
- Use only one idea per pictograph.
- Use only correct colors and shapes.
- Locate the symbol as close as possible to any related words.

Words on the label must be legible by the average person, some of whom may have uncorrected visual impairment. ANSI Z535.4 (Ref 22) gives requirements for wording and colors to be used, which differ from standards issued by OSHA and the CPSC. ANSI Z535.4 also specifies letter size. Signal words must be at least 3 mm high (9 point type), and the text must be at least 1.5 mm high (5 point minimum). ["Point" is a unit of measure for typeset letters; there are essentially 72

points per inch.] This is a consensus standard and represents the minimal requirements acceptable to those involved in developing the document. Many believe the lettering should be larger. Bailey (Ref 23), for example, notes that the "type size in books and magazines usually ranges from 7 to 14 points with the majority being about 10 to 11 points. Probably the optimum range is from 9 to 11 points--sizes smaller or larger can slow reading speed."

A warning label should be permanent. A warning should not fade or fall off before the end of the service life. Most labels are decalcomanias. Fortunately, they are available with a base of tough wear-resistant material and good adhesive backing. Some products have warnings on stamped or embossed plates permanently secured to the product. Operator manuals and/or maintenance manuals commonly accompany the product as shipped from the manufacturer but do not always find their way to the product in its operational situation. Providing a tough, dirt- and lubrication-resistant envelope that contains the manual and is "permanently" attached to the product (e.g., a power press or similar machinery) by a short chain can be useful for the worker.

CFR 1910.145 (OSHA) specifies requirements for accident prevention signs. By reference, two ANSI standards, Z35.1, "Specifications for Accident Prevention Signs," and Z53.1, "Safety Color Code for Marking Physical Hazards," were incorporated. Designers should consult these as soon as a decision is made to incorporate warnings. It should be noted, however, that in 1979, ANSI Z53 Committee on Safety Colors was combined with ANSI Z35 Committee on Safety Signs to form ANSI Z535 Committee on Safety Signs and Colors. Five subcommittees were formed to update the Z35 and Z53 standards and write two new standards. These are listed in Ref 22, 24, 25, 26, and 27. The Society of Automotive Engineers has a recommended practice, J115 (Ref 28), relating to safety signs. This is generally consistent with the ANSI 535 series, but there are some differences. (This situation is an example of old standards still having the force of law in OSHA standards, even though these old standards have been replaced by much more recent standards.)

Smith and Talbot (Ref 29) discuss a label on a 20 ft (6 m) long fiberglass ladder. This is also discussed in some detail in the article "Human Factors in Design" in this Volume (see Fig. 3 and the accompanying discussion in that article).

Although warning that helps prevent an injury may not make great advertising copy, it is a necessity. Warnings are not new. When Samual Jones began manufacturing "Lucifer" matches (smelling of "hellfire and brimstone") in 1829, he printed the following warning on the boxes: "If possible, avoid inhaling the gas that escapes from the combustion of the black composition. Persons whose lungs are delicate should by no means use Lucifers." In terms of the above discussion, this is a relatively good warning.

Sources

There has been much written with regard to warnings in both the technical and legal literature. The best technical source currently available for understanding the nature of warnings and the difficulty in writing them is Lehto and Miller (Ref 19, 20).

Human Factors/Ergonomics

Human beings interact with all products in designing, manufacturing, operating, and maintaining them. Human beings constitute the most complex subsystem in any system because of their abilities and limitations. In addition, the number and variety of actions that a group of persons can take in any situation, either as individuals or as a group, generates a high probability that any deficiency in the system will be linked to, and affected by, personal factors that can generate an accident. In other words, the human being is the most erratic, and the least controllable, parameter in any system.

Additional information can be found in the article "Human Factors in Design" in this Volume.

Products Liability and Design

Charles O. Smith, Engineering Consultant

Introduction

PRODUCTS LIABILITY is a legal term for the action whereby an injured party (plaintiff) seeks to recover damages for personal injury or property loss from a producer and/or seller (defendant) when the plaintiff alleges that a defective product caused the injury or loss.

If a products liability suit is entered against a company, the plaintiff's attorney and technical experts will attempt to convince a jury that the manufacturer did not exercise reasonable care in one or more features of design and/or manufacture, and that because the company did not exercise reasonable care, an innocent party was injured. The defendant's team will attempt to convince a jury that the manufacturer was not responsible for the injury.

Products liability is not new. The first law code known to be in writing was established by Hammurabi, King of Babylon, about 4000 years ago, and it contained clauses which clearly relate to products liability (Ref 1).

Who may be a plaintiff? Essentially any consumer, user, or bystander may seek to recover for injury or damages caused by a defective and unreasonably dangerous product.

Who may be a defendant? Any corporation, business organization, or individual who has some degree of responsibility in the "chain of commerce" for a given product, from its inception as an idea or concept to its purchase and use.

The situation is schematically summarized in Fig. 1.

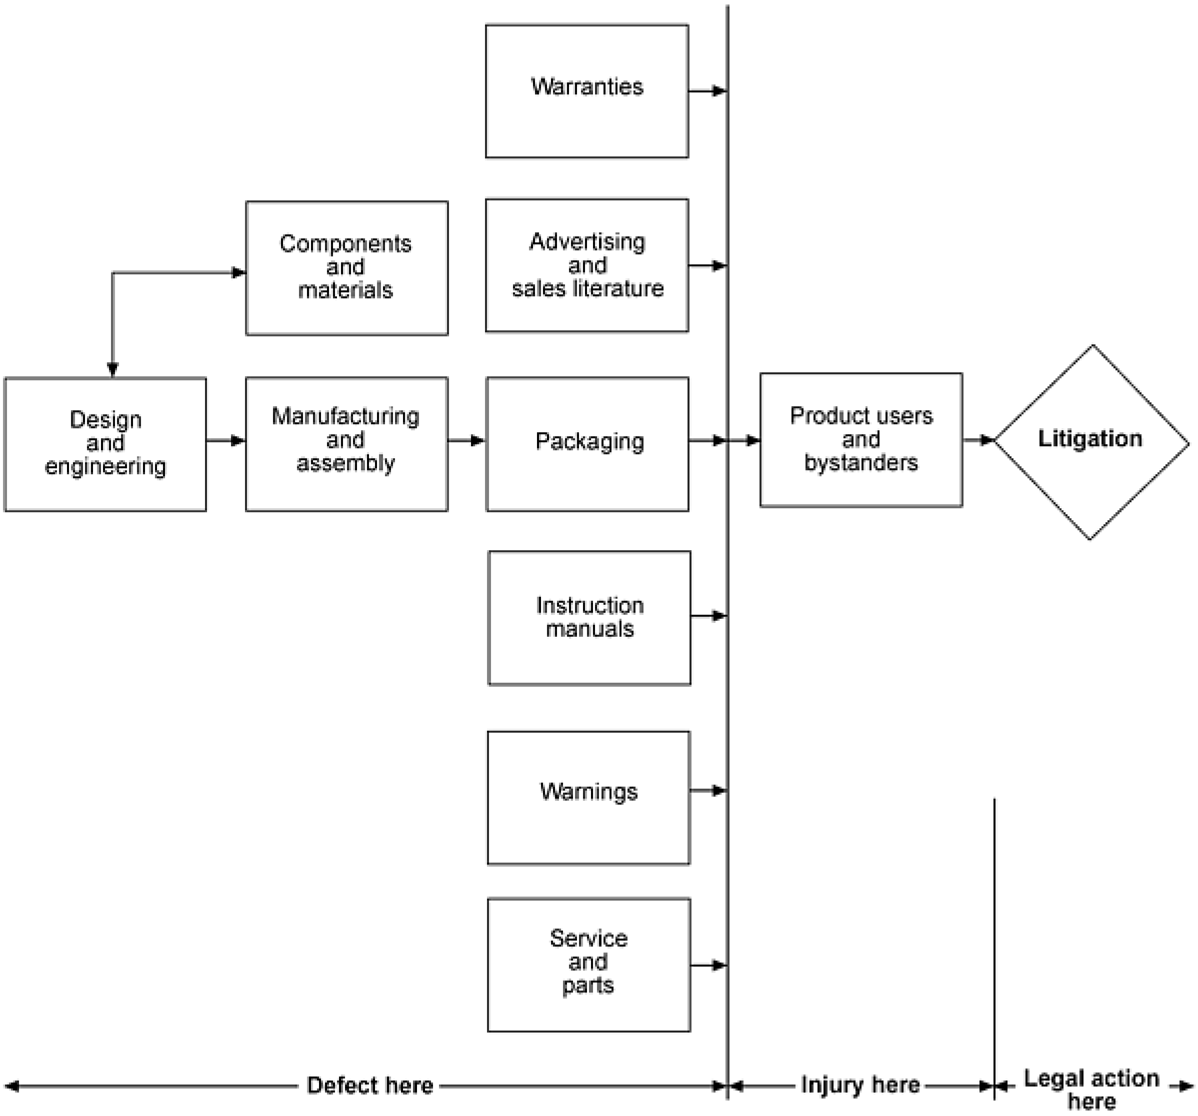

Fig. 1 The essence of products liability

Legal Bases for Products Liability

The three legal theories on which a products liability lawsuit can be based are negligence, breach of warranty, or strict liability. All three are predicated on the fault system (i.e., a person whose conduct causes injury to another is required to fully and fairly compensate the injured party).

The basic method of imposing liability on a defendant requires the plaintiff to prove that the defendant acted in a negligent manner. Under the negligence theory, the plaintiff must essentially establish proof of specific negligence (i.e., prove that the defendant was almost intentionally negligent). Proof of specific negligence is a difficult task.

A user of a product may, as a result of express oral or written statements, or implication, reasonably rely on the manufacturer's express or implied assurance (including advertising material) as to the quality, condition, and merchantability of goods, and as to the safety of using them for their intended purpose and use. If the user relies on these assurances and is injured, suit can be entered on the basis of breach of warranty.

Both negligence and breach of warranty require proof of some fault on the part of the defendant (i.e., the focus is on the action of an individual). Strict liability, however, focuses on the product itself (Ref 2):

1. One who sells any product in a defective condition unreasonably dangerous to the user or consumer or to his property is subject to liability for physical harm thereby caused to the ultimate user or consumer, or to his property, if (a) the seller is engaged in the business of selling such a product and (b) it is expected to and does reach the user or consumer without substantial change in the condition in which it is sold.
2. The rule stated in Subsection (1) applies although (a) the seller has exercised all possible care in the preparation and sale of his product, and (b) the user or consumer has not bought the product from or entered into any contractual relation with the seller.

Although these three bases apply in general, it should be recognized that there are variations. Interpretation and application may vary greatly depending on the jurisdiction.

Products Liability and Design

Charles O. Smith, Engineering Consultant

Hazard, Risk, and Danger

There is substantial confusion about the meaning of words such as hazard, risk, and danger. Webster (Ref 3) defines danger as: "liability to injury, pain, damage or loss; hazard; peril; risk." Webster makes some distinction by further saying: "Hazard arises from something fortuitous or beyond our control. Risk is doubtful or uncertain danger, often incurred voluntarily."

One can also consider a hazard as any aspect of technology or activity that produces risk; as the potential for harm or damage to people, property, or the environment; and as including the characteristics of things and the actions (or inactions) of individuals. One can also consider risk as a measure of the probability and severity of adverse effects.

With all the products liability litigation in the United States, there has developed a clear distinction among these three words for legal purposes. In this context, a *hazard* is a condition or changing set of circumstances that present an injury potential (e.g., a railroad crossing at grade, a toxic chemical, a sharp knife, the jaws of a power press). *Risk* is the probability of injury and is affected by proximity, exposure, noise, light, experience, attention arresters, intelligence of an involved individual, and so on. Risk (probability of exposure) is obviously much higher with a consumer product than with an industrial product used by trained workers in a shop environment. *Danger* is the unreasonable or unacceptable combination of hazard and risk. The U.S. courts generally hold that any risk that can be eliminated by reasonable accident prevention methods is unreasonable and unacceptable. A high risk of injury could be considered reasonable and acceptable if the injury is minimal and the risk is recognized by the individual concerned.

As might be expected, there is extensive and ongoing debate over the meaning of "reasonable" and "unreasonable." The American Law Institute (Ref 2) says *unreasonably dangerous* means that: "The article sold must be dangerous to an extent beyond that which would be contemplated by the ordinary consumer who purchases it, with the ordinary knowledge common to the community as to its characteristics. Good whiskey is not unreasonably dangerous merely because it will make some people drunk, and is especially dangerous to alcoholics; but bad whiskey, containing a dangerous amount of fusel oil, is unreasonably dangerous." The American Law Institute (Ref 2) further says: "There are some products which, in the present state of human knowledge, are quite incapable of being made safe for their intended and ordinary use. . . . Such a product, properly prepared, and accompanied by proper directions and warnings, is not defective, nor is it unreasonably dangerous."

Products Liability and Design

Charles O. Smith, Engineering Consultant

Definitions of Defects

The American Law Institute (Ref 2) says that a product is in a defective condition if "it leaves the seller's hands, in a condition not contemplated by the ultimate user, which will be unreasonably dangerous to him." Peters (Ref 4) indicates that a California Supreme Court decision, *Barker v. Lull* (Ref 5), established a good assessment of "defective condition." This provides three definitions (or criteria) for manufacturing defects and two for design defects:

Manufacturing defects

- Nonconformance with specifications
- Nonsatisfaction of user requirements
- Deviation from the norm

Design defects

- Less safe than expected by ordinary consumer
- Excessive preventable danger

Manufacturing Defects

A failure to conform with stated specifications is an obvious manufacturing defect, and not a new criterion. The aspect of user satisfaction may not be well known, but in the legal context it has long been recognized that a manufacturing defect exists when there is such a departure from some quality characteristic that the product or service does not satisfy user requirements. Under the third criterion (deviation from the norm), added by *Barker,* a manufacturing defect occurs when a product leaves the assembly line in a substandard condition, differs from the manufacturer's intended result, or differs from other, ostensibly identical units of the same product line.

Design Defects

A product may be considered to have a design defect if it fails to perform as safely as an ordinary consumer would expect. This failure to perform safely is interpreted in the context of intended use (or uses) in a reasonably foreseeable manner, where "foreseeable" has the same meaning as "predicted" in failure-modes-and-effects, fault-tree, or hazard analyses. It appears that many "ordinary" consumers would have no concept of how safe a product should, or could, be without the expectations created by statements in sales material, inferences from mass media, general assumptions regarding modern technology, and faith in corporate enterprise.

A design defect also exists if there is excessive preventable danger. The real question is whether the danger outweighs the benefits. A risk-benefit analysis should include at least five factors:

- Gravity of the danger posed by the design (i.e., severity of the consequences in the event of injury or failure)
- Probability (including frequency and exposure of the failure mode) that such a danger will occur
- Technical feasibility of a safer alternative design, including possible remedies or corrective action
- Economic feasibility of these possible alternatives
- Possible adverse consequences to the product and consumer that would result from alternative designs

Additional relevant factors may be included, but design adequacy is evaluated in terms of a balance between benefits from the product and the probability of danger. Quantification of the risk-benefit analysis is not required but may be desirable.

Proving design adequacy places the burden of proof on the defendant. Once the plaintiff proves that the product is a proximate cause of injury, the defendant must prove that the benefits outweighed the risk. Discussion of manufacturing and design defects of various products is given in Ref 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, and 24.

Note: No paper, book, or handbook relative to products liability can be truly current. In addition, there is substantial variation among jurisdictions (federal, state, and local). All cited publications, however, do have something that is currently pertinent.

Other Defects

The engineer must be alert for other possibilities. Smith and Talbot (Ref 25) point out that a marketing defect exists when there is a failure to provide *any* warning of hazard and risk involved with use of a product, provide *adequate* warning of hazard and risk involved with use of a product, or provide appropriate, adequate directions for safe use of a product. In other words, a marketing defect exists when a product, free of design and manufacturing defects, is unreasonably dangerous due to absence of warnings and directions. The designer/manufacturer has control over the directions and warnings provided. The designer/manufacturer is the most knowledgeable about the product and thus presumably the most able to determine the necessary directions and warnings.

Suits against manufacturers often allege a defective product. Careful investigation, however, sometimes shows that the problem is due to improper maintenance (e.g., Ref 26). The designer/manufacturer obviously has no control over the maintenance actually conducted but can try to minimize the possibility of improper practices by providing proper and adequate instructions with the product. In any event, the designer should not overlook the possibility of misuse and improper maintenance on the part of the user.

Example 1: Failure of a High-Speed Steel Twistdrill.

A 1.905 cm ($\frac{3}{4}$ in.) stud broke in the vertical wall of a metalworking machine known as an upsetter. A parallel vertical wall left a limited amount of space in which mechanics could work. A pilot hole was drilled with a 0.476 cm ($\frac{3}{16}$ in.) drill. The drill was held in a Jacobs chuck in a portable drill press which, in turn, was held to the workpiece by an electromagnet. After the pilot hole was finished, the drill press was removed, the pilot drill was replaced by a 1.587 cm ($\frac{5}{8}$ in.) high-speed steel drill, and the press was repositioned.

One man was doing the drilling while another man was squirting oil into the hole. When the drill was about 1.27 cm ($\frac{1}{2}$ in.) to 1.90 cm ($\frac{3}{4}$ in.) into the pilot hole, there was a "bang." The drill shattered, causing a chip to lodge in the right eye of the oiler, ultimately resulting in loss of vision in that eye. Suit was entered against the drill manufacturer alleging a defective drill.

The plaintiff's attorney retained a metallurgist who examined the fragments. An unetched longitudinal section showed a large nonmetallic inclusion parallel to the axis near the center of the drill. After etching, this section showed carbide bands in a martensitic matrix. Hardness measurements indicated 65 to 66 HRC at the edge of the flute with a bulk hardness of 62 to 64 HRC. The drill tip is shown in Fig. 2.

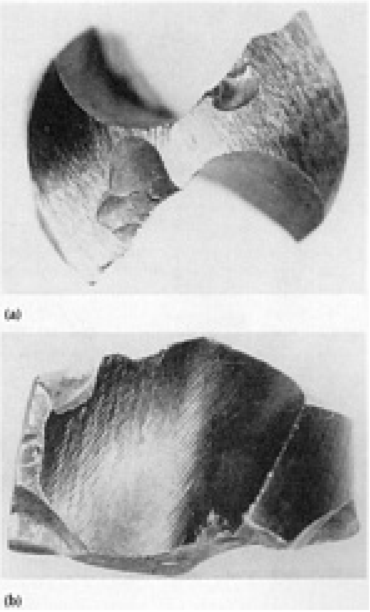

Fig. 2 The tip of the broken twistdrill. (a) End view. (b) Top view

A second drill from the same lot was also examined. There was carbide banding but to a significantly lesser degree. Hardness was measured as 63 to 64 HRC at both the flute edge and in the bulk of the drill.

Plaintiff's expert concluded that the failed drill was defective while the other drill was satisfactory. He claimed that failure was a cumulative result of the following defective conditions: the steel contained nonmetallic inclusions that were detrimental to the properties of the drill; the carbide segregation was excessive, causing the drill to be brittle; and the cutting edge of the flutes was excessively hard. In his opinion, this high hardness made the edge brittle, so that the edge would chip during drilling. The chips caused the drill to bind and then shatter in a brittle manner because of excessive carbide segregation.

Plaintiff alleged defective design, defective manufacture, unsuitable or defective material, lack of sufficient quality control, and failure to foresee.

The defendant manufacturer believed the twistdrill met all specifications for M1 high-speed steel. Both the supplier and manufacturer inspected for carbide segregation, with the poorest rating being "slight to medium." A "medium" rating was permitted. Heat treatment and nitriding practices were consistent with those published by ASM International. After heat treatment, the drills were within the specified range of 64 to 66 HRC.

Some twenty other inspections for dimensional accuracy, shape, and finish were made after heat treatment. Fourteen drills were given a severe drilling performance test (manufacturer's routine) with no breaking or chipping.

One could argue there was nonsatisfaction of user requirements. The counter argument was that there was too high a demand on the drill.

Conclusions by the plaintiff's experts can be viewed as indicating a deviation from the norm. (Of the 5360 drills made from this one lot of steel, the manufacturer received only this one complaint.) The observed nonmetallic inclusion had a maximum width less than 0.0127 mm (0.0005 in.) and a maximum length less than 0.84 mm (0.033 in.). It was located in the shank, more than 6.35 cm ($2\frac{1}{2}$ in.) from the drill tip and along the central axis, which is subjected to essentially none of the bending and twisting loading. While the inclusion is relatively large, it is not likely that it could contribute to the failure.

The largest carbide band was about 8 mm ($1\frac{1}{3}$ in.) long and located about one-fourth of the distance from the central axis to the outer edge. It was also some distance from the drill tip. This location implies relatively light loading.

The manufacturer made hardness measurements on the two drills examined by plaintiff's expert. The results are given in Table 1. These indicate no significant difference between the two drills. The higher hardness at the cutting edge is expected and reasonable for a nitrided M1 steel. The hardness of both drills is within normal specification ranges.

Table 1 Hardness examination of drills

See Example 1 in text.

Measurement	Average hardness, HRC[(a)]	
	Bulk	**Cutting edge**
Plaintiff's measurements		
Broken drill	62-64	65-65
Unbroken drill	63-64	63-64
Defendant's measurements		
Broken drill	64.9, 64.8	65.1[(b)], 66.5[(c)]

(a) Tukon readings (100 g) converted to HRC.

(b) At 0.1270 mm (0.005 in.) from the surface.

(c) At 0.254 mm (0.001 in.) from the surface

The manufacturer examined a number of other M1 drills that had satisfactorily met (corporate) standard drilling tests. One of these had a nonmetallic inclusion $1\frac{1}{2}$ times longer than in the failed drill. Two had edge hardnesses in the 66 to 68 HRC range with carbide banding more pronounced than in the failed drill.

From the viewpoint of design defects, was the drill less safe than expected by the ordinary consumer? Maybe. Presumably the workers did not expect drill failure. It is well known, however, that twist drills do fail, no matter how well designed and manufactured. Using a drill to remove material after drilling a pilot hole is a common practice and clearly foreseeable. It is clearly more hazardous than drilling without a pilot hole. The drill may have been less safe than expected, but it seems more credible that too much was expected.

Existence of a design defect related to "excessive preventable danger" seems doubtful. The drill design was highly similar to that used by other manufacturers. All dimensions, tolerances, clearances, and so on were consistent with those used by other manufacturers and were based on years of drill use by a great variety of users. There is no question of potentially severe damage and relatively high probability of exposure. But there are no apparent alternatives that are technically and/or economically feasible.

What is your judgment on the validity of the allegations? How should this litigation be resolved?

Examination of Fig. 2 indicates that one cutting lip is about 0.725 cm (0.286 in.) long while the other is about 0.802 cm (0.316 in.) long, so that the chisel edge is about 2.7 mm (0.018 in.) off center. The shorter lip will contact the work before the longer lip and thus bears all of the initial drilling stresses. The larger of the two chipped areas along the cutting edges in Fig. 2 is on the shorter lip. The broken point also had improper clearance angles (one was close to a negative angle). It was clear that the point of the broken drill was not the original point put on at manufacture but came from regrinding (presumably from "eyeballing" rather than using a jig). The work conditions, including a small pilot hole, a portable drill press, relocation of the press between the two drilling operations, and a questionable supply of coolant, placed abnormal stress on the drill.

The case was eventually settled out of court, with the plaintiff receiving a sum of less than $10,000 at a time when similar injury cases were receiving judgments of $50,000 to $150,000. This was clearly a so-called "nuisance settlement" to get rid of the suit. Much greater detail, both technical and legal, can be obtained by reference to Ref 27, 28, and 29. A side aspect of this case relates to the expert witness. It developed that the plaintiff's expert was not sufficiently knowledgeable about high-speed steels, although he was a competent metallurgist.

Two additional examples arising from litigation are given in the article "Human Factors in Design" in this Volume.

Preventive Measures

What are the implications of the above example for the design engineer? It is necessary to look carefully at the completed design to be sure that it is indeed appropriate and that it does not incorporate problems for which proper technological solutions have existed for some time. (For example, an independent assessment by a design review board, whose members have no parental pride in the design, is highly appropriate.) In addition, there must be recognition that many, perhaps most, consumers have no concept of how safe a product should be. An engineer making a subjective judgment about safety must understand this lack of appreciation of an appropriate safety level.

Acting as a prudent manufacturer is not enough. The focus should be on the product itself, not the reasonableness of a manufacturer's conduct. Obviously, there will be no viable lawsuits if there are no injuries or if there are no violations of the law. Undoubtedly the best practice is to sell a well-designed, well-manufactured product. The manufacturer needs to make certain that all reasonable preventive measures have been used in the design and manufacturing process. Much evidence, however, suggests that one of Casey Stengel's comments applies in the area of preventive measures: "In many areas we have too strong a weakness." While many preventive measures are well known to most design engineers, some comments may be appropriate, even if only in the sense of a checklist of items to be considered.

Design review is an effort, through group examination and discussion, to ensure that a product (and its components) will meet all requirements. In a design of any complexity, there is necessity for a minimum of three reviews: conceptual, interim, and final. Conceptual design reviews have a major impact on the design, while interim and final reviews have relatively less effect as the design becomes more fixed and less time is available for major design changes. *It is much easier and much less expensive to include safety in the initial design than to include it retroactively*.

A more sophisticated product may require several reviews during the design process. These might be: conceptual, definition, preliminary (review of initial design details), critical (or interim review, perhaps several reviews in sequence--review details of progress, safety analyses, progress in hazard elimination, etc.), prototype (review of design before building a prototype), prototype function review, and preproduction review (final review--last complete review before release of the design to production).

These periodic design reviews should review progress of the design, monitor design and development, ensure that all requirements are met, and provide feedback of information to all concerned.

A design review is conducted by an ad hoc design review board composed of materials, mechanical designers, electrical designers, reliability engineers, safety engineers, packaging engineers, various other design engineers as appropriate, a management representative, a sales representative, an insurance consultant, an attorney in products liability, outside "experts" (be sure they are truly expert!), and so on. Members of the design review board should not be direct participants in day-to-day design and development of the product under review, but the engineers should have technical capability at least equal to that of the actual design team. Vendor participation is highly desirable, especially in conceptual and final design reviews.

Design review checklists should be prepared well in advance of actual board meetings. These checklists should cover all aspects of the design and expected performance, plus all phases of production and distribution. A new checklist should be developed for each new product.

It is good practice for a designer/manufacturer to have some sort of permanent review process in addition to the ad hoc board for each individual product. This permanent group should evaluate all new products, reevaluate old products, and keep current with trends, standards, and safety devices.

If properly conducted, a design review can contribute substantially to avoiding serious problems by getting the job done right the first time. Formal design review processes are effective barriers to "quick and dirty" designs based on intuition (or educated guesses) without adequate analyses.

Some Common Procedures. Many engineers and designers are familiar with such techniques and procedures as hazard analysis; failure modes and effects analysis (FMEA); failure modes, effects, and criticality analysis (FMECA); fault tree analysis (FTA); fault hazard analysis (FHA); operating hazard analysis (OHA); use of codes, standards and various regulatory acts, and the Occupational Safety and Health Act (OSHA). These are discussed in the article "Safety in Design" in this Volume. Some other aspects of products liability are perhaps less well known and require some comment.

Prediction methods are necessary in applying FMEA, FTA, and so on. From statistics it is possible to predict performance of a large group of similar products, but it is *not* possible to predict performance of any one individual item of that group. Various statistical and probabilistic techniques can be used to make predictions, but these are predicated on having good data bases.

State of the Art. The meaning of the term *state of the art* should be defined for each specific product. This might be done by comparing the product to those produced by competitors, but this comparison may not be enough. A jury is not bound by negligent practices of a negligent industry, and unfortunately, in some areas industry practices and standards are low-level consensus practices and standards. Being in step with the state of the art may not be enough--one should be ahead of the state of the art (i.e., better than the competitors). It is not enough to explain what was done, because the plaintiff's expert witnesses may point out what could have been done. Purely economic reasons are not a valid defense argument in the courtroom and should be avoided.

Quality Assurance and Testing. A primary function of quality control is to feed back inspection, testing, and other data, showing designers what is happening and revealing any need for design improvement. Manufacturers should test products in various stages of development, including field service, especially if critical components or subassemblies are involved. Final tests are necessary on each individual product or on representative samples of plant output. Care must be taken that quality control is not relaxed, intentionally or unintentionally, for production expediency.

Foreseeability is a factor that requires special attention. It is necessary to determine not only how the product is intended to be used but also every reasonably conceivable way that it can be used and misused. (Who has never used a flat-tang screwdriver for some other purpose?) All reasonable conditions of use, or misuse, that might lead to an accident should be detailed. The designer must conclusively demonstrate that the product cannot be made safer, even to prevent

accidents, during use or misuse. The problem of foreseeability is one that seems especially difficult for engineers to accept.

Consumer Complaints. Data on product failures from test facilities, test laboratories, and service personnel are valuable. Each complaint should be quickly, carefully, and thoroughly investigated. An efficient reporting system can result in product corrections before large numbers of the product reach users, or a product recall before there has been a major exposure of the public to an unsafe product.

Warranties and Disclaimers. Warranties and disclaimers are attempts to limit liability. When used, they must be written in clear, simple, and easily understood language. Both should be reviewed by highly competent legal counsel knowledgeable in both the industry and products liability. A copy of the warranty and/or disclaimer must be packaged with the product. All practical means must be used to make the buyer aware of the contents. It must be recognized, however, that warranties and disclaimers, no matter how well written, are an extremely weak defense.

Warnings and Directions. Directions are intended to ensure effective use of a product. Warnings are intended to ensure safe use. Both should be written to help the user understand and appreciate the nature of the product and its dangers. If directions and warnings are inadequate, there is potential liability, because it cannot be said that the user had contributory negligence in failing to appreciate and avoid danger.

The burden of full and effective disclosure is on the manufacturer. Directions and warnings, although essential, do not relieve the manufacturer of the duty to design a safe product. The law will not permit a manufacturer, who knowingly markets a product with a danger that could have been eliminated, to evade liability simply because a warning is placed on the product. *One must design against misuse.*

This topic is discussed in greater detail in the article "Safety in Design" in this Volume. A label is discussed in some detail in the article "Human Factors in Design" in this Volume.

Written Material. All advertising, promotional material, and sales literature must be carefully screened. Warranties can be implied or inferred by the wording on labels, instructions, pamphlets, sales literature, advertising (written and electronic broadcast), and so on, even though no warranty is intended. There must be no exaggeration in such material. The manufacturer must be able to show that the product is properly rated and that the product can safely do what the advertisement says it will do. Additional information on the level of language is given in the article "Safety in Design" in this Volume.

Human Factors. Many products and systems require operation by a human who thereby becomes an integral part of the system. As such, the human can have a very significant effect on system performance. One must recognize that the human being is the greatest, and least controllable, variable in the system. Many attorneys believe that most products liability suits result because someone (usually the designer) did not thoroughly think through how the product interfaced with society.

Additional information can be found in the article "Human Factors in Design" in this Volume.

Products Recall Planning. It is a fact of life that mistakes are sometimes made even by highly experienced professionals exercising utmost care. When such errors occur, a product recall may be necessary. Unless the specific troublesome part can be readily and uniquely identified as to source, production procedure, time of manufacture, and so on, there will be great difficulty in pinpointing the problem within the producing organization. Placing one advertisement for recall purposes in newspaper and magazines (not including TV) throughout the country is very expensive. An obvious economic need, as well as a regulatory requirement, exists for manufacturers (and importers) to have systems in place for expeditious recall of a faulty product.

Records. Once involved in litigation, one of the most powerful defenses that manufacturers and engineers can have is an effective, extensive, and detailed record. Records should document how the design came about, with notes of meetings, assembly drawings (including safety features), checklists, the state of the art at the time, and so on. These records, while no barrier to products liability lawsuits, will go a long way toward convincing a jury that prudent and reasonable care has been taken to produce a safe product.

Paramount Questions

No matter how carefully and thoroughly one executes all possible preventive measures, it is necessary to ask:

- What is the probability of injury?
- Who determines the probability of injury?
- What is an acceptable probability of injury?
- Who determines the acceptable probability of injury?

As Lowrance (Ref 30) suggests, determining the probability of injury is an empirical, scientific activity. It follows that engineers are better qualified by education and experience than most people to determine this probability. Presumably designers will use organized approaches to cope with the complexity. One obvious place for assessing this probability is the design review process. While design review is a most valuable aid for the designer, it is *not* a substitute for adequate design and engineering.

As Lowrance (Ref 30) further suggests, judging the acceptable probability of injury is a normative, political activity. Obviously, assessing the probability of injury is not a simple matter. Assessing the acceptable probability of injury is far more complex and difficult. Use of the word "acceptable" emphasizes that safety decisions are relativistic and judgmental. It implies three questions:

Acceptable in whose view? Acceptable in what terms? Acceptable for whom? This use of "acceptable probability of injury" avoids any implication or inference that safety is an intrinsic, absolute, measurable property.

In assessing acceptable danger, one major task is determining the distribution of danger, benefits, and costs. This determination is both an empirical matter and a political issue. It involves questions such as:

Who will be paying the costs? Will those who benefit be those who pay? Will those endangered be those who benefit? Answers to these questions may be based on quantifiable data but often must be based on estimates or surveys. A related major task is to determine the equity of distribution of danger, benefits, and costs. This asks a question of fairness and social justice for which answers are a matter of personal and societal value judgment.

Who determines the acceptable level of probability of injury? In terms of ability to judge acceptability, designers/engineers are no better qualified than any other group of people and, in general, are less qualified than many others. It is often alleged that engineers (because of their inherent characteristics, education, and experience) are less sensitive to societal influences of their work and products than others. As for most stereotypes, there is some truth in this view. Clemenceau reportedly said: "War is much too serious a matter to be entrusted to the military." Perhaps product design is much too serious a matter to be entrusted solely to designers and (especially) business managers.

Jaeger (Ref 31) has summarized the situation thus:

> Nowadays it seems to me that the risk problem in technology has turned out to become one of the most pressing questions concerning the whole of industrial development. This problem is of fundamental as well as of highly practical importance. The answer to the question "How safe is safe enough?" requires a combination of reflective and mathematical thinking as well as the integration of technological, economic, sociological, psychological and ecological knowledge from a superior point of view.

If the designer cannot adequately make the determination, then who can? Various ideas have been proposed (e.g., Ref 32), but no suggestion yet made is fully satisfactory. The designer/producer must resolve this for each product. References 30 and 33 can be helpful in developing sensitivity to assessing an acceptable probability of injury.

Acceptable Level of Danger

It has been suggested that an acceptable level of danger might be 1 in 4000 per year, or 1 in 10^6 per hour. Statistics indicate that this is about the danger of dying from an automobile accident in the United States. One might infer that U.S. citizens consider this an acceptable level in view of the fact that little apparent effort is expended in trying to decrease the accident rate. The National Highway Traffic Safety Administration indicates that about 50% of fatal traffic accidents in the United States are alcohol related. If there were severe penalties for driving under the influence of alcohol (as there are in some other countries), this danger would presumably decrease to about 1 in 8000 per year. Either level of danger may be rational for the public as a whole (obviously debatable), but it probably is not perceived as such by a bereaved family. Such a rate hardly seems acceptable for consumer products. It certainly is unacceptable for nuclear applications. While the majority of manufactured products have a much lower level of danger than this, many of these products are considered to have a level of danger too high to be acceptable. Juries regularly make this decision in products liability actions.

One aspect of a potentially acceptable level of danger is the manner in which it is stated. Engineers might prefer to state the level in terms of probability. The general public, however, might well prefer it otherwise, or even unstated. The general public must be aware of fatalities from automotive accidents. It is possible that if automobile manufacturers were to point out that there is an annual chance of about 1 in 4000 that an individual will be killed, and a much greater chance of being injured (even seriously, such as spinal injuries, which not only incapacitate the victim but require constant attention by others), the attitude of the public might be different.

It must be recognized that while it is possible to reduce the level of danger to a very small number, *danger cannot be completely eliminated,* no matter how much effort is expended. We do not think there is any one level of acceptable danger. Each situation must be judged independently. The question is not what level of danger the engineer/designer thinks is acceptable for the public but what level the public perceives to be acceptable.

Introduction

COMPETITIVE PRESSURES continue to increase in all aspects of the business world of today. For companies to prosper, they must adopt new processes and tools that allow them to work more effectively and efficiently while providing better products to their customers. One manifestation of this is a continuing effort to incorporate concurrent engineering into the product development environment. Integrated product development (IPD) support organizations are beginning to appear in companies that realize the importance of this concept. Another important development is the drive for controlled product development based on a single, master product model concept.

If a master model is to be used as the basis for product development, it must be very rich in intrinsic information. To make the concept viable, the product model must support not only physical design, but analysis, testing, design optimization, simulation, prototyping, manufacturing, maintenance, and many other product development processes. The model has to define all of the product being designed including how parts connect and move with respect to each other. The model must provide an unambiguous representation of the physical product within the product development system. Modern, solids-based computer-aided design/computer-aided manufacturing (CAD/CAM) systems provide a good share of what is needed for companies to develop products using modern methods.

In reality, product design and CAD are processes. Computer-aided design tools can be used to simplify that process, but a CAD tool by itself does not inherently create good design and product development practices. That goal must be accomplished through changes in how individuals and organizations apply CAD/CAM and other tools and methods. In fact, the changes an organization makes in its product development processes are what produce payoffs in faster new product introduction, lower development costs, higher quality, more new products, competitive innovation, and increased profits.

A complete discussion of modern product development processes is a book-length topic of its own. Suffice it to say that the appropriate application of up-to-date technologies can greatly facilitate product development. Modern CAD/CAM systems are one of many technologies that can enable good practices. This article concentrates on describing this important technological area.

Recently, the techniques used to design products have changed dramatically. The advent of parametric, feature-based design creation has caused all of the major CAD vendors to rethink their product offerings and to redesign their CAD systems to present users with a more flexible, easier design process.

Indeed, these changes are having a major impact on the role of CAD in product development. Many companies today are making the transition from two-dimensional drafting and three-dimensional wireframe/surface modeling to complete three-dimensional, solid modeling of new product designs. This leads companies to produce more complete, computer-based product designs that can be used to expand and facilitate more refined product analysis, soft prototyping, computerized simulation, and nonphysical testing. All of these improve productivity, reduce product development time, improve quality, and allow more design creativity.

Because of the close interrelationship of solid modeling with product design in current CAD/CAM environments, additional technologies must be included in any discussion of modern CAD/CAM systems. These are constraint modeling, feature modeling, associativity, assembly design, and design intent. They are described in this article after a brief history of CAD technology. The article closes with a discussion of CAD applications.

John MacKrell, Principal, CIMdata, Inc.

Computer-Aided Design: A Brief History

The first commercial CAD systems were introduced in the late 1960s. Two of the earliest, successful products came from Computervision and Applicon. Both companies were heavily influenced by earlier work in the aerospace and automotive industries as well as academic research centers, such as Lincoln Laboratories at the Massachusetts Institute of Technology. In general, these early products basically worked in two dimensions and supported drafting functions. Such so-called electronic drafting boards proved quite efficient when drawings had to be updated and modified frequently. But they did not significantly change the product design process. Through the early 1970s CAD system capabilities were improved to include three-dimensional wireframe and surface design. With these new capabilities, CAD began to be useful for numerical control (NC) programming and some engineering analysis but remained insufficient for real, complex engineering design.

The first commercially available solid modelers appeared in the late 1970s (Euclid from Matra Datavision was the first general CAD system to include solid modeling as its primary design method). By the mid-1980s, virtually all major CAD products had solid modeling capabilities; however, many of them treated solids as an add-on technology, not as their primary modeling method. They arrived to great fanfare and high expectations as the solution to all design problems. The promise was that solids-based CAD would produce large savings throughout design and engineering. However, the reality was quite different: these savings did not materialize because the systems were unnatural and difficult to use, and affordable computing hardware did not provide enough computing power to efficiently create and manipulate the models.

Early solids-based systems relied on Boolean combinations of simple primitive solids (blocks, cylinders, spheres, cones, tori, etc.) to build up complex part designs. While Boolean combinations can be used to create very complex designs, they do not match well with the traditional sketching methods that designers have used for most of recent history (several hundred years of formal engineering design, most of it done by creating orthographic-view drawings). The terminology used for these Boolean operations (union, difference, and intersection) is also nontraditional and confused designers and other users, who wanted to make holes, bosses, and other design elements. Boolean methods are also difficult to use when a design has to be changed during the product development process--sometimes requiring parts of the design to be discarded and completely reconstructed.

Sweeping operations (extrusions and rotations) of two-dimensional outlines fit with the designer's sketching methods better, but still require Boolean operations to create details that cannot be included in the swept outline. Examples of this are keyways and bolt holes through a flange.

It was not until 1988 when Parametric Technology Corporation (PTC) introduced its Pro/ENGINEER product with a fundamentally different approach to design modeling that solids became easily accessible and generally productive. The approach established by PTC has three basic components that had been known, but not developed into a coherent, commercial product. These are parametric design, the use of design features, and data associativity. Most other CAD vendors now offer similar capabilities. In the newest constraint-based systems (notably Matra Datavision Euclid Designer, Hewlett-Packard SolidDesigner, SDRC I-DEAS Master Series, Dassault CATIA, and others), the user can create controlling equations and parameters on existing geometric models and make local modifications with ease.

Parametric modeling is a type of constraint modeling, as is variational modeling. Designs modeled in a constraint modeler capture many pieces of information about the shape and size of a design in the form of dimensional and geometric properties. These are related to each other by a set of equations known as relationships or parametric equations. When any dimensional or geometric property is changed, the set of equations can be re-solved to find the effect on all other related dimensions; the geometric description of the design is then updated automatically. This concept is more fully described in the section "Constraint- and Feature-Based Computer-Aided Design" in this article. Simply stated, constraint-based design allows users to make changes easily to their designs that follow their "design intent" without having to re-create or move primitive solids.

Design features are similar to "super" primitives. They are predefined or user-defined groups of geometry with well-defined dimensional attributes and a datum point (or origin) with which they can be easily positioned in the design. Design features include countersunk holes, through holes, tapered holes, bosses, pockets, tabs, draft angles, blends, fillets, shells, and many others. They simplify the design process by combining complicated but easily sized geometry with the appropriate Boolean operation (such as difference to remove a hole) and simplified positioning. They are generally called-out by their common names, such as counterbored hole. Features can also contain other attributes such as the NC instructions required to machine them, or cost-of-manufacturing information.

Parametric Technology Corporation combined parametrically controlled form features with data associativity (further explained below) to create a more easily used design system that produced easily modified designs. Now, most of the other major CAD vendors have copied these techniques or developed similar capabilities.

The current state-of-the-art CAD/CAM systems use constraint-based features along with surface and solid models to create design geometry much more efficiently than was possible with earlier CAD technologies.

Computer-Aided Design

John MacKrell, Principal, CIMdata, Inc.

Overview of CAD Technology

Modern CAD systems use many forms of geometric modeling. This section is an attempt to provide a very simple, easily understood description of them. In some cases the explanations are oversimplified, but the important points for someone trying to understand how CAD systems work are covered.

The earliest CAD systems used two-dimensional wireframe geometry to create drawings--in much the same way that for the past several hundred years formal drawings have been used to convey and document engineering designs. Due to this long history, two-dimensional drawing is comfortable and natural to use as a design medium, but works best for documenting designs that have already been worked out by manually sketching, making a physical model, or other methods. Many products are too complex to actually design using two-dimensional drawings, and some objects are nearly impossible to define by a set of two-dimensional drawings. For very simple parts and parts that are essentially turned, two-dimensional geometry provides sufficient definition, but for complex parts two-dimensional drawings are just not as complete or efficient as other types of computer-aided design models.

With a two-dimensional wireframe system, the design is created by drawing lines, arcs, circles, and other curves on a plane (i.e., virtual paper) in the computer--much as they would be drawn on a traditional drafting board. Orthographic projections are used to convey the three-dimensional shape of the design. The advantages of CAD over manual drafting methods come in the form of much easier drawing modifications (the designer can erase and redraw and move views around with ease) and in the provision of construction aids of the computer such as selection of existing geometry, construction guides and grids, trimming lines, creating tangents, and many others. However, the design information captured in two-dimensional CAD systems is little better than that developed on a drafting board. The true shape of parts is not determined in a way that helps designers check interferences, develop complex intersections, define free-form surfaces, compute mass properties, create NC programs, perform engineering analyses, or accomplish other common tasks. As is shown in Fig. 1, a cube is defined by two or more views, but the computer cannot automatically determine the volume enclosed by the cube.

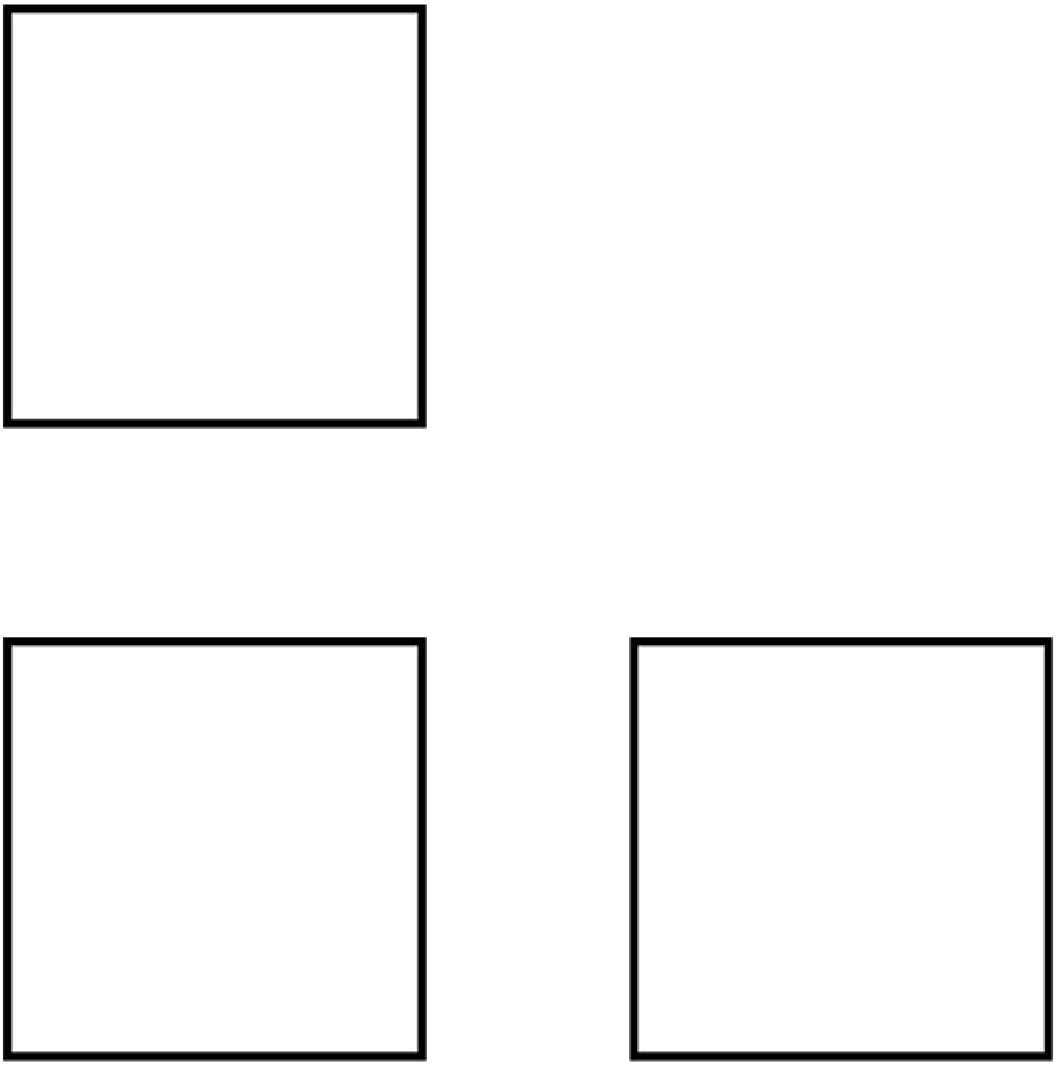

Fig. 1 Cube defined by orthographic projection of two-dimensional geometry

A three-dimension wireframe adds a third dimension to two-dimensional geometry, but it does not help very much. With three-dimensional wireframes the geometry of parts is still not fully defined. The surfaces between the wireframe edges are not defined, and the computer is unable to determine what is inside or outside of the part being designed. Many of the problems associated with two-dimensional wireframe designs remain. For instance, hidden line removal must be done manually. However, three-dimensional wireframe geometry is easy to transfer from one CAD system to another. As shown in Fig. 2, the three-dimensional wireframe cube can be intersected by a plane, but because the surfaces of the cube are not defined, only the four points where the plane intersects the cube's edges can be determined. The computer cannot determine how to connect them into a square.

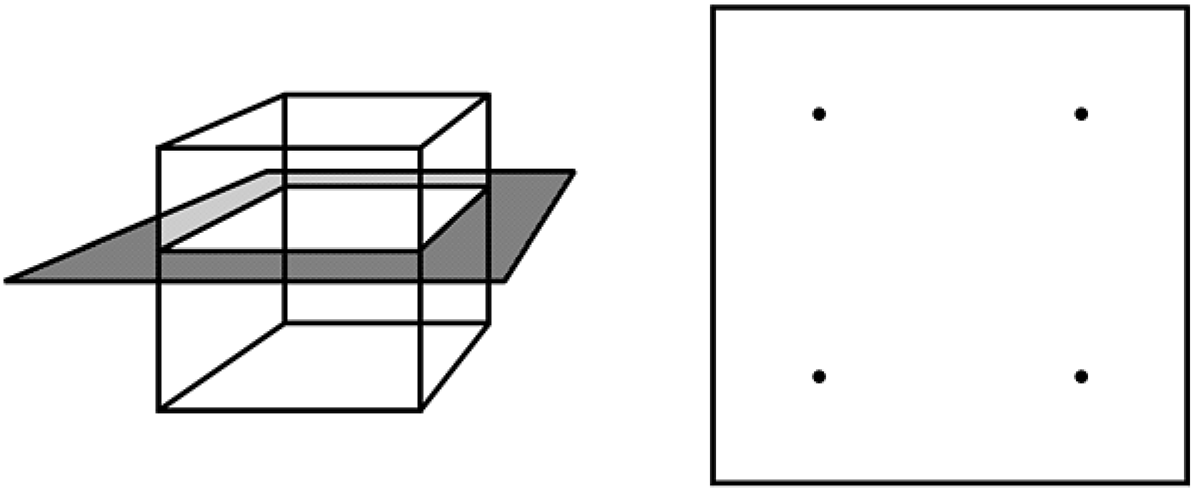

Fig. 2 Cube defined by three-dimensional wireframe geometry

The next logical step, one that also parallels the evolution of CAD systems, is to define the surfaces that form the "skin" of the design. With the addition of the surfaces, the model becomes much more complex as well as more useful for supporting CAD/CAM applications. The definition of the part is more complete, and the surface geometry can be used to drive NC and finite element modeling. Actual intersections between surfaces can be determined by the computer so that the edges of complex objects can be easily created. However, the computer remains unable to determine the properly bounded intersections between complex parts and cannot automatically insert features such as holes into parts. Surface models do not reliably permit the automatic and correct removal of all hidden lines in a view of a group of parts. Surface models do provide information that can be used to produce NC part programs and rendered, color- shaded images. Other analyses such as finite element modeling and analysis (FEM/FEA) can also be done on surfaced models.

Surface models do not allow any large degree of automation to be applied to engineering analysis and manufacturing applications. The definition is not complete enough (in the vast majority of cases) to allow the computer to determine what is inside and what is outside of the part being designed or to compute mass and other complex properties. Even a completely closed surface model lacks the topological information needed to automatically perform these types of computations. Figure 3 shows that cutting a surface model of the cube provides a square, but does not automatically determine that the inside of the square represents the inside of the part.

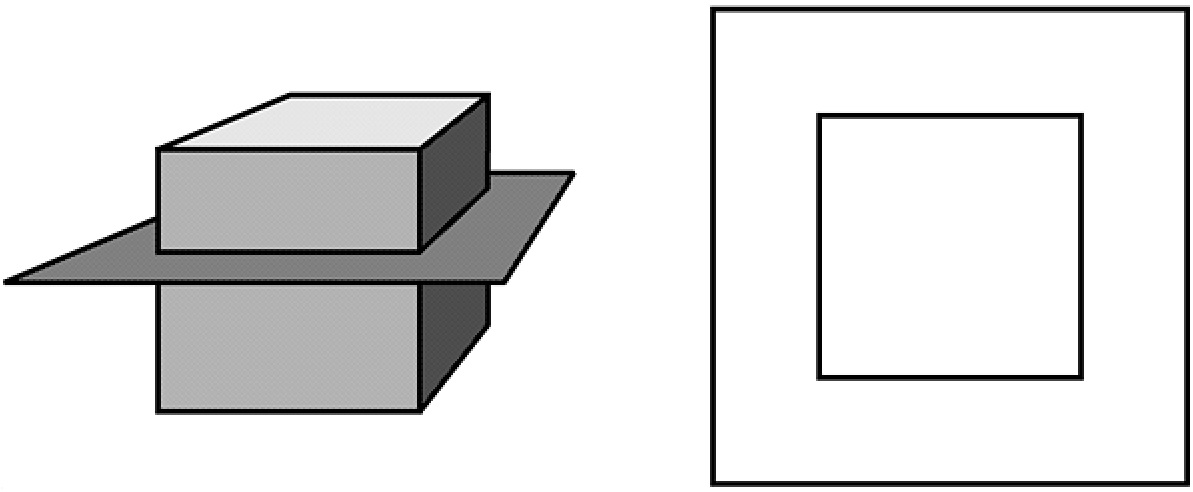

Fig. 3 Cube defined by a surface model

Other issues that occur with surface models include:

- Surfaces and patches can be left out of the model creating an incomplete definition of the part, known as an open-surface model.
- Surfaces and patches may overlap or have gaps between them resulting in an erroneous definition of the part geometry, and nonclosed volumes.
- Extra surfaces (inside or outside the part) can be defined, leading to incorrect designs.
- Intersections of surfaces can be imprecise, creating errors in the accuracy of intersection curves
- Nonmanifold conditions can occur at tangencies, edges shared by more than two surfaces, and hanging surfaces, creating parts that cannot be manufactured.

The surface model does not contain information that tells the computer on which side of each surface the material of the object is located. Solid modelers add an ordering to the surfaces and curves found in surface models. This ordering, called topology, allows the computer to determine the volume that is enclosed by the bounding surfaces of the object as opposed to the volume that is outside those surfaces. A solid modeler is able to determine the relationship of any point in space to the solid model--whether it is inside, outside, or lies on the surface of the solid. In Fig. 4, the solid model of the cube, when intersected with the plane, results in not only the square of intersection edges being known, but knowledge that the shaded area is inside the cube.

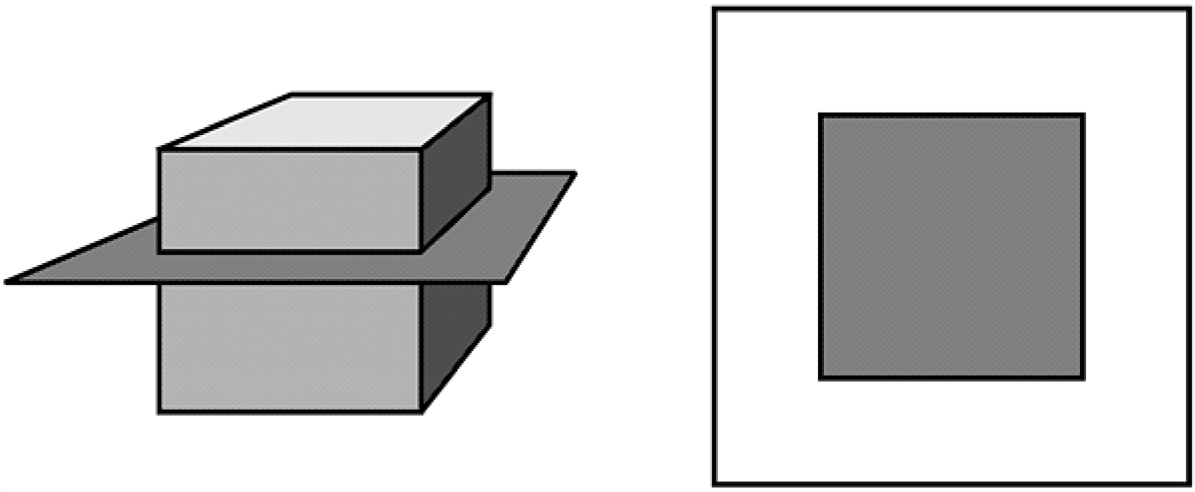

Fig. 4 Cube defined by a solid model

This is what allows solid modelers to perform automatically Boolean operations between two solid models. Boolean operations are used to combine two solid models into a more complex part. Boolean operations can be used to add material to or remove material from a solid. These operations provide the basis for creating complete and unambiguous descriptions of physical objects within CAD/CAM systems.

The problem with solid modeling has been that Boolean operations are rather difficult to use in many situations. Many designers have found them to be counterintuitive and difficult to control. Form features combined with constraint parameters have greatly simplified how designers work with solid modelers to design parts and assemblies.

John MacKrell, Principal, CIMdata, Inc.

Constraint- and Feature-Based Computer-Aided Design

Solid modeling has been around since the early 1970s but it has historically been hard to use, which has delayed its acceptance by many designers. Using Boolean operations and primitives to "sculpt" a solid model has never been an obvious, straightforward concept. Designers have difficulty positioning the primitives, too many operations are required to complete a design, and it is too difficult to change designs. In traditional systems (both manual and CAD) it has been the responsibility of the designer to remember all of the interrelationships among various parts of the design. A simple example of this is that if the diameter of a hole is changed, then the designer must remember to change the diameter of the bolt that passes through the hole. Also, for something as simple as a countersunk hole the problem doubles in complexity--the designer has to remember to change both the diameter of the main hole and the countersink hole as well as the corresponding piece on the mating part. Tracking all of the interrelationships in an assembly can be a daunting task, even in a simple design. Allowing the CAD system to track these relationships automatically translates directly into saved time and fewer design errors. Constraint-based modelers provide a viable solution to these problems.

While constraint modelers provide a more easily used paradigm for sketching and developing modifiable, evolving designs, they also present some problems of their own.

Geometric modeling systems allow designers and others to define the positions of points, lines, curves, and surfaces in two-dimensional and three-dimensional space. The ability of the user to position and move these geometric elements is controlled by the rules embodied in the modeling system being used. For example, in some systems, to move a point that has already been created the point must be deleted and re-created at its new location. This can become very time consuming when modifying a point that happens to be at the ends of several connected lines--each line must be deleted and redrawn to the new location of the point. In some drawing systems, points can be dragged to a new position. The problem then is: which lines, circles, and so forth, that share the point also should drag or change shape, and how?

Constraints are used to create a set of rules that control how changes can be made to a group of geometric elements (lines, arcs, form features, etc.). These rules are typically embodied in a set of equations. The equations can be simple (point A is at location x, y, z) or complex (the length of line B is one-half the length of line A) and can contain geometric as well as numeric positioning information. Four types of constraints are in common use today--numeric, geometric, algebraic, and attributes. Numeric constraints provide positions (x, y, z locations), lengths, diameters, spline parameters, angular values, and other measurable values. Geometric constraints include parallelism, perpendicularity, colinearity, tangency, symmetry, and other nonnumeric parameters that control the positional relationships of one piece of geometry with respect to another. Algebraic constraints combine numeric and geometric constraints in very simple equations (diameter of C = one-half the length of A) or extremely complex sets of equations that include IF-THEN-ELSE branches, inequalities, and calls to external subroutines (e.g., if diameter is less than or equal to 10 then part thickness is 0.125, else part thickness is 0.25). Attribute constraints (e.g., color, material, surface finish, thread type, maximum stress) define other characteristics of the part or its function.

Figure 5 illustrates three typical two-dimensional constraint situations. The pie-shaped piece is fully constrained in the upper view. The center point ($P1$), the radius of the arc (r), the included angle (Δ), and the geometric constraint fixing the top edge as "*horizontal*" completely and unambiguously specify the complete shape and position of the part. In the lower-left example, the "*horizontal*" constraint has been removed. While the remaining constraints still define the shape of the part, its position is no longer specified--it could be oriented at any position around the dotted circle. In the lower-right view, the shape and position of the part are overspecified. Neither $P2$ nor $P3$ add any useful or necessary information about the size or orientation of the piece. Note, however, that $P3$ could be used in place of Δ, and that $P2$ could be used in place of both r and "*horizontal*".

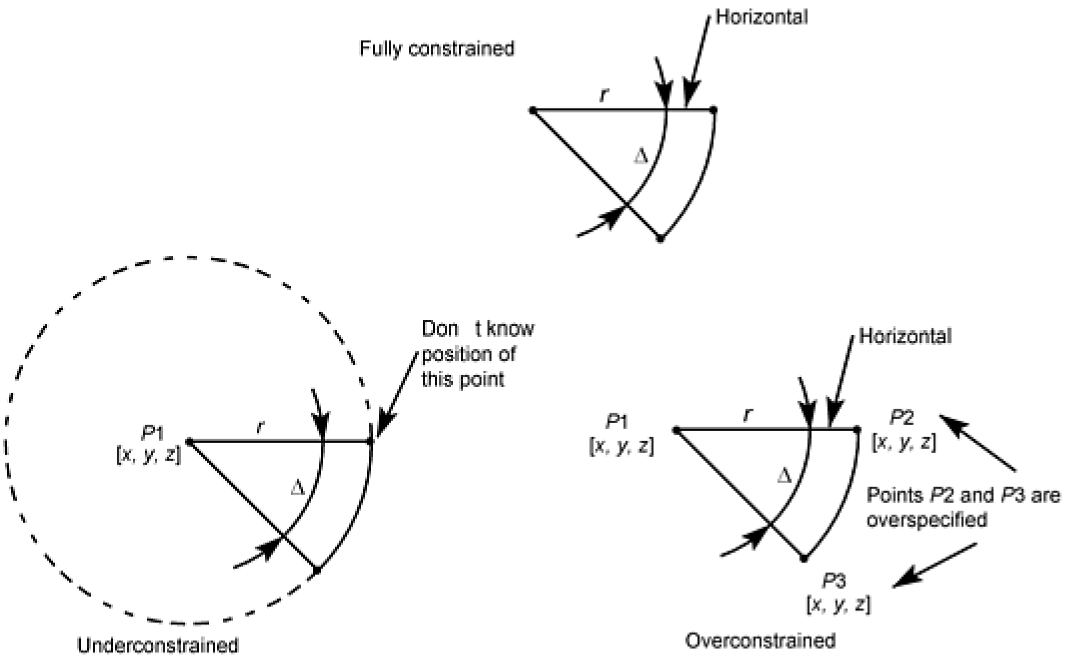

Fig. 5 Simple constraint example

In Fig. 6, note the changes as highlighted in the upper right corner due to the change in the topmost parameter value. In particular, note that the topology of the object has changed, with the square hole being completely suppressed.

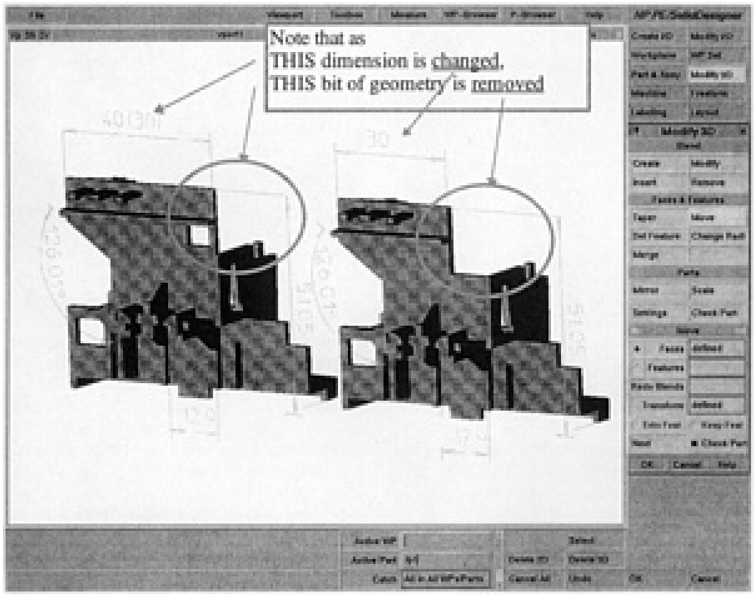

Fig. 6 Object before and after parameters are changed. Courtesy of Hewlett-Packard

Two types of constraint modelers are in general use today: parametric and variational. These types have to do with how the set of constraining equations are defined and solved. In parametric systems all of the constraint equations are captured and solved in the order in which they are created; the design is controlled by a directed graph of operations. The variables used in each equation must have been defined by a previously stated constraint; that is, each geometric element is placed with respect to some previously placed element. However, most systems allow the user to rearrange the order of the equations, thus modifying the implied design intent. In variational systems the set of equations is solved simultaneously

so that their ordering is not so important. For instance, if points *A* and *B* are located by user-defined dimensions and point *C* is located by references to the locations of *A* and *B,* then three equations define the constraint system:

$$A = \text{point}(x1, y1, z1)$$
$$B = \text{point}(x2, y2, z2)$$
$$C = (A - B)/2$$

In a parametric system, points *A* and *B* can be moved and point *C* will automatically follow. In a variational system any two of the points (for example, *A* and *C*) can be moved, and the third point (*B*) will automatically follow.

Each of these techniques has advantages and disadvantages when compared to the other, but neither holds an overbearing advantage over the other. Whether their differences are important depends on how the design process is to be carried out. The major differences are the order dependence of parametric modeling and the generally slower speed of variational modelers.

Constraint order dependence forces designers to think about the process they will use for a given design and to predetermine the independent parameters that will be used to control changes to the design. The designer may not know enough about the design early in the design process to make valid choices for dependent and independent constraints. In fact, unless the designer devotes considerable preplanning to the design process, the wrong constraints may be selected and the parametric definition will need to be reordered at a later time. Indeed, as the design evolves, unanticipated constraint dependencies are likely to arise; these can force changes to the parametric interdependencies. Changing the parametric ordering can be difficult because the interrelationships among parameters quickly become complex, and even the original designer may not quite understand the nuances of these interrelationships. This is especially true for someone who did not create the design in the first place and has to decipher the meanings and interdependencies of the parameters that have been used by someone else to create the design. Remember that no two designers execute a design problem using exactly the same method.

This problem is alleviated somewhat because most commercially available parametric modelers now allow users to redefine the parameterization and reorder the parametric equations to allow different parameters to control the design. Parametrically defined designs work extremely well for parts and assemblies that have a clearly defined hierarchy of features and components and a few important design parameters that control their overall form. An example of this is families of parts whose sizes are controlled by a few dimensions, such as length and diameter for bolts.

Variational systems require more computing power because they must solve a generally complex set of simultaneous equations (this is precisely the feature that allows them to solve for any variable, not just explicitly defined dependent variables). The method of solution requires numeric approximations that converge on an acceptable result. This can lead to failures in the solution process, although most CAD products appear to handle this convergence quite well. Both of these problems require more computing power than the straightforward, stepwise solution of parametric systems; however, current computer systems are powerful enough to handle substantial systems of equations in "real" time, or so quickly that users do not feel delayed in their work. Variational models work well for designing parts and assemblies where there are no easily defined parameters that control the overall form, or when the design is evolving such that the designer cannot predetermine how the features of the design are going to interrelate. With variational techniques, designers do not have to give a lot of forethought to the hierarchy of the design constraints and can freely change the design without being limited by the order in which constraints were defined and features were added to the design.

Many other factors have an impact on how useful a constraint modeler is. These include the user interface and how well the modeler can deal with a variety of design issues.

Constraints should be applicable to all types of geometry (two-dimensional and three-dimensional curves, surfaces, solid form features, between parts in assemblies, etc.). Some systems have restrictions that allow constraints to be created only during two-dimensional sketching; they allow the sketch to be extruded or rotated to form a solid model, but if the constraints are changed then the solid must be regenerated. In any case, some recomputation of the model is required whenever a constraint is changed. Fortunately, most of the major CAD systems do not restrict constraints to two-dimensional cases, and all of the major CAD vendors have plans to extend their constraint modelers to handle three-dimensional constraints. Surfaces represent another problem area. The issue is whether all of the geometry that controls the definition of a surface can be constrained (control points, slopes, tangency with an adjoining surface, etc.).

How a system handles over- and underconstrained geometry is also an issue. See Fig. 5 for an example of each. Some CAD systems do not allow over- or underconstrained models to be created and stored. They force the user to fully constrain the model. Other systems allow one or both of these conditions to exist. This gives users freedom to work with partially developed designs. In any case, the CAD system should indicate when geometry does not contain a full set of constraints (it is underconstrained) and when it has too many, conflicting constraints (overconstrained). This can be done in many ways--for example, by highlighting geometry that is not fully constrained or that has conflicting constraints, or by reporting the number of degrees of freedom remaining in the model (each degree of freedom corresponds to a missing constraint). In the best case, problems are highlighted on-screen so the user can see exactly what is amiss.

Unconstrained sketching allows the designer to sketch in two-dimensional and expand to three-dimensional without having to supply any dimensions (these can be added later). In this way, a preliminary model of a part can be created very quickly and refined later on.

The vast majority of objects designed in practice are assemblies of interacting parts. A major area of design errors occurs in the interfaces and fit of these parts. So, for designs of assemblies it is imperative that the CAD system allows constraints to be defined among parts of the assembly. When this cannot be done, the designer must remember to update multiple parts whenever the geometry of any of the interfaces of the parts are modified.

Features. All of the major constraint-based CAD systems combine constraints with form features. Form features are a higher-level construct than points, curves, and surfaces. They allow designers to work with a more natural syntax, dealing with slots, bosses, through holes, blind holes, and so forth, rather than Boolean operations on blocks and cylinders.

Form features allow designers to add relatively complex but common shapes to their designs using only a few commands instead of having to create the shape through sweeping or Boolean operations. Features combine geometry with a set of dimensions and with inherent knowledge of how the feature combines with solid objects to which it is applied. The set of dimensions allows the user to size the feature as it is being included in their design and to resize it after it has been applied (see Fig. 7 for an example). Features know how they are to be combined with other geometry, for instance a hole feature will automatically be subtracted from the part on which it is applied, while a boss feature will be added (unioned) to the part.

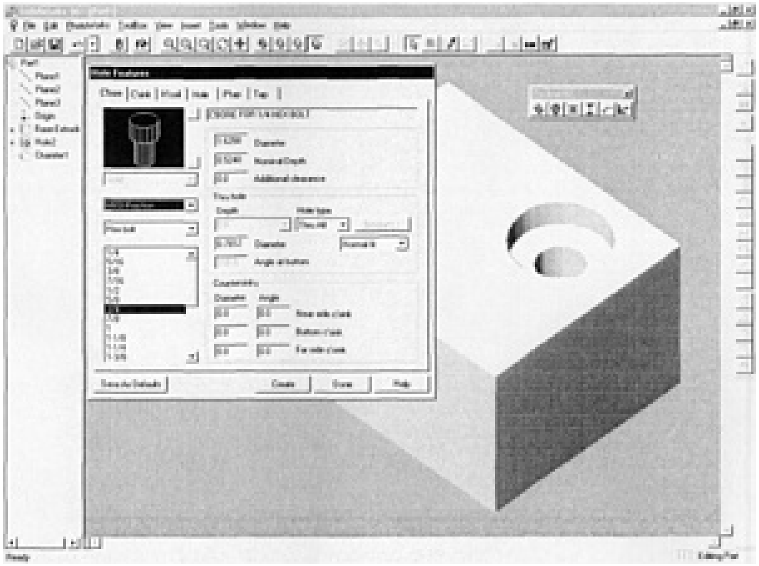

Fig. 7 Dialog for setting parameter values of a counterbored feature. Courtesy of SolidWorks

Features are located in the design by positioning them with respect to their own, local coordinate datum. For example, a hole can be positioned by locating the centerpoint of one of its ends at a point on the surface into which the hole passes. The concept of "through" features is very important. A through hole is defined so that it always passes through the object on which it is applied. If the object is made thicker, the through hole does not become a blind hole (as would occur if the hole were made by subtracting a cylinder primitive that has a fixed length), rather, the hole lengthens so that it continues to pass through the part. Variations on through holes include definitions that pass from one face or surface through the

next face encountered (but not through any other faces). This prevents the hole from passing through unintended portions of a part. In Fig. 8, a through hole with a fillet is moved to a new location by modifying the positioning parameter of the hole. Not only does the hole get longer, but its fillet changes shape substantially to match the new geometry surrounding the hole.

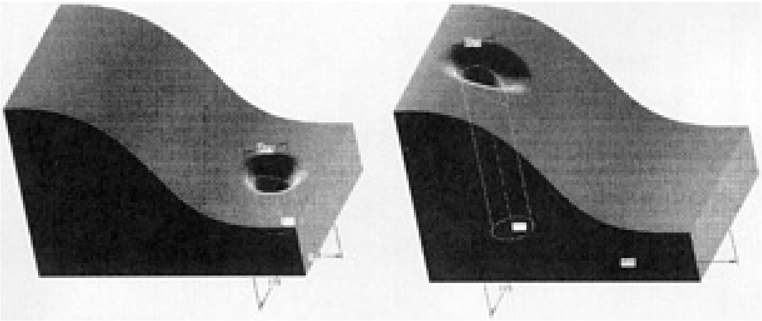

Fig. 8 Through hole feature before and after modification. Courtesy of Parametric Technology

Most systems provide a library of the most common features. They may also have special sets of features that are tailored for use with specific applications such as sheet metal and mold design. Many systems also allow users to define their own sets of features that are specific to the user's business needs.

Features may contain information in addition to their own geometry and size. For example, manufacturing data such as surface finish and the NC operations required to machine the feature can be stored with the feature. This information can be retrieved by applications to help automate their processes.

Some NC programming systems are beginning to use manufacturing features. These are similar to form features, but contain additional information to help streamline the NC programming process. Note that in many cases the features used by designers are not the same as those required by manufacturing systems. As an example, a designer may design a spoked wheel as a set of boss or spoke features while a manufacturing engineer views the same part as a group of pocket features.

While support for other modeling operations such as Boolean operations and tweaking or local modifications is not always required, these can make the designer's job significantly easier by providing flexible methods for modifying geometries. Local operations include application of draft angles and fillets provided in all of the major CAD systems, but can be extended to other local modifiers such as face lifting and edge dragging. Much greater designing flexibility is gained when these operations work within constraint modeling systems and augment the feature modeling operations typically used in constraint systems.

Computer-Aided Design

Data Associativity

Data associativity is the ability of the CAD system to share design information among applications such as design, drafting, CAE, and NC without each application having to translate or transfer the data. Associativity also requires that applications "know" when geometry or other information has been changed so that the application can adjust its own data to suit those changes. Because it helps keep design and other product development modifications synchronized, associativity is an enabler for concurrent engineering. Associativity ensures that as the design changes all of the users of the design data have an up-to-date version of the design. As implemented in CAD systems today, associativity is either unidirectional or bidirectional. Unidirectional associativity provides design changes "downward" to other applications

such as drafting and NC. Changes made to the design appear in drawings and NC toolpaths automatically, but changes made in drawings or NC do not change the design. This is also known as downward associativity.

With bidirectional associativity, changes made to any design information in any application (design, analysis, drafting, NC, etc.) are automatically reflected in all other applications of the CAD system. So, when a detailer changes a dimension in a drawing, the geometric model changes as well.

An obvious issue with bidirectional associativity is that people other than designers may be able to change the design. In large product development teams this may violate the team's rules for design control. In small teams, bidirectional associativity can be used to allow highly interactive concurrent engineering. Of course, it should be left to each organization to decide how they want to use or allow associativity.

Most CAD systems provide control over associativity, allowing it to be disabled for certain parts or users, or allowing individual users to decide when associative design changes will affect their own work sets. For instance, an engineer who is working on a finite element model may want to delay accepting design changes that would require remeshing the model until after a preliminary analysis is complete. A product data management (PDM) system can also be used to control who can change designs, drawings, NC part programs, and so forth.

As noted above, bidirectional associativity may or may not be an issue depending on the operating style and rules of the organization. If all team members need to be able to make changes to designs, then bidirectional associativity is a good feature. If some members of your teams are not permitted to make design changes, then either controllable bidirectional associativity or associativity limited to downward changes is needed.

Two types of associativity are commonly in use in current CAD systems, manual and automatic. With manual associativity, the CAD system recognizes that information has changed in one application, but it does not update the related information in other applications until the user tells it to. In automatically associative systems, any change in data in one application (such as the geometric modeler) causes appropriate changes in related data to occur without user intervention in all other applications that use the changed data (such as drafting or NC).

An issue with automatic data associativity is that, in general, the associative update fails when the topology of the model is changed. For example, an NC program may not be able to automatically update a tool path when a feature such as a hole or boss is added to or deleted from the geometric model. In these cases, the user will have to take some action to complete the update.

Computer-Aided Design

Assembly Design

Assembly design is the process of creating groups of parts that operate together. Most organizations actually create products that are assemblies as opposed to individual parts. For these groups, it is important that parts can be designed in relation to one another, sharing dimensions and other parameters.

A key element of constraint-driven assembly design is the use of joint or mating conditions. These define how two parts connect with each other and how they are allowed to move with relationship to each other. In many CAD systems, the parts of an assembly automatically follow their mating conditions. As one part is moved, the parts that mate with it move so as to preserve the constraints of the mating conditions.

Constraints among parts in assemblies allow designers to control the size and positions of mating features without having to manually update both parts. Constraints among parts are essential to the support of the design of complete assemblies.

In addition, product or assembly structures are a required capability in assembly design systems. They provide a logical model of the relationship among the components (subassemblies and parts) of an assembly. When presented as a graphically displayed tree, they also can be a convenient user interface structure for navigating through complex assemblies (see Fig. 9). In some systems, the product structure can be created and controlled by a PDM system. This

allows the structure to be used as a control mechanism for restricting access to certain portions of the assembly to particular product development team members.

Capturing Design Intent

One of the most important advantages of using constraint modelers is that they allow the CAD system to capture some of the designer's intentions. Most designed devices can be characterized by one or more primary and secondary factors that, when changed, alter the size or shape of the device. These might include the length of an engine stroke or the weight of a ship. Each of these is determined by the operational intent of a design, and they may be critical to the success of the device being designed. One of the problems faced by designers is to understand how changes in these factors affect the actual shape, size, and operation of the device being created. Many more detailed forms of design intent exist as well. For example, that two sides of an engine block casting are to be parallel may not affect the operation of the engine, but may be important for manufacturing reasons.

Design history does not necessarily equal design intent. If the intent is simply to get from New York to Washington, whether one flies, drives, or rides a bicycle has little bearing on achieving the goal, but certainly determines the history of events that occur in reaching the goal. Likewise, if three designers are given the same mechanism to design, they are all likely to proceed through very different sets of steps to reach their final designs, although the three designs may result in nearly identical solutions that satisfy the original intent. So, how can design intent be captured?

In addition to the history of steps taken to create a design, the designer must be able to create constraints that embody the functional intent of the device, for example, the relationship between the stroke and bore of a piston determines the displacement of an engine. These controlling parameters are much more important than other constraints (such as the length of the engine block) that may, in fact, be defined earlier during the designer's work within the CAD system. Of course, it is good design practice to think through the design before proceeding with the actual concept development in the CAD system, but it remains extremely difficult to predetermine or even to recognize beforehand every factor that may drive a complex design.

The designer needs the flexibility to proceed with a design according to how creativity drives the process, without having to worry that the CAD system is going to make assumptions about design intent that may be incorrect or difficult to change. Therefore, the CAD system needs to provide mechanisms that allow constraints to be easily reordered, new constraints to be created, and old constraints to be removed.

Because design intent is documented so that the design is easier to update or change, it must represent not only the spatial or geometric relationships among parts of the design, but their operational intent or interrelationships as well. For example, it may be critical to know that a particular joint must be able to both rotate and slide for a mechanism to operate as intended.

The design intent must also be kept in a form that other designers can understand. This requires a capability to document the intent (such as is done in a design notebook). Some systems allow notes to be created and viewed with the design. These notes can contain design parameters, their definitions, present values, and effects. In those systems that allow parametric notes, the value of a design parameter can be changed by selecting it in the note and typing a new value in its place (the design model then is automatically changed to reflect the modified value in the note). However, few of the CAD systems available today provide anything comparable to a traditional design notebook capability.

Computer-Aided Design

Applications of CAD Systems

CAD/CAM systems provide much more than the definition of the solid model as a design. The geometric model is only the starting point of a design. It provides the basic geometric definition of the design so that other essential design processes can be performed. Solid models are used to drive engineering analyses of various kinds, drafting and product documentation, prototyping, NC programming, rendering and visualization, manufacturing planning, and other product development activities.

These activities provide the information needed to complete the product development process. Several uses of CAD models are briefly described below; some of these are described in much more detail in other articles that follow in this Section of the Handbook.

Integrated Product Development (IPD). For companies that operate their product development process as a team activity using the concepts of IPD, the need for tightly integrated development tools is apparent. In the past there was a tendency to break the development activity into a number of discreet steps--concept design, detailed design, analysis, drafting, manufacturing engineering, and so forth. So too, the tools used to develop products were independently developed to support this task-oriented process.

Only recently have CAD vendors begun to deliver highly integrated suites of products that support collaborative, team-oriented product development. An integrated product development process requires several key capabilities. These include:

- Support for assembly modeling that is ubiquitous, that extends throughout the tool set
- A fully associative environment for all design data and activities
- Product data management to control access to, and aid in distribution of product data and changes
- Data exchange versus data translation
- Product simulation within the CAD system (soft prototyping)
- The ability for users to incorporate their own, proprietary tools, data, and processes into the development environment

Several CAD vendors now attempt to fulfill the needs of IPD users. While none have been completely successful, there continues to be progress. As more companies embrace the IPD concept, these systems should continue to grow in capabilities.

Drafting and Product Documentation. Documenting products includes more than drafting (see the article "Documenting and Communicating the Design" in this Volume). In addition to the detailed drawings that have traditionally been used to describe designs, other types of printed and drawn materials are produced. These include specifications, assembly and manufacturing instructions, maintenance manuals, user and instruction manuals, spare parts lists and drawings, and marketing materials among others. Many of these documents require the use of extensive text combined with drawings and artwork of various types.

Solid models can be used to help prepare many types of drawings including exploded assemblies, perspective views, cutaway views, photo-realistic renderings, etc. These can be transferred into technical publication, page layout, word processing, and art programs for inclusion in printed and electronic documents. See also the section "Product Visualization" below.

With parametric solid modeling systems, dimensions in drawings can be generated automatically. Solids also provide automatic hidden-line removal, shaded-image views, and section views. Figure 10 illustrates an information-rich alternative to traditional drawings one that is based on having solid models.

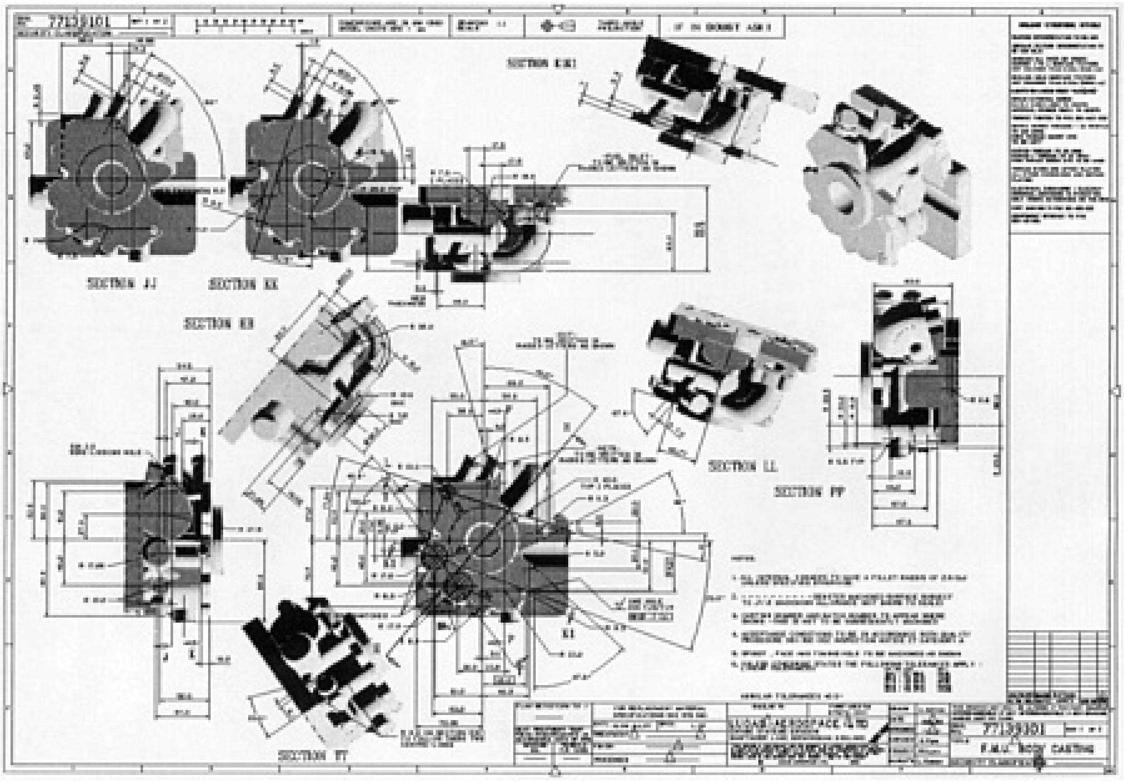

Fig. 10 Detailed drawing with shaded views. Courtesy of Computervision

Product Visualization. The visualization of the product being designed affects not only how the user sees the design on the CAD system display, but also how pictures of the product can be used in product documentation and other printed materials. Shaded and hidden line displays of solid models on the monitor of the CAD system are common today. In many systems, a shaded image of a part or a complete assembly can be rotated or moved in real time. This is a great help to users in visualizing the shape of the model, manipulating the objects being designed, and simulating (animating) the motions of assemblies. Most systems require advanced graphics hardware to accomplish this level of dynamic display. Other helpful display options include viewing the solid with transparent surfaces so that hidden edges and internal features can be seen and selected, perspective views that look more realistic than isometric projections, dashed hidden lines, and others. All of these can be created automatically for solid models, and enhance the usability of the CAD system.

Solids-based CAD systems can provide automatic generation of exploded views in perspective or isometric projection, with hidden lines removed. These provide a significant savings in effort over manual methods of producing these types of drawings. Many CAD systems can provide very realistic renderings of product concept models, as shown in Fig. 11.

These can include surface textures, shadows and reflections from multiple light sources, backgrounds, and other realistic effects.

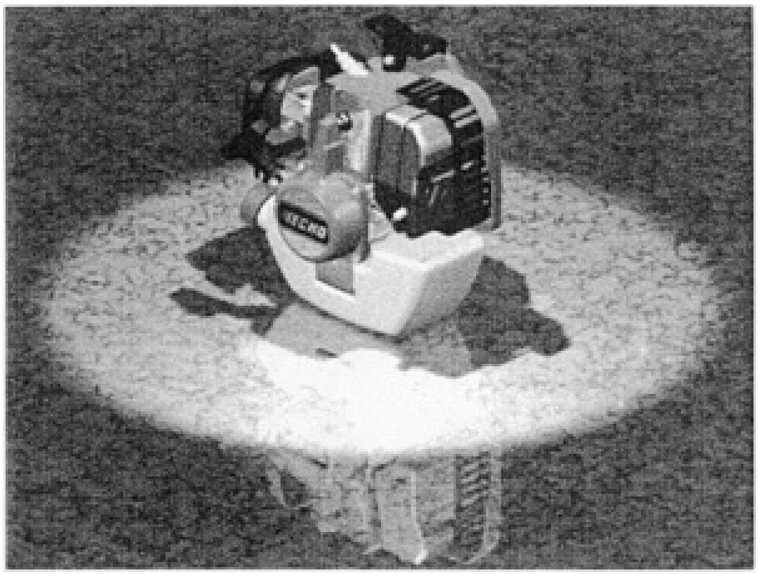

Fig. 11 Rendering of a solid model with textures, reflections and other effects. Courtesy of Matra Datavision

Structural Analysis. Products that support structural analyses typically use some form of FEM/FEA. This technical area is complex enough, with a number of specialized products, that it would require a book dedicated to it to be adequately covered. This description is deliberately basic. Structural analysis is described in more detail in the article "Finite Element Analysis" in this Volume.

FEM/FEA systems require that a mesh of finite elements be created that covers the model to be analyzed. These elements are typically applied to the surfaces of the model or throughout the solid. Surface element types include triangles, quadrilaterals, and other two-dimensional shapes. Solid elements are tetrahedrons, bricks (or cuboids), or other simple three-dimensional shapes. The elements typically vary in size, with smaller elements used in areas where it is desired to have a refined analysis (such as areas where high stresses are expected, or in areas of fine detail such as around holes). Combined with the elements are loads (forces applied to the model) and constraints (restrictions on how the model can move; anchors, sliding or rotating joints, etc.). Output from the analysis may include plots of stress in the model, deformations, and other parameters (see Fig. 12). Computer-aided design systems may use third-party supplied solvers for FEA or their own, proprietary, built-in solver.

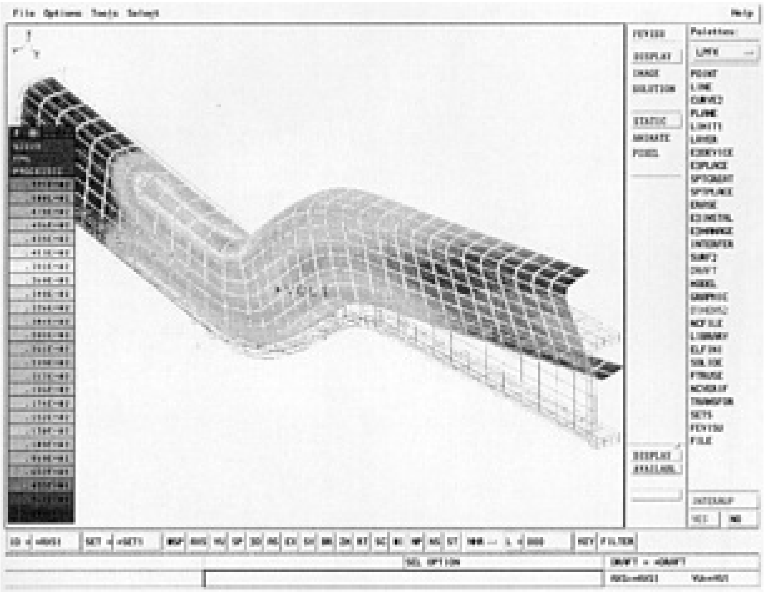

Fig. 12 Display of deflection and stress from FEA. Courtesy of Dassault Systèmes

Solid models provide the basis for CAD systems to generate automatically complete surface and solid element meshes. Automatic solid meshing allows these systems to perform design optimization where the FEA analysis is linked to geometric constraint parameters on the model. These parameters can be changed by the system, based on the results of the analysis, thus changing the shape or size of the model. The mesh is regenerated and the analysis re-executed, and so forth, until some user-defined criteria is satisfied. This type of design optimization is impracticable without a solid model.

Mechanisms Analysis. Solid models of mechanisms can be analyzed for their behavior in both static and dynamic conditions. In static cases, the positions of the linkages and parts of the mechanical assembly can be measured and plotted as illustrated in Fig. 13. In dynamic cases, the velocities, accelerations, and other parameters of the actions of the mechanism can be found. In most systems the range of motion of the mechanism can be simulated dynamically on-screen. See the article "Mechanism Dynamics" in this Volume for more information.

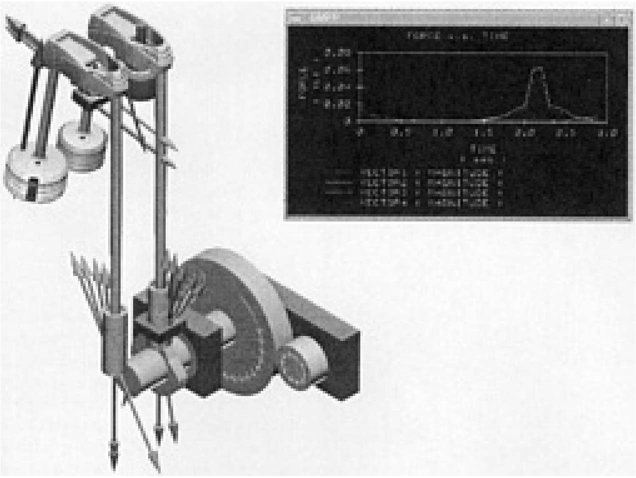

Fig. 13 Mechanism loads and constraints displayed with results graph. Courtesy of Aries Technology

Numerical control programming is the process of developing a set of instructions that automatically control a machine tool or other manufacturing device. All machine movements and operations can be controlled by the NC

program. The machine tool system consists of the machine itself and the control system that operates it. In NC machining, material is removed from a piece of stock until the desired shape is achieved.

In computer numerical control (CNC), a dedicated computer is included in the device that controls the machine tool. Computer numerical control machines can be programmed right at the machine or off-line in an NC programming or CAD system. Distributed Numerical Control (DNC) systems receive their NC programs from a centralized computer by means of a network or direct connection. After it receives the NC program, a DNC machine can create parts on its own from the program stored in its local memory. A Direct Numerical Control (also DNC) system uses a central computer to operate directly one or more machine tools, without transferring the NC program to each machine.

Most solids-based CAD systems provide NC programming for a variety of machine tool types. These generally include two- through five-axis milling machines, lathes, punches, laser and other cutters, drills, wire electric discharge machines, and others. High-end systems may also support multifunction machines such as mill-turns and four-axis lathes.

Most NC programming has been done on surface models, applying toolpaths to one surface at a time and manually identifying holes and other nonmachined areas in surfaces. Solid models allow NC systems to produce toolpaths on entire parts with less human intervention, because the relationships among the surfaces of the part can be determined automatically.

Numerical-control programming systems are beginning to take advantage of manufacturing features as well as geometric features. Manufacturing features, while they are similar to form features used in solid modeling, include information that is specific to manufacturing operations (e.g., defining pockets instead of a set of bosses). They can also contain information that is used by the NC programming system to define operations, such as surface finish or type of operation to be used. An entire NC program fragment that machines the particular feature might be included in the feature.

In the NC programming environment, the user develops the machining scenario. The computer can then play the sequence of machining operations so that the user sees a visual simulation of the machining process (see Fig. 14).

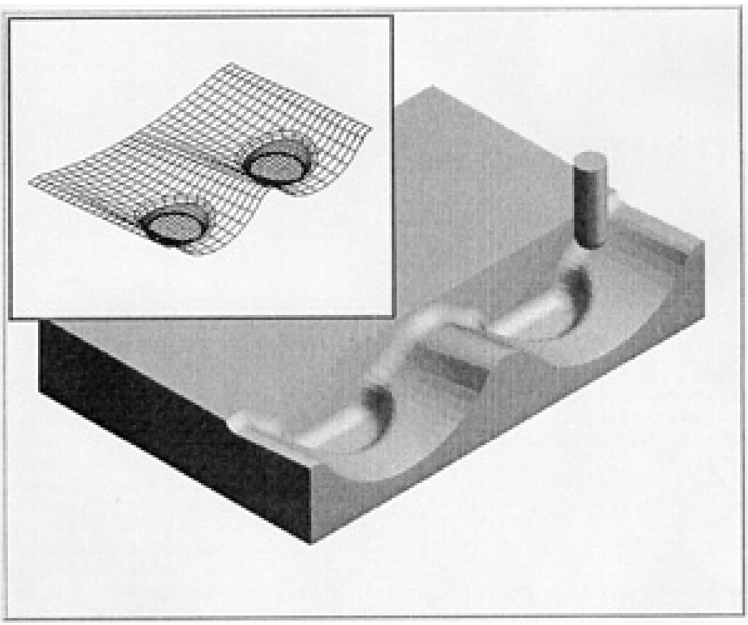

Fig. 14 Numerical-control tool cutting simulation. Courtesy of DP Technology

Rapid prototyping systems allow a design to be created as a physical object or assembly that can be used for visualization and functional testing. Rapid prototyping systems create the model from plastic, powdered metals, or other materials in a process that builds up the object one layer or slice at a time. The prototyping machines are driven in much the same way as NC machines, using geometry extracted from the solid model. These prototype models can be held, examined for fit and function, used as patterns for molds, and used for other functions. In some cases, rapid prototyping

machines are used for pilot and short-run product manufacturing. For more detailed information see the article "Rapid Prototyping" in this Volume.

Wire harness design and layout functions are provided by many CAD systems. These allow users to develop wiring schematics, design connectors, define where wire bundles split and merge, describe wire-routing parameters such as bend and sag, and indicate locations in the mechanical assembly through which the harness may or may not be allowed to pass. Given these types of information, the wire harness package routes the wires from connector to connector. When defined as solid models, additional functions can be performed--such as interference detection of the wire bundle with the other parts of the assembly, bundle volume, and weight.

Harness routings can be controlled by parametric constraints and they may be associative to other geometric data, so that as the shape of the mechanical assembly changes the wire harness changes accordingly. Finally, the wire harness can be laid out to form a manufacturing pin board diagram and for other assembly documentation.

Similar techniques are used for designing tubing, such as hydraulic systems.

Mold, tool, and die design problems can benefit from the application of some specialized functions. For mold design, material flow and cooling analysis, solid mold-base feature and fixture libraries (see Fig. 15), draft features, complex surface design, and materials libraries are available. These help designers analyze mold performance and simplify the design process by providing easy access to information specific to the plastic-molding process.

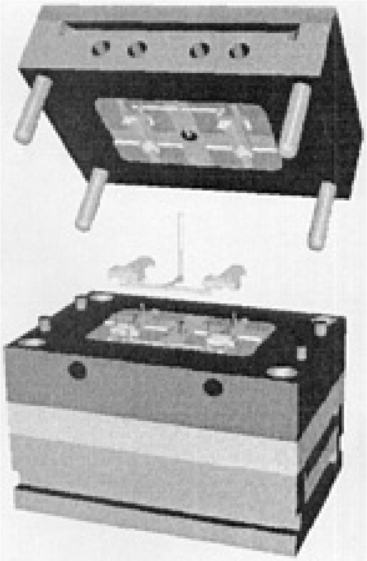

Fig. 15 Mold assembly design. Courtesy of SDRC

For tool and die work, libraries of fixtures and tooling are available. Analysis of drawing processes is only beginning to be made available within CAD systems. Analyses include material stretch at each stage of the drawing process, tear analysis, surface curvature analysis, and suggestions for creating progressive dies.

The books and articles listed as "Selected References" contain additional information about solid modeling and CAD/CAM. Many of the books and articles contain further references for additional study.

Mechanism Dynamics and Simulation

James E. Crosheck, CADSI

Introduction

MECHANISM SIMULATION is a subject of such breadth that it is the topic of numerous books and journals and the focus of hundreds of learned papers. The technology is evolving at an ever-increasing rate due to advances in computer technology and numerical analysis techniques. As an overview of this subject as it impacts the rapidly changing design environment, this article offers a series of glimpses into some of the areas of application, providing a direction that the reader may pursue in depth on their own or with the aid of software vendors, consultants, academics, and so forth. A very limited set of references at the end of this article, primarily standard texts, provide the depth that some readers may find valuable. For most readers, the details of the underlying equations are not the immediate concern--rather the questions are related to taking advantage of the technology in an appropriate, cost-effective, and timely manner. Once the direction for solution of the engineering problem is clear, the finer points of the theory and its application can and should be reviewed further to ensure that the solution process properly matches the problem.

Two complementary reasons are usually the impetus for simulation of mechanical systems. First is performance prediction: will the design meet the specifications over the range of conditions in which it is expected to operate? Second is the detailed information that can be extracted from a simulation on component loads, displacements, and accelerations. This information provides the best estimate of the environment of the component, an estimate that is needed for detailed strength analysis using finite element or other techniques.

This article presents an overview of the use of mechanism analysis (kinematics and dynamics) and simulation. It provides indications of the directions in which mechanism simulation is growing and how it is integrated in the evolving computer aided design and computer aided engineering (CAD/CAE) fields. Mechanism simulation is best used as part of a concurrent CAD/CAE approach to design. Current practice seldom utilizes simulation to develop the best design. This article discusses the current state, evolution of, and direction of application for these techniques in a variety of fields. It is presented in the context of material selection and, in turn, component sizing, which is dependent on material selection. The examples presented are not exhaustive; rather, they are used to provide indications of the direction in which simulation is growing. They are intended to illustrate current trends and to stimulate thoughts of opportunities for application by the reader.

Mechanism Dynamics and Simulation

James E. Crosheck, CADSI

Definitions and Basic Concepts

According to Webster's Ninth Collegiate Dictionary, simulation is the "imitative representation of the functioning of one system or process by means of the functioning of another." In current technology, designers typically look to simulation for the solution of questions through computer models that use computational techniques or CAE. The range of techniques varies from queuing theory models used to predict flow of materials through a manufacturing plant to finite element models to predict stresses, heat transfer, or temperature distribution. Of particular interest in this article, and of growing interest in general, is the simulation of the motion and performance of mechanical systems.

This article explores how simulation of nonlinear mechanical systems, which emulates physical systems, is accomplished through the use of representative computer models incorporating a number of interdisciplinary engineering tools. A distinction is made here between linear and nonlinear solutions. Linear equations of motion can be solved using frequency domain analyses. This involves Fourier or Laplace transform techniques that are usually computationally very efficient. Unfortunately, most systems exhibit nonlinear behavior due to their large range of motion, nonlinear stiffnesses, varying mass properties, nonlinear damping, intermittent contact, or excitation from nonlinear forces. Solution techniques for nonlinear systems are demonstrated with examples solved with one of the software packages used in the current engineering environment for the solution of design problems. At the time of this writing, the majority of solutions of mechanism problems are done with one of four commercial systems: DADS from CADSI, Adams from MDI, Applied Motion from PTC, and Working Model from Knowledge Revolution. The examples presented were prepared with a single program, DADS, due to the author's familiarity with it. Similar capability is available from other vendors, and they should be consulted for a description of current features. (The author would highly recommend using a commercial code for simulation of any nontrivial mechanism problem. As recently as the last decade, many engineering analysts wrote their own computer programs to solve specific problems. As the capability of commercial systems has evolved, so has the tendency to write and maintain isolated, specialized programs become less cost effective.)

Before continuing, it is important to provide some definitions for the types of analyses that are commonly performed as part of the general category, mechanical system simulation. A mechanical system is composed of a set of parts or bodies that are connected by joints to form an assembly. The system is forced to move or allowed to move by some form of control system and/or by external forces. For the majority of the problems in mechanical system dynamics, the bodies can be regarded as rigid. However, there are an increasing number of cases in which the flexibility of the part is important in the overall performance of the system. For these cases, some codes will allow the use of information such as mode shapes and frequencies from finite element analyses to calculate small, structural displacements that are superimposed on the large displacements of components of the system. Examples of this are discussed below. Bodies are normally connected by joints, but in many cases the bodies are constrained by elastic elements such as bushings or are confined by intermittent contact with other parts of the system. Again, examples of these real-world situations are briefly described below.

Another term that is useful in the following discussion is "degrees of freedom" (DOF). This quantity is the number of independent directions that a body or system of bodies is free to move. A single body floating in space has six degrees of freedom, three translational and three rotational. If the body is restrained to ground, all six of the DOFs are removed. Suppose two bodies are connected by a rigid hinge joint. The original two bodies had twelve DOFs, but are now reduced to seven. The hinge joint only allows motion in one direction, a rotation of one body relative to another. If one of the bodies is now attached to ground, the complete system only has one DOF left. If the rotation of the hinge is now enforced as a function of time, the system has zero DOF--all independent motion is now defined or restrained. These restraints are algebraic relationships between the original independent DOFs. Note that it is mathematically possible to over-constrain a body. For example, placing two hinge joints between two bodies applies ten algebraic relationships between the motion of the two bodies, but six is the most physically possible. Physically and intuitively, two hinges that are understood to be at arbitrary orientations between the two bodies will lock them together, removing six DOF. Further, if the hinges are aligned as on a door, the system still allows rotation of one body relative to the other. This aspect of the idealization of a system is not followed further. However, it may shed light on some of the art left in simulating a mechanical system (or on some of the skill required in developing computer code to interpret the connections between bodies).

The categories of analyses that are used for mechanical systems include:

- *Kinematics:* Solves an algebraic system of equations with zero DOFs to determine the position, velocity, and acceleration of all bodies at a sequence of user-specified time steps. This means that all motion is prescribed as a function of time. This is often used as a means of checking range of motion and also to verify that the design will allow motion/velocity/acceleration to be in the expected range.
- *Inverse Dynamic:* Solves the same set of equations as a kinematic analysis, but uses the calculated accelerations to find the joint reaction forces. These calculated forces depend on both the external forces

generated by the time-dependent, imposed displacements and also the inertial forces.

- *Static Analysis:* Solves a system with a positive number of DOFs to find the position that minimizes all body accelerations subject to external forces and gravity. The resulting position is the equilibrium position for the system. This solution is algebraic, resulting in balanced internal and external forces in the absence of system motion or inertial forces.
- *Quasi-Static:* Solves a sequence of static analyses for different configurations of the system.
- *Assembly:* Solves a set of nonlinear equations to find the position that minimizes the constraint error for all constraints in the model. These constraints are primarily due to alignment of joints between the bodies or placing bodies with enforced displacements. This is sometimes used as a prelude to the actual solution if the system is defined "manually," one part at a time, allowing small errors in locating the bodies. This solution is done or at least checked prior to the start of all analyses.
- *Dynamic:* Solves a system with a positive number of DOFs and numerically integrates the equations to determine the position, velocity, and accelerations of all bodies plus the joint reaction forces.
- *Linearization:* Not really a separate solution procedure, this technique provides information that can be used to communicate with other programs or that can be used for diagnosis of modeling problems. Eigenvalues and the corresponding eigenvectors of the linearized model can be a means of detecting inconsistent data for mass, stiffnesses, or incorrect constraints between parts. Linearized equations for the mechanical (or complete) system allow stability to be easily assessed. A linearization of the model about the current operating condition is also a convenient technique to pass information to control system synthesis and other simulation programs.

Theoretical Background. The theoretical foundations for mechanism kinematics and dynamics can be found in numerous texts and papers. For those interested in a rigorous understanding of the field, a good starting point is texts by Haug, Kane, Greenwood, and Erdman (Ref 1, 2, 3, 4, 5, 6).

The basic equations are not complex: a set of second-order differential equations (DEs) that define the force balance on each component of a system plus a set of constraint equations that tie the components together with joints or more general relationships. The resulting equations are normally described as differential-algebraic equations (DAEs). The equations, or one of the variations, can be found in the references listed and are not the primary concern of this article.

However, it should be noted that there are alternative formulations in both academic and commercial software. The simplest formulation uses a Cartesian coordinate system for all forces and displacements. This simplicity also results in a penalty in the form of a larger number of equations in the solution set. Alternatively, relative coordinate formulations create complex relationships in the solution set in exchange for a significant reduction in the number of, or elimination of, constraint equations. Each method has both merits and limitations. For commercial software, the preferences are usually more critical to the software developers than they are to the users of the software. Available commercial codes solve the DAEs or DEs for a wide range of problems with adequate accuracy and in a reasonable amount of computer time and resources. As computer speed and storage increase, the solutions are approaching real time. Potential users of a code should test it on sample problems of their own design and evaluate the tools in conjunction with its own capabilities and its ability to be a part of their product development cycle.

Later sections discuss some further considerations in application of commercial codes, but this is an appropriate point to highlight a technical issue that concerns many application-oriented users. The issue is speed versus accuracy (or better, speed *and* accuracy). Solution of the DAEs requires integration of a set of DEs that are often "stiff" due to physical conditions such as intermittent contact of bodies, stiff springs, compressibility of hydraulic fluid, and so forth. (The definition of "stiff" is not precise, but usually means that the system contains high frequencies and widely spaced eigenvalues.) The accuracy of the solutions varies significantly from code to code. Some implementations feature solutions that track high-frequency components of the solutions at the expense of increased computation time. Others allow the user to tune the integrator to achieve the level of accuracy desired. These options can provide faster solutions if the high-frequency content is not of interest. The critical aspect of this trade-off is recognition by the user that a trade-off is being offered--often this is not clear in the supporting literature. Users of these commercial codes should test the software on problems of the types they expect to routinely solve. Ideally, results should be validated against test data. Unfortunately, time constraints limit the amount of user testing that can be done, resulting in the need for a certain amount of faith in claims of vendors and their demonstrations.

Mechanism Dynamics and Simulation

James E. Crosheck, CADSI

Performance and Function

Some disciplines pose high demands on performance that are difficult to predict without either prototype testing or detailed mechanism dynamic analysis. One example would be a military vehicle that is expected to handle a wide range of loads over a variety of terrain. Maneuvers such as a slalom run on a side slope, obstacle avoidance at highway speeds with full cargo loading, and "high-speed" runs over cross-country terrains need to be reviewed and addressed for the suspension design before the initial prototype is built and tested. In such cases, the loads analysis is secondary to the need to meet stringent performance specifications. The loads are of vital importance for durability and reliability reasons, but only after there is assurance that the concept will meet the performance requirements.

Another example is the antenna deployment of spacecraft. It is difficult to test the lightweight, flexible structures in an earthbound environment. Mechanism analysis, particularly dynamics, is very valuable in checking the functioning of the system before expensive "testing" in actual operation in space. Large numbers of low-frequency modes are often prevalent in these devices (for example, hundreds of modes are predicted to be less than 2 Hz in the Space Station) and the flexibility is often critical to proper performance of the system. Unfortunately, the opposite is also true, that component flexibility may be the source of unexpected behavior that causes problems. Sometimes these problems can be observed with the dynamic simulation prior to actual deployment and corrected prior to deployment. Unfortunately, there will also be a portion of the cases that are not found before actual use of the system. These lead to two observations for users of the technology. First, as many cases as possible should be analyzed before the design is fixed. This increases the possibility of finding as many unexpected phenomena as possible. Second, simulation is still partially an art. If a model is constructed that cannot demonstrate the "problem" behavior, it is a failure of the modeler, not of the technology. For example, if the lockup of a joint is dependent on an over-center latching technique, and it, in turn, only works if a part flexes to allow the latching to occur; a rigid representation of the part is not acceptable. In general, modeling "errors" can usually be traced to assumptions made about the behavior of the system, or parts of the system. These incorrect assumptions are often made to simplify the model, reduce the amount of input data needed, or speed the solution of the simulation. Hindsight is a great teacher in such situations, and each such experience results in a better analyst for the next case!

Example 1: Mechanism Dynamics and Simulation in the Design of Bowling Balls.

Rather than delve into a detailed example early in the article, it is appropriate to examine a "simple" problem. Bowling is a deceptively simple game. Use a ball that weighs 16 lb or less and drill some holes in it so it is easy to handle a ball of that weight. Stand a few feet behind a foul line, take three or four steps forward while swinging the ball, release the ball and let it slide or roll down the lane until it hits the set of ten pins 60 ft away. The objective is to knock all ten down with one or two throws. Soon the novice bowler hears advice to throw a "hook" (a curved trajectory) to get more strikes (all ten

pins knocked down on the first throw). They also begin to hear debate over the merits of different balls and ways to drill the balls.

Ebonite International has used computer simulation to develop bowling balls that provide a significant improvement in performance over existing balls. Simulation allows Ebonite engineers to design a new ball on the computer and test its performance under controlled conditions in under 30 min. This compares to weeks of time and thousands of dollars previously required to build and test a prototype. Designed using simulation, Ebonite's recently introduced Wolf ball offers a higher level of performance under a broader range of lane conditions.

Ebonite produces bowling balls using the open-casting method. The new Wolf ball has a core made of tungsten graphite, which with a density of 6.0 g/cm^3 is the heaviest material ever used in a bowling ball. Rather than being spherical, the core of the ball is pill-shaped, making it possible to vary the location and degree of the ball's hook so it can be adjusted to a bowler's style and varying lane conditions. In general, bowlers want more hook because it increases the angle at which the ball contacts the pins, which creates a bigger "pocket" within which a strike is most likely.

Although a bowling ball seems to be a simple object, the dynamics of a bowling ball as it travels down the lane are actually quite complex. The ball undergoes gyroscopic influences caused by the core design of the ball and interacts with a lane surface that has varying friction, due to varying levels of oil. The gyroscopic motion also affects the friction by influencing the amount of oil that builds up on the ball. Finally, when the ball reaches the pins, an enormously complex, intermittent contact problem is created, with the ball contacting the pins, the pins contacting other pins, and the pins contacting the lane and gutters.

The design of bowling balls has gone through a dramatic series of changes. Previously, bowling balls were uniform, or had a spherical core located in the center of the ball. Because the ball had a uniform inertia, it made no difference (from a rotational dynamics standpoint) how the ball was drilled.

The early 1980s saw the introduction of nonspherical, symmetric cores shaped in patterns such as a light bulb or a dumbbell. This type of ball has two principal inertias, one along the axis of the core, and another perpendicular to it. If the axis of the core coincides with the initial rotation of the ball, it will behave in a similar manner to earlier balls, as it will if the initial rotation is in the plane perpendicular to the core axis. However, if the initial rotation of the ball is about any other axis, interesting things start to happen.

First, the rotation axis precesses about the core axis; that is, the motion of the rotation axis describes a cone about the core axis. Generally, increasing the differential between the least moment of inertia axis and the axis of rotation, and judiciously positioning the rotation axis, increases track flare. This in turn increases the amount of friction between the ball and the lane, which allows for a greater hook. The larger hook increases the angle at which the ball hits the pins, increasing the probability of a strike. As a result, nonspherical cores have substantially increased the scores of bowlers that have learned to use them effectively. Nonspherical cores have been adopted by all bowling ball manufacturers and represent the current state-of-the-art. An additional advancement was the introduction of the asymmetric core.

The asymmetric cores used in the most recent bowling balls (Fig. 1) typically are shaped like pills or spheres with opposing sides flattened. The performance of a ball with a conventional symmetric core can be varied only by changing the axis of rotation of the ball in relation to the core axis, while the asymmetric core has three distinct principal inertia axes in relation to which the rotation axis can be positioned. An asymmetric core therefore provides the ball driller with a wide range of track flare potential, which can be used to tailor the ball's performance to a given bowler.

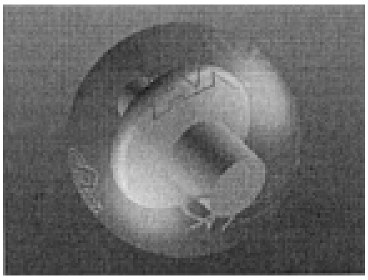

Fig. 1 Modern bowling ball construction with nonspherical, asymmetric cores

This new design concept provides a great deal of additional freedom for ball designers, with many more potential ball configurations. However, it also adds difficulty in evaluating all of the possible designs. First of all, there is a much wider range of possibilities for the core shapes. Second, once the core shape is defined, it needs to be drilled in such a way that bowlers can get the full range of performance they desire. Finally, it is up to the manufacturer to precisely determine the performance, in particular the amount of hook, that will be produced by each drilling pattern.

The traditional approach is to build a prototype and test it on the lane; a time-consuming and expensive process. First, it is necessary to build molds for both the core and shell. Then, it has to go through an extensive testing process to objectively determine its performance in relation to other balls. For the new asymmetric core balls, this would have been an overwhelming process. Thus, engineers decided to investigate alternatives using computer simulation.

Engineers begin the simulation process with a Pro/ENGINEER (Pro/E) CAD model of the ball, including its various shells and cores. The geometry and the mass properties (mass and inertias) are extracted from Pro/E and passed to DADS. The lane conditions are described, including oiling levels along and across the lane, and this is converted into a variable friction over the surface of the lane. A series of utilities were created to allow Ebonite to conveniently input ball initial conditions and grip positioning.

After the model is created, the analysis program simulates the movement of the ball down the lane (Fig. 2). Output includes the critical parameters of ball design such as: the reaction length or amount of distance before the ball begins to hook, the backend or sharpness of the hook, and the overall hook radius or magnitude of the hook. The engineers can watch an animation of the throw and can add representations of the track flare, rotation axis motion, and an "inertia map" to enhance understanding of the dynamics. Other utilities can automate changes to the model, allowing the engineers to try dozens of grip drillings, a range of mass properties, or changes in the throw. Tests have shown that the simulation correlates very well with physical testing.

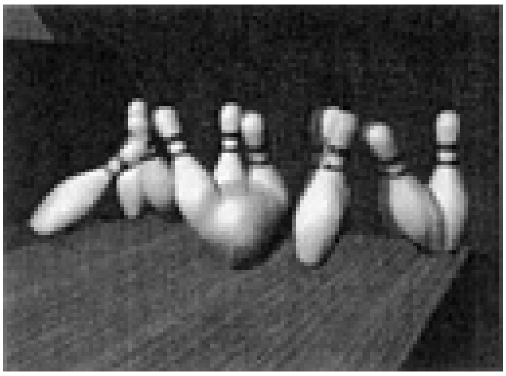

Fig. 2 Accurate simulation of ball performance as it contacts the pins

By repetitively performing simulations, engineers were able to hone the performance of the ball to a high level. The documentation that is provided with Ebonite's Wolf ball shows the precise hooking characteristics that can be created by a wide range of drilling positions. By selecting the proper position, bowlers can produce virtually any type of ball performance they desire. Despite the unprecedented number of alternate scenarios that were evaluated, the ball was developed in record time.

By using computer simulation to evaluate alternate design concepts, the design cycle has been compressed to a dramatic degree. The speed and convenience of simulation make it possible to consider many times the number of alternatives that the company was able to evaluate in the past using the build-and-test approach. As a result, the company has been able to make a quantum leap in bowling ball performance while actually reducing the number of engineering hours required.

Load Prediction

Perhaps the longest-running need in engineering has been reasonable estimates of loads to use in sizing components. Not long ago, it was common to put a few strategic accelerometers and strain gages on the mechanism, operate it in a range of conditions including its more severe ones, and then predict the loads on the connection points of components, usually through manual calculations. This process requires that a prototype or a similar mechanism exist for testing. In many cases, test data were not available for a variety of reasons and the loads were based on the equivalent of opinion polls (educated estimates of a group of engineers and technicians). The resulting loads from either incomplete testing or from poor estimating often were seen again later in increased warranty claims. Modern mechanism software allows a more accurate estimate of the loads within a system. This in turn is one of the primary ingredients to successful use of finite element analysis of the components (see the article "Finite Element Analysis" in this Volume).

One area in which mechanism analysis has been used successfully for several years is the suspensions of automobiles and trucks. A typical suspension model (Fig. 3) includes several interconnected components and supporting bushings. The steering input to the front wheels would be run through its range of motion, as would the wheel be run through its vertical range of motion from jounce to rebound (maximum vertical motion upward and downward). Throughout this exercise, characteristics of the suspension such as the caster, camber, and toe-in would be monitored. Forces at individual connections would be plotted. Side forces would be added to the tires to represent the turning forces and the process repeated. Comparison of simulation results with previous designs, successful or not, provides guidance on the quality of the new design concept.

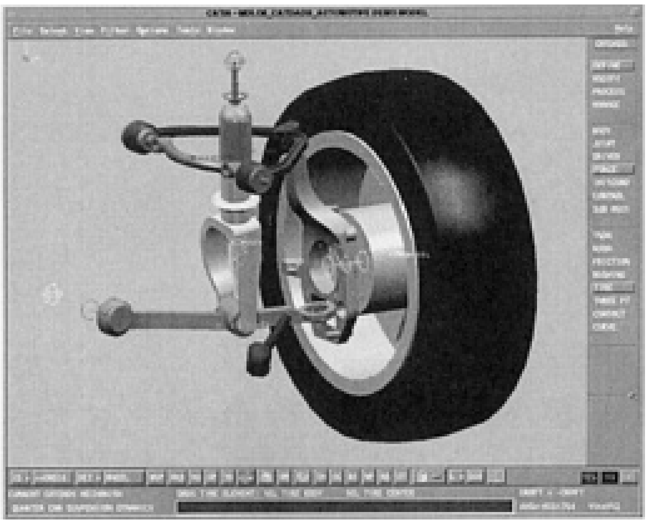

Fig. 3 Simulation of suspension systems allowing load predictions to be made

Note that the above process does not really use dynamics in the analysis. Kinematics or quasi-static analysis has been and continues to be an effective tool for suspension design. However, as cars become lighter and more flexible, the chassis becomes more critical in the response of the suspension. Add to that the trend to active or semiactive suspension components and the need for true dynamic analysis of the vehicle becomes important.

The flexibility of the components of a suspension plus the body are also very important to accurate prediction of behavior. Our experience has shown that the flexibility of a truck chassis can reduce peak loads on suspension components by 30 to 50%. If weight and cost are not a concern (not a typical commercial situation), simulation of a suspension that assumes rigid components merely leads to a conservative design. However, the combination of regulatory and economic forces urge designers to be as accurate as possible in their predictions of vehicle behavior. In turn, this pushes designers to incorporate and quantify as many simulation effects, such as flexibility, as they can.

More accurate design loads can be used to reduce cost and improve payload without risking higher failure rates. This implies a need to use dynamic analysis for the fine tuning of the analysis results before the final design decisions are made. The loads can and should be used as input to stress analyses to ensure that the choice of materials for the parts of the suspension are acceptable. Note that the interaction of the other parts of the engineering activity suddenly become more obvious. The properties of a particular material or particular alloy must be balanced against its cost and ease of use in manufacturing. If a change is contemplated, this may imply a need to re-evaluate the mechanism performance due to changes in mass properties of the part. This in turn may require another iteration in the stress analysis. However, loads are only part of the need for prediction of the behavior of a mechanism.

Example 2: Simulation to Predict Loads in Aircraft Landing Gear.

The first certification of an American business jet in Russia was accomplished using a mechanism simulation approach that saved three to six months and $100,000. The primary issue in the Russian certification of the Gulfstream IV-SP was the ability of the landing gear of the jet to withstand the rough runways that are common in that country. Conventional methods of validating this capability, developing custom dynamics software or physical testing, would have taken at least six to twelve months. Instead, it took only three months to simulate takeoffs, landings, and taxiing on rough runways using an off-the-shelf program that predicts mechanical performance.

Gulfstream Aerospace is a designer, developer, manufacturer, and marketer of technologically advanced intercontinental business jet aircraft. In 1966, the company created the large cabin, business jet category with the introduction of the Gulfstream II. The Gulfstream IV-SP entered service in 1986 and is still in production, with 305 manufactured to date.

The Gulfstream IV-SP landing gear essentially consists of an oleopneumatic strut. Two chambers, one filled with oil and the other with air, are connected by a bulkhead with a small orifice. The gear is arranged so that when it contacts the ground, oil is forced through the hole into the chamber where it compresses the air. The resistance of the oil generates a damping force that is proportional to the square of the velocity of the strut. The compression of the air by the oil generates a force that helps to keep the gear extended while the plane is on the ground. The oil plays the same role as an automobile shock absorber while the air is comparable to the springs.

Computer simulation of a landing gear is challenging because of the nonlinearities involved. Geometric nonlinearities arise when the geometry of the landing gear changes over time and changes the very nature of the problem. The translation (extension) of the struts dramatically changes the landing-gear configuration. For example, the swing arm goes through 60° of travel during each landing and takeoff.

Gulfstream worked with CADSI to analyze the main gear and nose gear of the aircraft in landing and taxi simulations (Fig. 4 and 5). The DADS software package allows engineers to develop mechanisms without simplifying assumptions that reduce the accuracy of specialized landing gear code. This software package is also able to incorporate flexibility of components required for accurate simulation of landing-gear struts, and closed-and-open loop control systems needed to simulate the performance of the oleopneumatic strut.

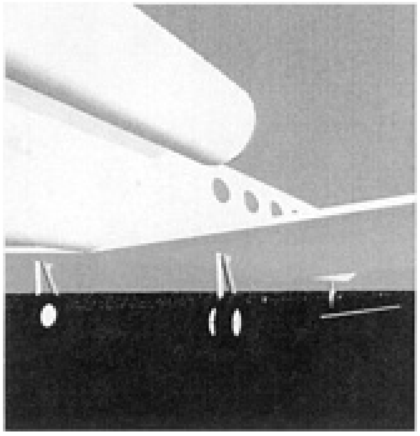

Fig. 4 Taxi simulations that predict loads from the landing gear into the aircraft

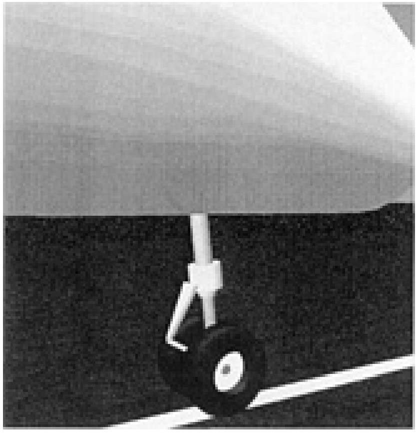

Fig. 5 Landing gear mechanism geometry changes significantly during taxi or landing

The initial main landing gear model was constructed to simulate a drop test and consisted of eight bodies representing the ground, aircraft, post, piston, cylinder, arm, inboard wheel, and outboard wheel. Eight joints connect the bodies together: bracket (aircraft to post), revolute (post to arm), revolute (arm to inboard wheel), revolute (arm to outboard wheel), spherical (arm to piston), translational (ground to aircraft), translational (cylinder to piston) and universal (post to cylinder). This combination of bodies and restraints leaves each landing gear system with four relative degrees of freedom. One is the vertical translation of the aircraft, another is the motion of the arm and piston relative to the post and cylinder, and the other two are the rotation of the wheels.

The oleopneumatic characteristics of the strut were modeled using DADS control elements. The control system measures the magnitude and velocity of the strut displacement, calculates oil velocity through the orifice and pressure drop across the orifice, and finally determines the force due to the oil flow. The ideal gas law with heat flow involved is used to determine the force due to the air pressure. The total strut force is the summation of the force due to oil flow, the force due to air pressure, and a constant force due to seal friction.

This model was validated by simulating a drop test, the primary method for testing landing gear. A physical drop test involves mounting the gear on a slide attached to a vertical rail. A bucket full of lead bricks is attached to the gear to simulate the weight of the aircraft. The landing gear is instrumented with pressure transducers and accelerometers and dropped to an instrumented steel platform. The simulation results were plotted against physical measurements generated during actual drop tests and found to match well. The next step was enhancing the initial model to include flexibility of key components. The basis of a flexible body in DADS is a mesh of grid points and a set of mode shapes generated by a finite element model of the part in question. MSC/Nastran was used in this case because finite element models had already been prepared for the required components at Gulfstream. The flexibility of the main structural post and trailing

arm in the main landing gear were represented with modal coordinates. Each modal coordinate value represents the contribution of that particular mode shape to the overall deformation of the part. Drop-test simulations with flexible bodies added to the model showed near-perfect correlation with physical measurements.

The next step was to add a rigid airframe, aerodynamic equations, variable thrust, and braking. The resulting model was capable of handling realistic landing, takeoff, and taxiing scenarios. The aerodynamic equations calculate lift, drag, and lateral forces, as well as roll, pitch, and yaw moments. These are based on angle of attack, sideslip angle, freestream velocity, dynamic pressure, wing area, mean wing chord, and wing span, as well as many other coefficients that are related to the physical characteristics that determine the aerodynamic characteristics of the aircraft. Logic was added to the model to account for the actions of the pilot such as pulling back on the stick to lift the plane off the runway.

Control elements define the thrust, split it into local X and Z components, and apply the forces to the aircraft. Brake torque is required to simulate a rejected takeoff condition. Brake torque is also applied through control elements. For the rejected takeoff condition, a maximum brake torque is available. The torque is ramped in from zero to the full value over a 2 s time interval. The final modification to the model incorporated a finite element model of the complete airframe. The model is composed primarily of bar elements in a "stick figure" layout along the principle members of the airframe. Also included are the flight control elements with combinations of rigid elements and springs to provide correct stiffness in the model. Concentrated masses are used to define mass and inertia values.

When the Russian certification effort began, the simulation model had already been developed and validated for other purposes. Gulfstream engineers obtained roughness survey data for representative Russian airports from a manufacturer of commercial airliners that had previously gone through the certification process. These survey data were reduced to power spectral density functions that described the runway as a function of roughness frequency. The takeoff, landing, and taxiing simulations were rerun using these data as input to the model.

Gulfstream engineers closely examined the results to determine the response of the structure and the loading on critical components. Both maximum design load conditions and repeated load conditions were investigated. The most sensitive area in the landing gear with respect to runway roughness had previously been shown to be the trunnion where the landing gear attaches to the airframe. The nose landing gear trunnion is the most critical because the nose landing gear has the least stroke and is the most prone to bottoming out. When this occurs, serious damage to the landing gear can result.

The simulation results showed that the aircraft could handle all but the roughest Russian runways without any ill effects. The Russian regulatory authorities were extremely impressed with the analysis results. In particular, the animated simulations provided by the software made it easy for government employees without a strong technical background to easily comprehend effects of landing on runways of various roughness. The certification process proceeded more quickly than expected, allowing Gulfstream to be the first American business jet producer to penetrate the rapidly growing Russian market.

Mechanism Dynamics and Simulation

James E. Crosheck, CADSI

Direct, Concurrent Interfacing of Multiple-Simulation Programs

Most mechanisms are an integral part of a system. Rarely are there simple mechanisms that can be treated in isolation from the controls or the driving forces on the system. In some cases, it is a reasonable approximation of reality to move the mechanism in isolation from the rest of the system. More often, both the large range of motion of a mechanism (which introduces nonlinearity) and the details of its control system must be studied at the same time. For example, the use of kinematics and quasi-static analysis of suspension systems to successfully design their components and review their anticipated behavior has been discussed. However, as designs embrace active components and as the flexibility of the chassis becomes more important in performance (handling and noise creation or transmission), dynamics must become a standard part of the design process.

Software is a transient entity. Codes are becoming more modular, more objectlike, allowing easier coupling and interchange of information. Some mechanism programs now can be linked to traditional control system analysis packages to allow for more complete system simulation. To be accurate, the software linkage must be direct. Intermediate files,

which are sometimes used to pass data between "cooperating" programs, indicate that each program is really operating independently of the other and that variables in the two cannot be integrated simultaneously (and accurately). A proper linkage of mechanisms and controls requires integration of the complete set of equations, the DAEs of the mechanism and the state equations in the control system simultaneously. In that environment, the control program can be used in the mode for which it is most powerful, as a control system analysis and synthesis program. Similarly, the mechanism program can be used to determine loads, accelerations, and so forth that are the forte of those codes.

Developing two separate models, one from the controls viewpoint and one from the mechanism side, is one approach that is often used. Normally, depending on the interest and concern of the engineer involved, a detailed model is developed from one vantage point and a cursory model is developed from the other viewpoint. This is simply a reflection of individual interests and expertise, not an indication of deliberate neglect. This also obviously does not allow a robust evaluation from both perspectives, and certainly not of the interaction of the control and mechanical system at all. The best technique is to use two separate programs that complement each other to solve such problems, that is, programs that "co-simulate" on the problem at hand.

Two simulation programs that complement each other as described are DADS and EASY5, by Boeing Computer Services. The details of the mechanism are modeled in DADS and the control system in EASY5 (this interface between the two codes is commercially referred to as DADS/Plant.) To force the concurrency needed, DADS is treated as a module within EASY5. (In control system terminology, the portion of the system that is being controlled is the plant. In this combined system, the mechanical portion of the system is the "plant." Hence, the name, DADS/Plant.) In this mode of operation, EASY5 integrates the equations of motion for the mechanical system as well as the state equations for the control system. DADS determines the velocity, and acceleration information that is needed in EASY5. EASY5 integrates to determine position information plus it predicts forces to be used in DADS. Figure 6 illustrates this interaction.

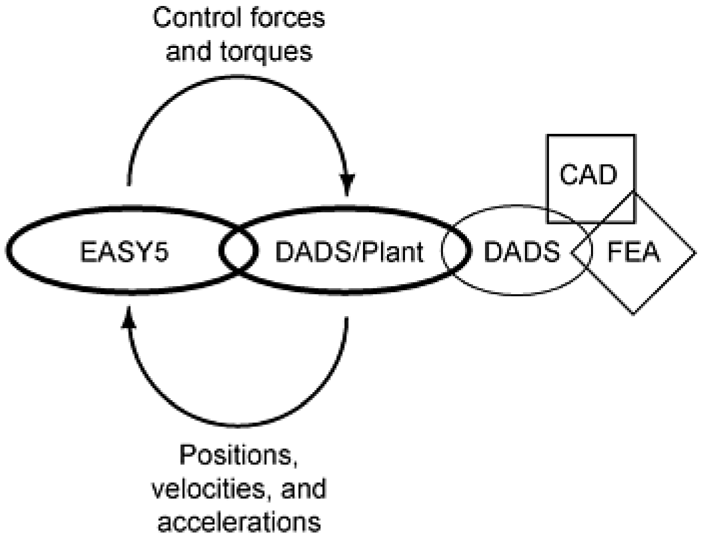

Fig. 6 Implementation of direct integration of control and mechanical system models. This is indicative of the information flow in the DADS/Plant code.

Note that this is a true direct integration of the programs rather than a process of exporting information from one program to another for use in a separate analysis. Similar techniques are possible with other popular control system analysis programs such as MATLAB/SIMULINK and $MATRIX_X$.

Example 3: Integration of Two Analysis Programs for Simulation of Backhoe Operations.

Most backhoes have an open-loop control system actuated by a hydraulic drive system. On the machine, the loop is closed by the operator. In this example, instead of relying on the operator to close the loop, an automatic control system modeled in SIMULINK, is used to control the system (Fig. 7).

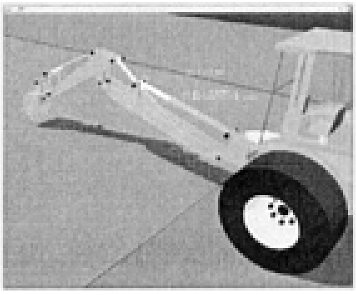

Fig. 7 Backhoe system with closed loop to counteract resonant vehicle motion

Directly linked as a subroutine of SIMULINK as an S-function, DADS/Plant assembles the equations of motion and uses SIMULINK to solve state equations of the mechanical plant model. Simulations can be viewed either graphically as *x-y* plots or with photorealistic animation of the related model geometry. DADS/Plant links the model geometry with the simulation results for interactive animation, which can be used to provide instant feedback to the engineer and other audiences.

The automatic control system allows the bucket to be controlled in order to counteract resonant vehicle motions and provide a smooth ride. This could be desirable to reduce operator fatigue when using the machine to transport material over moderate or long distances.

The first step in this process is to model the mechanism portion of the model in DADS/Plant while the hydraulic system is modeled in SIMULINK. This backhoe example consists of seven bodies connected by a series of joints that produce only four DOFs. These four DOFs allow the operator to position the boom and the tip of the bucket. By modeling and defining geometric relationships of the movable parts and the body properties such as mass, inertia, and joint descriptions, DADS/Plant is able to generate automatically complete nonlinear models.

Four hydraulic actuators are used to maneuver the backhoe. Each actuator is controlled by a spool valve. Each actuator defines two state equations: one for each pressure in the actuator. The pressure state equations are dependent on the volume and the rate of change of volume in the actuator. This requires the stroke of the actuator and the stroke velocity to be fed from the DADS/Plant model into SIMULINK. Further, to close the loop on the controller, the four DOFs of the bucket are needed in the SIMULINK controller.

The mechanism model is included in the block diagram (Fig. 8). A hydraulic system and controller are interconnected to the plant block to form a closed-loop system. The controller modeled in SIMULINK can compute hydraulic forces that are to be applied to the mechanism model to close the feedback loop. The plant elements receive force or torque signals from SIMULINK and, in turn, DADS/Plant passes body positions and velocities back to SIMULINK.

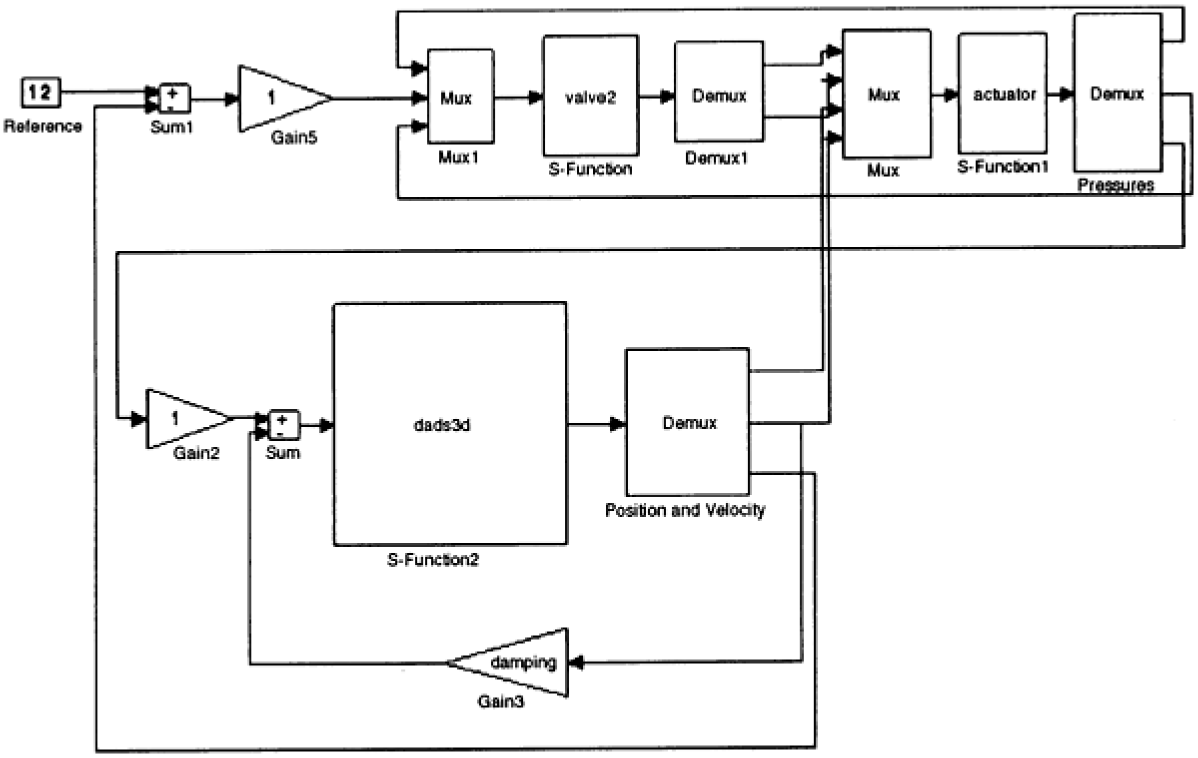

Fig. 8 Backhoe circuit block diagram

DADS/Plant models can be linearized from SIMULINK. By using the linearized models, users can apply any of the control design tools available with MATLAB, including classical or modern control design methods. The new controller can be incorporated in the SIMULINK block diagram for full nonlinear simulation.

Mechanism Dynamics and Simulation

James E. Crosheck, CADSI

Direct Interfacing of CAD Data and Simulation Programs

For mechanical systems, most of the critical data are tied directly to the information captured in a CAD system. Detailed geometry is certainly contained in the database, but material properties, mass properties of the parts, and locations and types of joints are specified or may be inferred from the geometry. This is especially true if the CAD system is a solid modeling system.

As a simulation specialist attempts to predict the behavior of a mechanical system, the accuracy of the input data is very important. The ease of use issue is also critical in acceptance of simulation in the engineering process.

One of the most common ways in which design accuracy is lost occurs when the analyst is using data that are not current. The simplest solution to maintaining data integrity is the direct incorporation of CAD information from the solid modeler into the simulation model. This direct or integrated approach is both faster and more error-free than indirect procedures that require translation of the geometry to IGES or other representations, followed by translation into the data format of the simulation program. The integrated approach of working on the database in the CAD system guarantees that the same data used by the designer are passed into the simulation program.

Overcoming the ease-of-use issue is addressed by integration of the simulation program within the solid modeler environment. This allows direct data exchange as well as adding menus and operations that produce the simulation model without requiring the user to leave the familiar solid modeling environment.

Example 4: Modeling of an Automobile Door Latch.

As an illustration of this modeling process, consider the analysis of the closing and latching of a car door. This model was validated against a set of results from a test fixture at an automotive manufacturer. The latch components were designed and assembled in the Pro/ENGINEER modeling system from Parametric Technology Corporation. The DADS multibody dynamics (MBD) program from CADSI has an integration module that runs within the Pro/E environment. This allows the designer to select parts, joints, constraints, external forces, and so forth, from within a familiar menu environment to quickly generate the model. The resulting model can then be used to predict motion, forces, accelerations, and so forth, to check correlation with test data.

The solid models of the latch mechanism and the complete assembly of parts are shown in Fig. 9. The assembly includes a pawl, a latch, a striker, and other parts including the door frame and door. One of the most critical sets of data is the contact surface shapes. Several parts have intermittent contact and slide against other parts during the closing. This geometric information is simple to extract from the CAD system by picking one segment of the edge that is part of a contact surface. The rest of the edge is then automatically traced and defined as a piecewise curve. Modern contact techniques use the geometry directly from the CAD database and allow Hertzian or other relationships to define the forces and penetration of the mating surfaces.

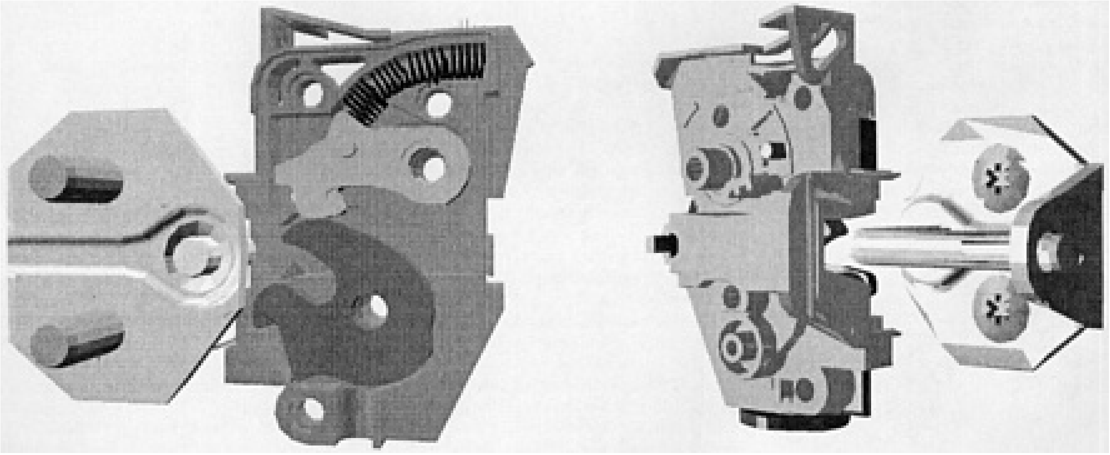

Fig. 9 Two views of an automotive door latch assembly

The analyst can actually run the simulation from the Pro/E environment. Often these simulations require further "tuning" by matching friction and damping coefficients (or other parameters) to correlate with test data. Once acceptable runs are made, the system behavior may be reviewed to determine if it meets the criteria for force levels, bounce, overtravel, and so forth. Both *x-y* plots and realistic animations can be quickly reviewed within this environment to show forces, displacements, accelerations, component interferences, and so forth. If it does not meet all criteria, the design can be quickly updated in the Pro/E model and the process repeated. Note the critical importance of using the CAD data directly; the data should be extracted automatically and accurately and used in a solution procedure that is tested and proven. Speed and accuracy contribute heavily to the value of simulation in the engineering process.

Mechanism Dynamics and Simulation

James E. Crosheck, CADSI

Interactions and Applications with Finite Element Analysis

Another tightly integrated pair of technologies is mechanism analysis with flexible components. Some mechanisms require one or more parts to flex in normal operation. Others have sufficient flexure in parts that it needs to be considered in understanding and predicting behavior. For simple parts, the response can be approximated as a simple spring-mass

behavior. For more complex parts, use of the full geometry of the part is the most direct and accurate approach. In these cases, finite element models (e.g., NASTRAN, ANSYS, ABAQUS, etc.) can be created from solid models through CAD systems. These models can then be used to define normal modes and eigenvalues for the constrained part. These can be supplemented with constraint or static modes (deflection shapes due to unit deflections or unit loads at attachment points) to form a set referred to as Craig-Bampton modes. These modes are then used in a technique commonly known as the component mode synthesis (CMS) technique. The procedure uses the set of modes as a basis set for approximation of the displacement of the flexible part and superposes that displacement on the rigid body motion of the part. The result is a highly accurate representation of the overall behavior of the system.

It should be noted that some codes have attempted to include a direct dynamic solution of the finite element model in a dynamic mechanism solution. This results in an increased number of DOFs in the model. Experience to date indicates longer solution times and often less accurate simulations. It is possible that this technique may have more promise in the future, but at this time a modal superposition solution is more widely accepted as the better solution technique.

Example 5: Integrated Mechanism Dynamics and Finite Element Analysis Approach to Interior Noise in Automobiles.

An example that many of us can identify with is the rattle of components in an automobile. As the noise level has been reduced with improved insulation and sound absorption in automotive interiors, sounds that were previously ignored or not otherwise perceptible became unacceptable to many owners. Rattles of cup holders, glovebox doors, windows, latches, and so forth, are now of concern.

The Ford Motor Company has been one of the pioneers in the development of analytic techniques to address these challenging problems before they are manifested in prototype or production vehicles. The following task is one that has served as a test bed for the techniques and is described only briefly, but the concept should be clear.

In rattle cases, the flexibility of one or more of the parts of the systems may be unintentionally "tuned" to the vibrations borne through the structure from the suspension or from the engine. Often, the part has several natural frequencies in the range of the input frequencies, making it difficult to avoid having one or more of these vibration modes respond to the input. In these cases, the amplitude of the response may increase until audible noise is heard. Often an intermittent (certainly nonlinear) restraint force is involved due to contact between a snubber or the latch on a glove box and its supporting structure.

The deflections of the glove box and the supporting structure are small, small enough to be treated as a linear response. The latch components are rigid in comparison to the glove box. These can be modeled very well with a multibody dynamics program. The snubbers between the glove box lid and the supporting structure are highly nonlinear in nature. Further, under rather small loads, the snubbers and springs can be compressed sufficiently to allow the latch and striker to lose contact and then hit again in rebound, creating one cycle in the noise mechanism. The spring holding the latch is set to produce a small load. The spring load cannot be increased significantly or else the glove box will be too difficult for the customer to close. This trade-off is typical of the dilemma confronted by designers.

The latch and striker separation allow two points of view. If the glove box is vibrating, the amplitude, while small, can be large enough to generate loads on the latch that accelerate the lid. When the loads release, the parts strike again. The other view is taken from the "outside," with motion imposed due to road input, engine vibration, and so forth. This input motion of the chassis drives the glove box lid through constraints such as the hinge and the latch and results in vibration of the lid. In this "chicken-and-egg" type of problem, only an integrated solution will yield the accurate answers needed to predict if a design concept reduces rattle.

So how is an integrated solution obtained? Finite element programs cannot easily predict the nonlinear action of the latch. However, the combined use of a finite element and a multibody code can.

In this case, natural frequencies and modes shapes for the glove box lid and some of the supporting structure were determined using MSC/NASTRAN. Frequencies in excess of 50 Hz were needed to cover the frequency range that had been seen experimentally, resulting in use of more than a dozen modes. These modes were then imported into the DADS program directly from the NASTRAN output files to augment the rigid body model of the glove box and latch system (Fig. 10). (Other popular finite element programs, such as ANSYS, PDA/Patran, and I-DEAS, can also serve as the source of modal information used for a flexible component.)

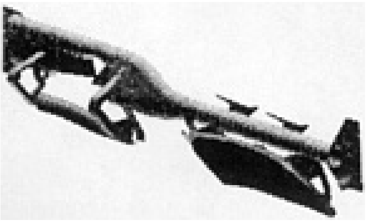

Fig. 10 Glove box and latch assembly

The glove box lid is represented by a combination of a rigid body motion that predicts how its center of gravity (CG) translates and rotates plus a superimposed small displacement motion based on a modal superposition of the modes imported from NASTRAN. This combined motion defines more precisely how the latch moves in space, how the snubbers are compressed, and so forth. This also more accurately predicts when and how much the latch separates from the striker.

This latter information on the intermittent contact can be correlated with noise heard from the latch and glove box. The validated model can now serve as the nominal basis in the search for design changes that will decrease the noise and rattle of a glove box of a passenger vehicle. This search involves iterative changes in the glove box shape, reinforcing ribs, material properties, and so forth, to tune the modes and modify the response. This tight loop from finite element software to multibody dynamic response solution (to test and correlation) can lead to a large improvement in the noise and rattle behavior without the heavy reliance on testing of numerous prototypes.

This example reinforces the point that one approach or technology is often not sufficient to support the engineering process quickly and accurately. In the above case the close link of structural and multibody dynamics to solve the problem is highlighted. While not noted above, it must be recognized that the latch geometry, the input geometry to the FE program, mass properties, and so forth, all came from a CAD system. A convenient means to extract that CAD data also was important to the timely and accurate solutions described.

James E. Crosheck, CADSI

Synthesis, Optimization, Design Guidance, Design Improvement, and Other Factors

Software is evolving into a more synthesis-oriented form, accounting for a broader range of the parameters in a complete design. Much of this is or will be based on the ability to extract design sensitivity (sensitivity of the design's performance, however that is measured, to design parameters) from a given nominal configuration. More and more, it is being recognized that analysis provides too little guidance to design. The results are typically a "go" or "no-go" result in any number of areas (stress, acceleration, force, response time, displacement, etc.). That information is valuable, but does not help pinpoint the design parameters that will improve products, or more important, direct changes. In lieu of this assistance from analysis, numerous trial-and-error attempts are usually made to determine which changes to make. More systematic procedures are occasionally used such as design of experiments (DOE) or Taguchi techniques (see the article "Robust Design" in this Volume and Ref 7) in conjunction with the simulation to guide the design. In the future, there will be sufficient intelligence built into software to provide significant assistance in the definition, as well as the "optimization" of a design.

This author contends that optimization of engineering designs is a misnomer. It is often the focus of papers, books, or lunchtime discussions/arguments. True optimization is seldom possible for real systems. Optimization of idealized, simplified systems is often performed and reported without acknowledging real-world limits such as schedules, manufacturing capabilities, or staff/financial resources. Seldom do the "optimizers" mention that the *design requirements*

are time dependent, driven by competitive and customer pressures. Quality improvement relative to current or competitive designs are more typical demands placed on the design process.

Some simulation or analysis software that claim to perform optimization are actually delivering limited parametric variations of a system. Those limitations are usually not understood. The typical approach performs a parameter sweep of one design parameter at a time. Peaks/valleys for each such sweep are then reported as a recommended next trial design. This technique is acceptable if there is no interaction between the design parameters, but that is seldom the case.

In this section a discussion of a blend of technologies is described that provides a robust solution procedure, is flexible, and is simple to apply. Multiple criteria can be used directly, and trade-off studies may be easily performed. These techniques are based on the statistical procedures of DOE and response surface models (RSMs) (Ref 8).

As a backdrop to this discussion, consider the use of statistical techniques for the creation of models of systems based on experimental tests. The system or process is considered as a "black box" for which a model is needed. The parameters that are thought to be important in describing the behavior of the system are selected and a range of these parameters defined for testing. A form for the model is then selected, usually a simple polynomial in the parameters used in the test. A test plan is created to vary these parameters for a series of tests, and output data are collected to characterize the response of the system. The parameter settings for the tests and the output data can then be used to define specific forms for the model of the response; these resulting models often are referred to as RSMs.

Chemical or manufacturing processes are complex entities that may be described in a narrow range of behavior based on collection of a set of parameters, but the exact mathematical relationship is difficult or impossible to define. In a similar fashion, a complex mechanical system, complete with a control system, can be defined (modeled) mathematically but impossible to comprehend in its entirety. It is attractive to restrict attention to a small subset of the input parameters and to approximate one or more output behaviors of the system as simple functions.

While application of the statistical techniques of DOE and RSM to simulations has been reported for at least two decades, it has only recently become an accepted procedure. The statistical focus has been upon the design of the testing procedure to ensure the maximum resolution of the model in the range of interest. This same "sampling" process can be used to create an accurate, yet simplified, model of the output in terms of the selected design parameters. Once such a model has been created, it may be used to determine how to improve the behavior by adjusting the design parameters. Because realistic designs have multiple-design criteria, multiple-response surfaces must be generated and all (or most) of them used in the design trade-off steps to follow. In principle, these surfaces can be used in an "optimization" scheme to determine the next design iteration. However, the designer usually has sufficient intuition about the design (and cannot explicitly define a mathematical relationship for some of the criteria that determine how good the design will be), thus direct involvement in the trade-off study is vital.

The term design sensitivity was mentioned earlier. What is it and how does it become involved? First, design sensitivity is a numerical measure of how important each parameter is relative to a particular output measure. If a sensitivity coefficient is positive for a given parameter, it implies that a positive increase in the parameter causes a positive change in the output criterion. Conversely, if the coefficient is negative, a positive change causes a decrease in the output. Larger coefficients are more important than small ones. Interaction effects can be identified and quantified relative to the direct effects.

It is not possible to cover the subject of RSM in depth in this article. However, it is important to know that the technique is providing a critical tool in the concurrent engineering suite. Within a single area, it provides a means to determine the importance of a given parameter relative to a specified output. It also provides a simple relationship that can be used to understand trends in design changes. It also provides an important link between technologies. Because several different simulation techniques can provide information regarding a particular performance criteria, all of the sensitivity coefficients that contribute to those effects can be collected together and used in a single trade-off study. A simplistic example might be the vibration felt at the driver's seat. This is influenced by the structural response (finite element analysis), by the suspension behavior (MBD simulation), by the powertrain vibration (MBD or control system simulation), by the seat response (MBD or other programs), by the air flow around the vehicle (computational fluid dynamics codes), and probably by other effects as well. Each of these codes could be separately exercised and the output used to determine the appropriate sensitivity coefficients with combined effects of design changes understood with simple techniques on a spreadsheet program or with more automated procedures.

These examples only sample the possible combinations, the state-of-the-art efforts, in the various fields that support the engineering sciences. However, these cases *do* provide a sense of the direction that must be followed to provide faster and more accurate predictions of system behavior.

Mechanism Dynamics and Simulation

James E. Crosheck, CADSI

Mechanism Dynamics/Simulation and Concurrent Engineering

The focus of this article is on the simulation of mechanical systems, but that cannot be treated as a separate technology. Data integration is becoming both a necessary and a pervasive part of modern engineering. The increasing interrelationship of a variety of technologies, foreshadows the future need for even more interplay of software applications. The integrated exchange of data for models must maintain data integrity, minimize modeling error, and, if successful, will promote concurrent engineering. Products will be of higher quality and be more innovative with the ability to do more "what-if" studies on the computer before committing to hardware.

As an overview of the emphasis on concurrent engineering, consider the current pressure both on decreasing time to market and on increasing quality and how this is reflected in the mechanical engineering process. "Normal" development (only a few years ago) involved preparation of one or multiple physical prototypes of the new product. These prototypes helped find the conflicts in dimensions, incorrect estimates of behavior, inadequate strength, and overall deficiencies in product response to market needs.

Simulation is heavily involved in the evolution of concurrent engineering. Modern CAD systems allow the capture and detailing of design concepts in a short time interval, particularly if the design is evolutionary. With the detailed information represented in CAD, many CAE processes can now be applied in concert to aid in ensuring both quality and speedy design review. This allows full utilization of the valuable modern CAD parametric modeling and visualization tools plus analysis capabilities to determine performance characteristics such as component interference and dynamic system properties.

For example, it is now commonplace to subject a mechanism to a performance review using a multibody dynamics program to predict a variety of information regarding the system. In addition to range of motion studies to determine component interference, important data are provided for loads on the parts of the mechanism. These loads can be used by a finite element program to predict stresses.

If these predicted stresses are too high, design changes are needed to bring the load/stress conditions within performance specifications. The changes in the mechanical system may come in a variety of ways: in its control system, in dimensions of the components of the system, in the manner in which external loads are applied to the parts, or in materials used in the parts. The changes and analyses are an iterative process until the design meets all necessary performance, manufacturing, and cost criteria.

As a result, some companies bypass the prototype stage and go directly to manufacturing, as Boeing did with its 777 airliner. With the amount of regulation in the aerospace field, this was only possible through the use of extensive computer simulations. In the automotive arena, single prototypes are now the norm with few surprises found at late stages in product development.

The above examples illustrate the continuing trend to use more simulation, to use more detailed simulation, and to do it on a shorter timeline. This has forced improvement of the export/import of data from one software package to another--or

even better, the integration of one software package into another. Many designers expected to see these data transfers performed in the past through standardized formats such as IGES or STEP or extensions thereof. Instead, most of the really significant progress has been made by individual companies that recognize the need and create a technique for the data exchange or the direct interaction of different software. Fortunately, such state-of-the-art direction and format has often evolved into pseudostandards. Ideally, all CAD vendors and those who derive data from their databases soon will provide convenient access to ISO (STEP) data models that can be directly exchanged.

The current status of mechanism simulation is focused primarily on analysis of a given design or process. There is pressure to use these techniques to provide direction to change designs or processes. Many software packages are now incorporating design sensitivity information calculations. Such directions as sensitivity of measures of quality as a function of design characteristics are being sought. Large companies are cascading sensitivity data from multiple analysis sources to provide a more general model of a product or process. If one simulation yields data used in another simulation, a chain rule procedure (see below) is possible to develop the desired complete model. These models can then be used as a means of "optimizing" the multiple criteria of concern. The chain rule is that used in calculus to determine a total derivative based on a sum of the partial derivatives of the quantity with respect to all its independent variables times the variation in each variable. To illustrate, suppose the designer wants the sensitivity of the peak force at a suspension connection point to changes in the thickness of several body panels. Obviously, the mass will change, but also the natural frequencies of the structure due to the panel thickness changes. The change in the natural frequencies due to the change in thickness can be calculated in standard procedures in programs such as NASTRAN. The total change in a given frequency can be estimated by summing the product of these structural design sensitivities and the respective design changes in the panel thicknesses. The flexible body data needed in a dynamic mechanism simulation are the natural frequencies, but these are now directly related to the panel thicknesses. Hence the thickness data and its sensitivity contributes to the dynamic system sensitivity. This cascading of data from one program to another allows more in-depth analysis of a system than is inherent in a single computer program.

In the future, more detailed simulations will be possible for mechanisms, stress analysis, fluid flow, queuing theory, resource allocation, and so forth, and will be done more reliably and faster due to more automated procedures to collect and distribute data. In addition, more sophisticated techniques will be developed to monitor results and guide design/process revisions, that is, to optimize them. Perhaps it would be just as good to think in terms of continuous product improvement or concurrent engineering or similar business strategies. In conclusion, simulation will become a pervasive activity in engineering, increasingly important for meeting schedules and product goals. Just as most companies have moved to CAD to capture design intent, most companies will use simulation in the future to ensure product quality and viability.

Mechanism analysis is only one portion of the CAD/CAE/CAM process, but is one that can have a significant influence on the final design. Individual tools such as CAD and simulation now allow significant improvement in accuracy and speed relative to their predecessors. Properly orchestrated, these tools can produce products that are closer to optimum with a shorter time-to-market and with reduced production costs. This will be accompanied by increased reliability and maintainability, if these tools are applied as hoped. If instead the tools remain isolated, then the the trends to concurrent engineering and the benefits thereof will not materialize. The extent to which the tools work in concert is only partially the result of efforts by the companies that create the tools. It is also a function of the users, the implementers of the tools, and their ability to change their organizations to take advantage of the new features and functions of the tools.

Finite Element Analysis

Donald L. Dewhirst, Ford Motor Company

Introduction

FINITE ELEMENT ANALYSIS is a computer-based numerical method for solving engineering problems in bodies of user-defined geometry. Interpolation functions are used to reduce the behavior at an infinite field of points to a finite number of points. The interconnectivity of these points is defined by finite elements that fill the appropriate geometry. The genius of the finite element method is that it enables the systematic solution of these field problems with as much fidelity to geometry as needed. The ability to model subtle changes in geometry permits the optimization of size, shape, or form to obtain minimum weight or maximum performance.

Table 1 summarizes the many engineering problems addressed by the finite element method. Because the method was originally developed for structural problems and because most engineers have at least an intuitive understanding of problems of force and displacement, finite elements are discussed here in terms of that class of problems. This permits the discussion to be concrete rather than abstract. The principles are the same regardless of discipline.

Table 1 Engineering problems addressed by the finite element method

Discipline	Typical unknown	Possible boundary conditions
Structural	Displacement	Stress or displacement
Thermal	Temperature	Heat flux or convective term or radiative term
Electrical	Voltage	Current source
Magnetic	Electromotive force	Magnetic field source or intensity
Fluid flow	Pressure, velocity	Velocity
Diffusion (Fickian)	Mass concentration	Flux of species
Diffusion (porous media)	Flow velocity	Boundary flow
Corrosion	Anode consumption rate	Electropotential

Crack propagation	Strain energy release rate	Stress
Acoustic noise	Sound pressure level	Velocity

Many good academic books have been written on the subject of finite elements (Ref 1, 2, 3, 4, 5). Reference 1 is particularly well indexed and treats issues of real concern to the practicing engineer. Reference 2 is unique in its thorough treatment of error estimation and adaptivity.

This article introduces the important issues of finite elements (especially accuracy and efficiency) in a nonacademic manner. It does not teach the reader to perform analysis.

Finite Element Analysis

Donald L. Dewhirst, Ford Motor Company

A Beam Paradox

An end-loaded aluminum cantilever beam that has a uniform rectangular cross section is analyzed. The designer proposes to add two cylindrical (circular) holes for reasons of access and weight reduction (Fig. 1). This problem could be approached as three-dimensional, but because nothing interesting is happening in the thickness direction, it can be simplified to that of plane stress in two dimensions. In this example, the *finite element mesh* is composed of two-dimensional elements, which are quadrilateral in shape (Fig. 2). There are 16 elements in each finite element model. These are explicitly labeled for the beam without holes; the labels are omitted from the beam with holes. The corners of the quadrilaterals, called *nodes* (sometimes *grids*), are defined by their spatial coordinates. The properties of the aluminum need to be specified. Assuming that the elastic strength of the material will not be exceeded, only Young's modulus, *E*, and Poisson's ratio, ν, are needed.

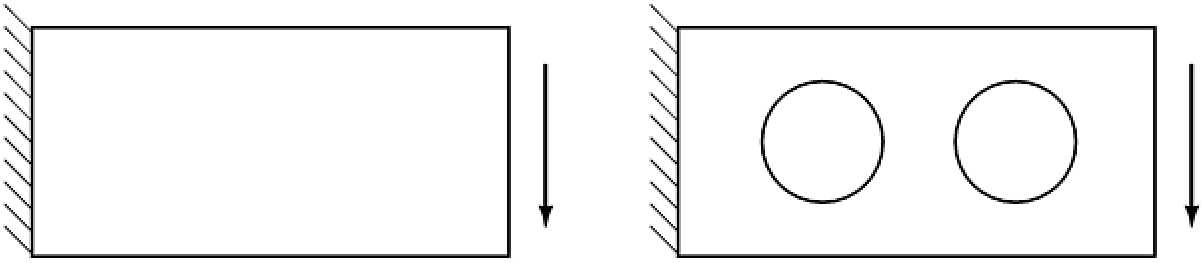

Fig. 1 Cantilever beam with and without access holes

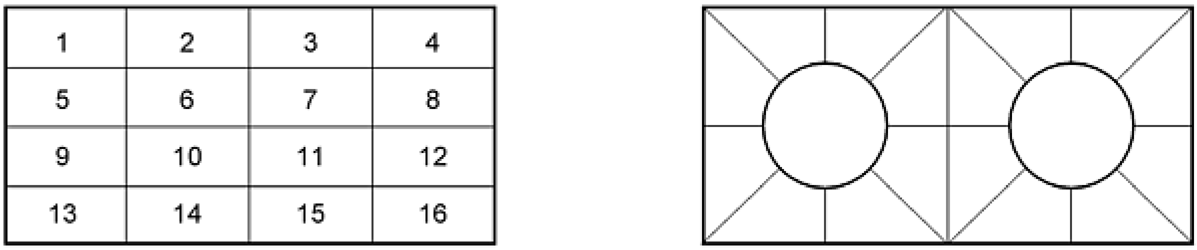

Fig. 2 Finite element meshes of beams of Fig. 1

Finally, the loads and displacement constraints at the boundaries need to be specified. This is usually the trickiest part of setting up a model. A boundary value problem, a problem of static equilibrium, exists. Something must be known about loads and displacements at the boundaries. Generally, the choice is whether to specify loads or displacements or some combination of the two. Care must be taken to prevent rigid-body modes; that is, the body must be anchored in space. A two-dimensional problem, includes three rigid-body modes; a three-dimensional problem includes six rigid-body modes. Figure 3 uses arrowheads to symbolize displacement constraints. In the present model, the entire left-hand boundary is fixed in the *x*-direction, and one node is fixed in the *y*-direction. This is sufficient to remove the rigid body modes and to develop a bending moment at the left end as a reaction to the applied downward shear force (Fig. 1) at the right-hand end. In addition to these displacement constraints, a load set is specified that includes a (parabolically distributed) downward shear load at the right-hand boundary and a similar upward shear load at the left end.

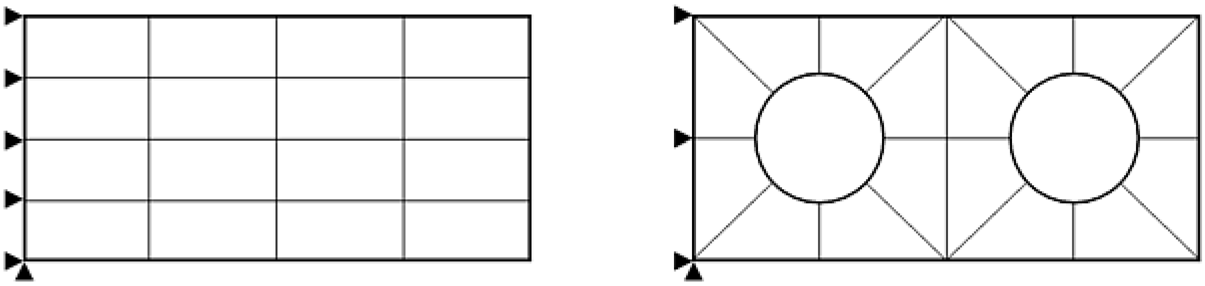

Fig. 3 Possible displacement boundary conditions

These two problems are solved using a commercial finite element code, and the peak displacements are obtained, as shown in Fig. 4 and 5. There is obviously something wrong with these results. They indicate that the beam *with* the holes is stiffer (has a lower displacement) than the beam *without* the holes. This violates common sense. What is happening? There are two likely answers to the question: not enough elements were used and/or the elements were too distorted to give the appropriate answers. This illustrates one of the fundamental problems facing the finite element analyst: how to design a finite element mesh that is fine enough to give good answers, but coarse enough to be cost effective, bearing in mind that element shape profoundly affects the results. Figure 6 illustrates the typical shape distortions of a quadrilateral element, namely *aspect ratio, skew,* and *taper.* (In three dimensions, one would add the possibility of element *warp.*)

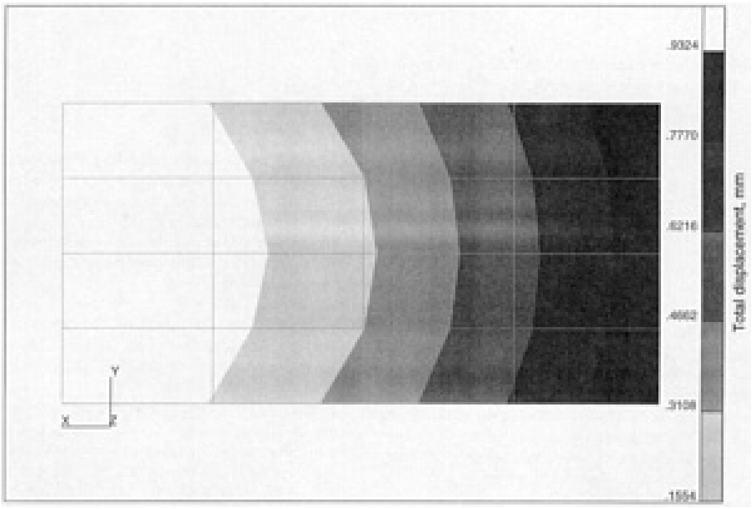

Fig. 4 Displacement contours for a cantilever beam under bending load, peak displacement 0.9324 mm

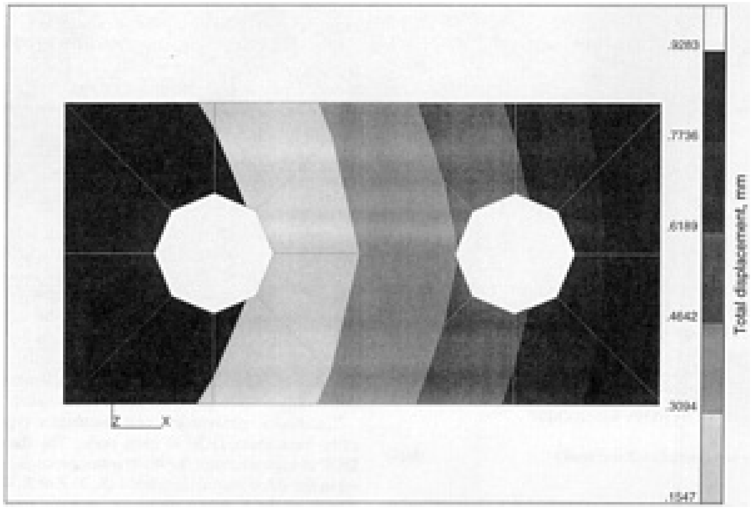

Fig. 5 Displacement contours for a cantilever beam under bending load, peak displacement 0.9283 mm

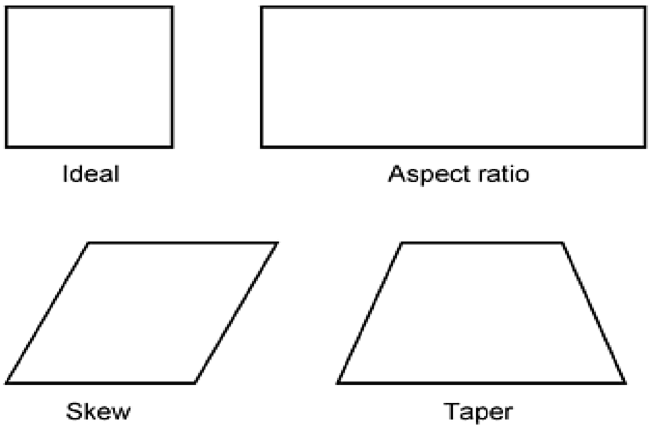

Fig. 6 Types of quadrilateral element distortion

Because this finite element problem is the first one to be approached, the effect of changing the mesh is considered. Three successively finer meshes for the beam with holes are analyzed, and some trends are plotted. The top curve of Fig. 7 shows the peak principal stress in the beam for each of four mesh densities. The principal stress is plotted as a function of the reciprocal of the number of degrees of freedom (DOF). (DOF is the product of the number of nodes multiplied by the number of unknowns per node; the reciprocal of DOF is used for convenience.) As the number of DOF increases, the reciprocal tends to zero. It is generally true that coarse meshes tend to underestimate the stress. Unfortunately, however, a *lower bound answer* is not necessarily guaranteed (Ref 1). Convergence to the appropriate solution by systematically increasing the mesh density is known as *h-convergence,* where the letter "h" is associated with element size. (The present meshes are uniform in size. It is possible to improve on these meshes by using a nonuniform mesh density. The improved mesh would be finer in regions where stress gradients are highest or where strain energy density is greatest.)

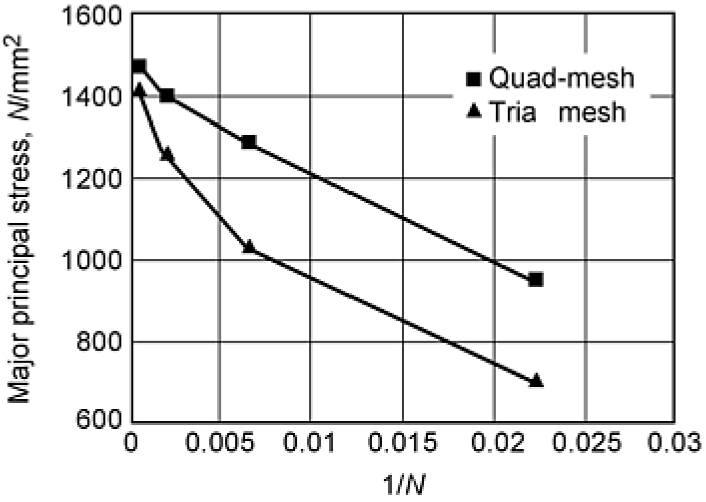

Fig. 7 Peak stress vs. reciprocal number degrees of freedom, quadrilateral and triangular elements

The four-noded quadrilateral is just one of several two-dimensional elements that could have been chosen for this problem. Nodal patterns identical to the mesh of Fig. 2 are used, but the beam is modeled with three-noded triangular elements. See the lower curve of Fig. 7. Both elements converge to the right answer, but the quadrilateral element gives better answers for the same number of nodes. Therefore, the quadrilateral element is more efficient for this class of problem than the triangular element.

Finite Element Analysis

Donald L. Dewhirst, Ford Motor Company

The Basis of Finite Elements

To understand why some elements outperform other elements in certain problems, it is appropriate to review the *Rayleigh-Ritz* (Ref 1, 6, 7) procedure on which the finite element method can be based. There are more general and mathematically sophisticated ways to approach finite element theory, but they are less intuitive and less instructive for the present purpose.

The Rayleigh-Ritz procedure is an approximate method for solving structural problems based on the *principle of virtual work.* The principle of virtual work states that the total potential energy of an elastic system is a minimum (or stationary) when the system is in equilibrium. (The total potential energy of the system is the sum of the gravitational potential energy and the elastic strain energy.) The Rayleigh-Ritz method reduces a continuum with infinitely many DOF to a system with finite DOF. It accomplishes this by assuming the displacements of the continuum to be a function of a finite number of undetermined coefficients. The solution for these undetermined coefficients is illustrated below.

The Reduction of an *Infinite* DOF System to a *Finite* DOF System. A continuous system with infinitely many DOF may be approximated by a system with finite DOF. This can be accomplished by assuming a shape function with one or more undetermined coefficients whose values are to be determined.

For example, the simply supported beam of Fig. 8, which is loaded by a central concentrated load, P, is considered. A sinusoidal shape function is assumed, such that:

$$y = A \sin(\pi x/L) \quad 0<x<L \qquad \textbf{(Eq 1)}$$

Here, A is the undetermined coefficient and y is the displaced position of the beam centerline. When $x = 0$ and $x = L$, then $y = 0$. It should also be noted that:

$$d^2y/dx^2 = -A(\pi/L)^2\sin(\pi x/L)$$

This second derivative, which is proportional to beam curvature and therefore to moment, also vanishes at $x = 0$ and at $x = L$. Therefore, both the deflections and moments are zero at the ends of the beam. These are the appropriate boundary conditions.

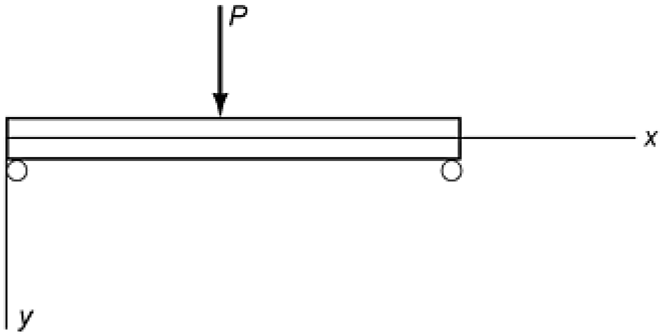

Fig. 8 Simply supported beam with central concentrated load, *P*

The Rayleigh-Ritz procedure can be used to determine the value of the coefficient A. The method consists of finding an expression for the total potential energy of the system in terms of A, differentiating that expression with respect to A, and equating the results to zero. That is, one finds the deformed geometry that provides the minimum value of the total potential energy. In symbols, this is: V = elastic strain energy + gravitational potential energy, or:

$$V = U + \Omega \qquad \textbf{(Eq 2)}$$

where:

$$U = \left(\frac{1}{2}\right)\int EI(d^2y/dx^2)^2dx \qquad \textbf{(Eq 3)}$$

E is Young's modulus (material stiffness), I is section modulus (geometric stiffness), and:

$$\Omega = P(-A) \quad \textbf{(Eq 4)}$$

For minimum potential energy:

$$dV/dA = 0 \quad \textbf{(Eq 5)}$$

so that:

$$dV/dA = d/dA[(\pi^4 EIA^2/4L^3) - PA] = 0 \quad \textbf{(Eq 6)}$$

and therefore:

$$A = (2PL^3)/(\pi^4 EI) \quad \textbf{(Eq 7)}$$

and:

$$y = (2PL^3)/(\pi^4 EI)\sin(\pi x/L) \quad \textbf{(Eq 8)}$$

A comparison of this solution with the known analytical solution shows that the deflections differ by 3% or less. However, the peak stress differs from the accepted solution by 19%.

A better approximation to this beam bending problem should result from adding another degree of freedom, for example:

$$y = A\sin(\pi x/L) + B\sin(3\pi x/L) \quad \textbf{(Eq 9)}$$

Following the same procedure as before and using $\partial V/\partial A = 0$ and $\partial V/\partial B = 0$, then:

$$A = (2PL^3)/(\pi^4 EI) \quad \textbf{(Eq 10)}$$

and:

$$B = (2PL^3)/(27\pi^4 EI) \quad \textbf{(Eq 11)}$$

Comparing this new solution to the analytical solution, deflections are everywhere within a ±1% band of the analytical solution, and peak stress differs from the accepted solution by 8%.

The finite element method can be thought of as an extension to the Rayleigh-Ritz method. There are two major differences:

- In the Rayleigh-Ritz method, the structure is treated in its entirety, as one "element." In the finite element method, multiple elements and nodes are used.
- In conventional finite elements, the values of the nodal displacements and rotations *are* the variables; they *are* the undetermined coefficients. This is advantageous, because it is intuitive to understand and more convenient to specify displacements and rotational constraints at boundaries than to deal with, say, amplitudes of sine waves.

In summary, the finite element method may be thought of as follows. The geometric continuum is divided into a number of elements (e.g., triangles, quadrilaterals, tetrahedra, etc.). The internal displacements of these elements are expressed in terms of the displacements at the nodes of the elements by means of interpolation functions, similar to the sinusoidal

approximation (usually, the interpolation functions are polynomials) illustrated in the beam problem. An energy expression is formed and minimized in order to obtain a set of algebraic equations. The solution of these algebraic equations provides the displacements at the nodes. The values of the displacements at each node are analogs to the coefficient *A* in the example above. Knowing the displacements at each node implicitly gives the displacements and stresses throughout the continuum. As a generalization, the displacements obtained by this method are typically more accurate than the stresses.

Continuum Elements

This section and the one that follows define and contrast two different types of elements: *continuum* and *structural.* A continuum element is one whose geometry is completely defined by its nodal coordinates. Hexahedra, pentahedra, and tetrahedra are the continuum elements commonly used in a three-dimensional domain. Quadrilaterals and triangles are the continuum elements commonly used in a two-dimensional domain.

Tetrahedra, pentahedra, and hexahedra typically have three DOF at each node. The three DOF at each node are the three translations (u, v, w) in the three spatial directions (X, Y, Z or R, Θ, Z or R, Θ, Φ). Figure 9 shows the assumed interpolation function that might be employed for each of these fundamental elements. Only the u displacement function is shown; the others have analogous form.

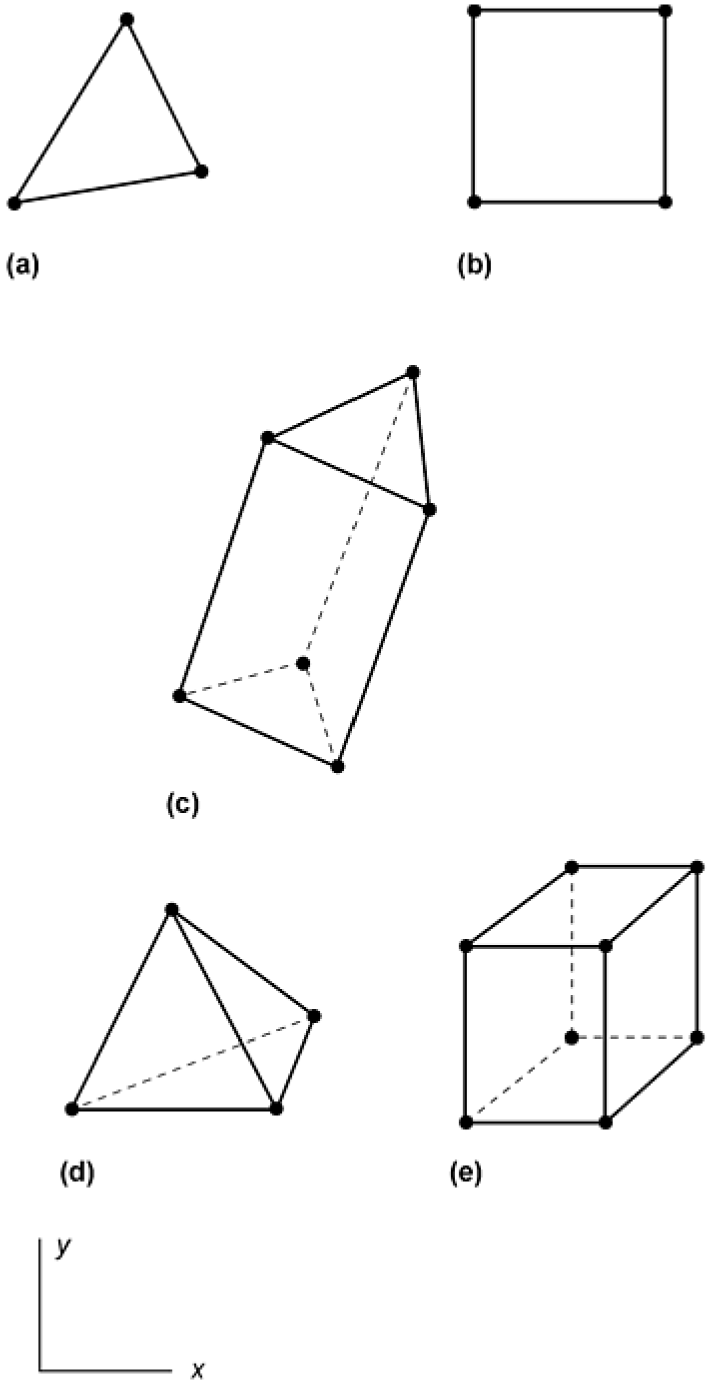

Fig. 9 Continuum elements (lower-order elements). (a) $u = a_o + a_1x + a_2y$; $\partial u/\partial x = a_1$; $\sigma = E\varepsilon_x = E\partial u/\partial x = Ea_1$ **= constant. (b)** $u = a_o + a_1x + a_2y + a_3xy$; $\partial x/\partial x = a_1 + a_3y$; $\sigma = E\varepsilon_x = E(a_1 + a_3y)$ **= linear. (c)** u **= directionally dependent. (d)** $u = a_o + a_1x + a_2y$. **(e)** $u = a_o + a_1x + a_2y + a_3xy$

Triangles and quadrilaterals typically have two DOF at each node, the in-plane displacements. Triangles and quadrilaterals can also be structural elements, for example when the bending (rotational) DOF are added. Structural elements are discussed below.

Figure 10 shows the possibility of enhancing continuum elements by adding interior nodes. (A node could also exist at the centroid, or multiple nodes could exist along edges.) The extra nodes supply more independent variables so that the displacement functions can contain more terms. The elements without interior nodes are sometimes called *lower-order elements,* and the ones with interior nodes are sometimes called *higher-order elements.* Most commercial codes permit the selective omission of the interior nodes. This permits joining of lower-order elements to higher-order elements. If

interior nodes *are* used, curved edges and faces are possible. When the same interpolation functions are used for both the geometry and the displacements, the elements are known as *isoparametric.*

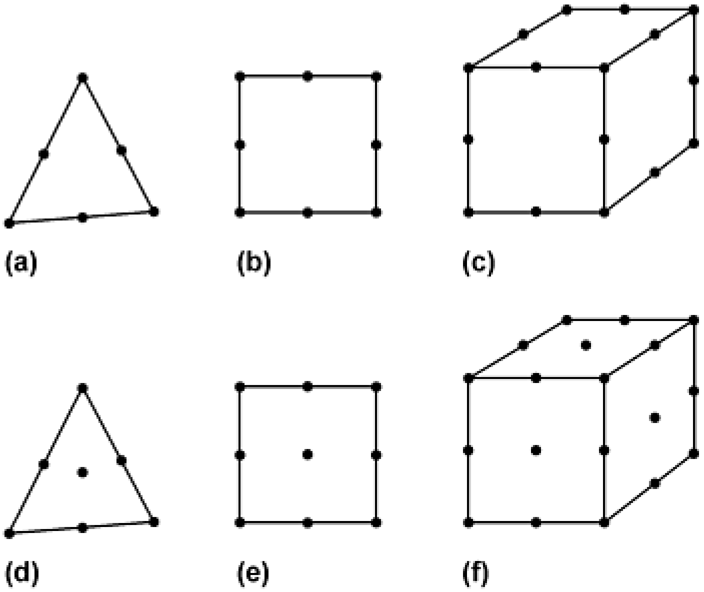

Fig. 10 Continuum elements (higher-order elements). (a) to (c) Sometimes called serendipity elements. (d) to (f) Sometimes called Lagrange elements

The optimum choice of element is code dependent and problem dependent. A generalization that is sometimes made is to use the higher-order elements for "smooth" problems, those relatively free of geometric and load discontinuities. Conversely, the lower-order element is used where there are abrupt changes in geometry, material, or loading.

Donald L. Dewhirst, Ford Motor Company

Structural Elements

In addition to the continuum elements depicted in Fig. 9 and 10, there are a number of elements that behave in accordance with certain structural assumptions that predate finite element technology. As long as these structural assumptions are valid, they provide for maximum solution efficiency (Fig. 11).

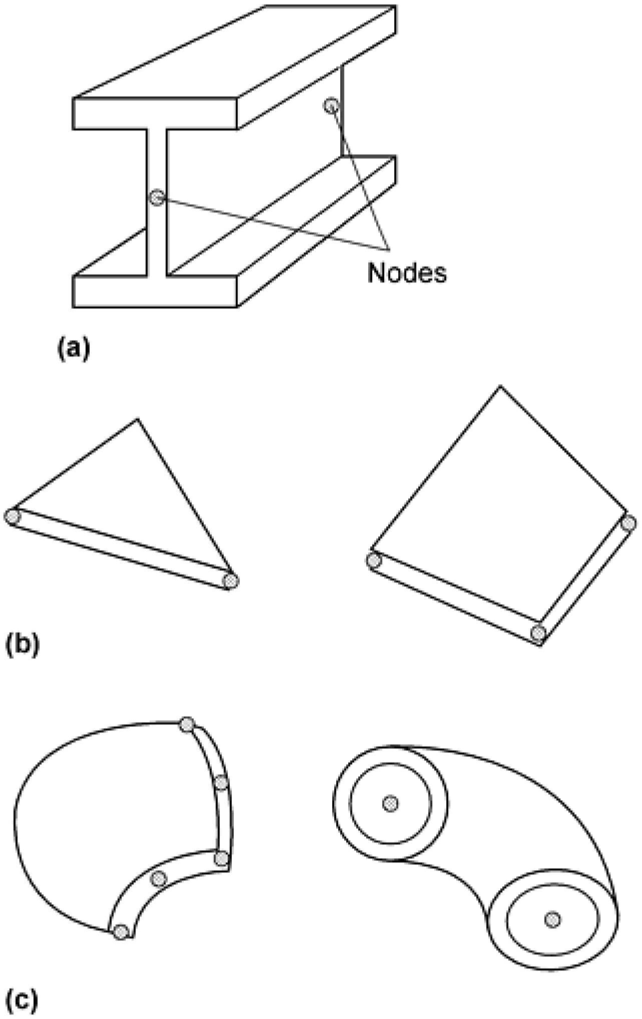

Fig. 11 Structural elements. (a) Beam element. A beam requires two or more nodes, two bending stiffnesses, torsional stiffness, orientation about the line connecting the nodes, material properties, and six degrees of freedom per node. (b) Plate elements. (c) Shell element. (d) Elbow element

Beam elements are typically based on the so-called *Euler-Bernoulli assumptions.* These assumptions are that plane sections of the beam remain plane under deformation and that bending stress is therefore directly proportional to the distance from the bending axis. The through-thickness normal stress is assumed to be zero. Shear deformations are not considered in the Euler-Bernoulli beam. The so-called *Timoshenko beam* adds shear deformation capability and possibly rotary inertia. The shear deformation is assumed to be constant throughout the beam depth, not parabolic. The Timoshenko assumptions tend to "soften" the response of the beam (i.e., displacements are higher and natural frequencies are lower than for the corresponding Euler-Bernoulli beam).

Plate elements are often based on the *Kirchoff assumption* that, after deformation, normals to the midsurface of the element remain normal to that surface. The Kirchoff assumption for plates is analogous to the Euler-Bernoulli assumptions for beams. More sophisticated assumptions are made for the *Mindlin plate element,* which is analogous to the Timoshenko beam. *Shells,* by definition, are curved surfaces. Finite element representation of shells may be as flat facets or as curved elements. In either case, the finite elements representing shells must carry membrane as well as bending loads. The use of elements based on these various structural assumptions generally results in a very efficient model, especially for vibration and buckling problems. Accuracy of stresses may suffer at edges or discontinuities in the structure. This could be an important consideration for composite materials, subject to delamination from local though-thickness tensile stresses at the edges.

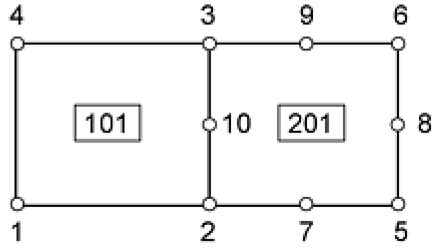
Donald L. Dewhirst, Ford Motor Company

Multipoint Constraints

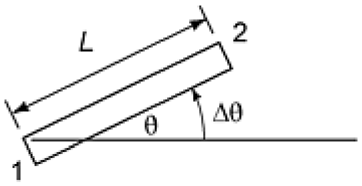
In a variety of situations, it is desirable to use multipoint constraints (MPC), that is, to constrain the displacement of a node to that of another node or to a function of the displacements of other nodes. These situations include:

- Joining incompatible elements
- Simulating a rigid body
- Joining structural elements to continuum elements
- Distributing a load in a convenient fashion
- Joining dissimilar materials
- Transition of mesh density

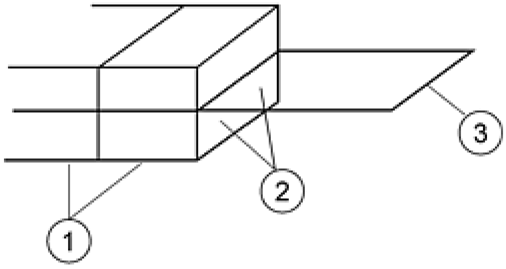
Examples of the first three are shown in Fig. 12. Some comments on these situations are made below.



(a)



(b)



(c)

Fig. 12 Multipoint constraints. (a) Joining incompatible elements. If *u* and *v* denote displacements in the *x* and *y* directions, respectively, and subscripts refer to the nodes, then $u_{10} = (u_2 + u_3)/2$ and $v_{10} = (v_2 + v_3)/2$. This assumes that node 10 is halfway between nodes 2 and 3. (b) Simulating a rigid body. For a rigid body motion $\Delta\theta$, $u_2 = u_1\ L \sin\theta\ \Delta\theta$ and $v_2 = v_1 + L \cos\theta\Delta\theta$. The motion of node 2 is constrained to that of point 1. (c)

Joining structural elements to continuum elements. (1) Solid continuum elements with three translational degrees of freedom per node only. (2) These nodes are slaved to nodes immediately above and below them in order to prevent simulation of the mechanism (hinge). (3) Plate element with bending stiffness (three translational degrees of freedom, two rotational degrees of freedom)

Joining Incompatible Elements. The eight-noded quadrilateral, 201, is joined to the four-noded quadrilateral, 101, by constraining the mid-side node of 201, node 10, to displace the average of the two corner nodes. In that way, no gap or interpenetration of the two elements can occur along their common edge. The MPC is an effective way to join these two different element types.

Simulating a Rigid Body. Figure 12 shows the simplest form of a rigid body in two dimensions. The node labeled "2" is constrained to the displacements of the node labeled "1."

Joining Structural Elements to Continuum Elements. Shell elements typically have five DOF per node, three translations, and two bending rotations. Three-dimensional continuum elements (i.e., solids) have only the three translational DOF. Joining these two element types will produce a hinge at their interface unless care is taken. Commonly, the hinge is prevented by constraining the interface nodes to immediately adjacent nodes. Reference 8 contains a thorough discussion of this problem.

Finite Element Analysis

Donald L. Dewhirst, Ford Motor Company

Linear versus Nonlinear Problems

A majority of the finite element problems solved by engineers use linearizing assumptions. Deflections are assumed to be small, and materials are assumed to be linear elastic. Under these assumptions, solution times are quite predictable. There exists a wide range of problems that are *nonlinear;* that is, the stress and deflection are not directly proportional to the load. These problems usually require iterative solution techniques and additional computer resources (e.g., disk space and solution time).

Problems of large deflection are one class of nonlinear problems. Problems of flat plates, for example, are usually assumed to be linear if the lateral deflection does not exceed the thickness of the plate. After that point, the plate stiffens due to membrane effects. Another type of large deflection problem occurs when the direction of the load follows the deformation of the structure. Still other types occur when a gap is closed or opened, or one component of an assembly strikes another.

Problems of inelastic material behavior are another class of nonlinear problems. Problems of creep, relaxation, hysteresis, phase change, and residual stress fall into this category. Fortunately, most nonlinear material models used in finite element solutions carry over from disciplines that predate finite element technology (e.g., theory of plasticity). However, for problems involving a high rate of deformation (e.g., the forming of metal or the crash of a vehicle), special finite element software based on so-called *explicit integration* techniques is available (Ref 3).

Finally, it is worth mentioning that finite element codes are available that deal with multiple disciplines simultaneously (see Example 3 below).

Finite Element Analysis

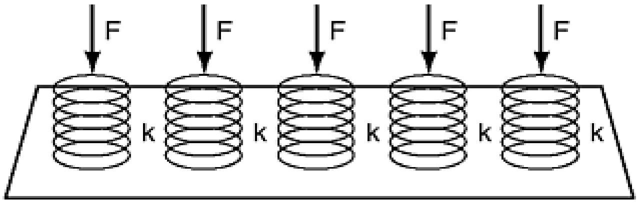
Donald L. Dewhirst, Ford Motor Company

Solution of the System of Algebraic Equations

For static structural problems, the finite element method results in a system of equations that can be expressed in matrix form as:

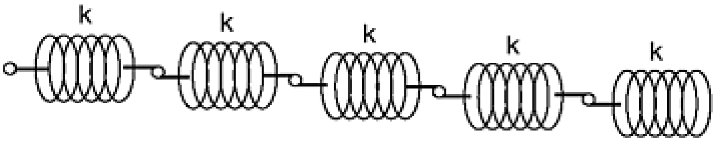
$$\{F\} = [K]\{u\} \qquad \text{(Eq 12)}$$

where **{F}** is a column vector of forces, **{u}** is a column vector of displacements, and **[K]** is a square matrix. There will be multiple **{F}** and **{u}** vectors for problems with multiple load cases. The size of the **[K]** matrix is the product of the number of nodes and the number of DOF per node. If all DOF of the problem acted completely independently of each other (e.g., a number of axial springs each separately attached to ground, but not to each other), then the stiffness matrix would be purely *diagonal.* All of the terms off the diagonal would be zero (Fig. 13).



All springs are uncoupled, leading to a diagonal matrix; for unit stiffnesses:

$$[K] = \begin{vmatrix} k & 0 & 0 & 0 & 0 \\ 0 & k & 0 & 0 & 0 \\ 0 & 0 & k & 0 & 0 \\ 0 & 0 & 0 & k & 0 \\ 0 & 0 & 0 & 0 & k \end{vmatrix} = \begin{vmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{vmatrix}$$



All springs are in series, leading to a banded stiffness matrix; for unit stiffnesses:

$$[K] = \begin{vmatrix} 1 & -1 & 0 & 0 & 0 \\ -1 & 2 & -1 & 0 & 0 \\ 0 & -1 & 2 & -1 & 0 \\ 0 & 0 & -1 & 2 & -1 \\ 0 & 0 & 0 & -1 & 1 \end{vmatrix}$$

Fig. 13 Form of stiffness matrix

Most structural problems have stiffness terms clustered, or *banded,* around the diagonal. This bandedness may be influenced by either the node numbering strategy or the element numbering strategy. Various solution strategies (solvers) are available in commercial codes, and they exploit (or ignore) bandedness in different ways. Some commercial codes offer only one solver; others may offer a half dozen or more. Be aware that some solvers are sensitive to the node numbering strategy (e.g., sparse solver, skyline solver), while some solvers are sensitive to the element numbering strategy (wavefront, multifront). Iterative solvers, on the other hand, are insensitive to node and element numbering, and are indeed insensitive to bandedness. For this reason, the iterative solvers are excellent for large, chunky continuum problems, the kind of problems with large bandwidth. Iterative solvers are usually well suited to parallel computers (multiple central processing units), whether the computers share memory or not. Iterative solvers, however, are not as efficient for problems with multiple load cases, because each load case requires a repetition of the iteration strategy.

Dynamic structural problems add mass and damping terms to the system of equations:

$$\{F\} = [K]\{u\} + [C]\{du/dt\} + [M]\{d^2u/dt^2\} \qquad \textbf{(Eq 13)}$$

where **{du/dt}** and $\{d^2u/dt^2\}$ are column vectors of velocities and accelerations, respectively. The viscous damping matrix **[C]** is usually assumed to be proportional to either the **[K]** matrix or the mass matrix, **[M]**, for computational efficiency. The **[C]** and **[M]** matrices are generally banded. Special techniques of lumping masses at nodes are often used to make the **[M]** matrix diagonal for computational efficiency. Dynamic problems can be solved in the time domain, using time-stepping procedures starting from known initial conditions. Because an additional solution is required for each time increment, this analysis is expensive. Dynamic problems, such as the determination of natural frequencies, can be solved in the frequency domain as opposed to the time domain. This is accomplished by assuming that the displacement vector is a harmonic function, i.e.,

$$\{u\} = \{\phi\}e^{i\omega t} = \{\phi\}(\cos \omega t + i \sin \omega t) \qquad \textbf{(Eq 14)}$$

where $i = \sqrt{-1}$, t time, $\{\phi\}$ is the modal vector (vector of unknown amplitude at the nodes), and ω is the natural frequency associated with the mode shape. This assumption creates an *eigenvalue* problem (Ref 5).

Symmetry

Symmetry arises when a geometric element is translated, rotated, mirrored, or swept. At least four major types of symmetry arise in finite element problems: bilateral symmetry, rotational symmetry, axisymmetry, and translational symmetry. The exploitation of symmetry can greatly reduce the computer resources required to solve a problem, and can sometimes move problem solution from infeasibility to feasibility.

Bilateral symmetry is synonymous with reflective or mirror symmetry. This is perhaps the simplest, most intuitive type of symmetry. It does carry with it the idea of *handedness,* i.e., right hand versus left hand. If the fundamental region being reflected is itself symmetric, then right hand versus left hand need not be considered. Figure 14 illustrates some examples of bilateral symmetry. Many biological forms have bilateral symmetry, at least in the structural sense. Perhaps none of the objects depicted in Fig. 14 is *perfectly* symmetric. If the small asymmetry is structurally significant, it is sometimes adequate to model the weaker half of the object. An example might be a connecting rod with a small oil-feed hole on one side.

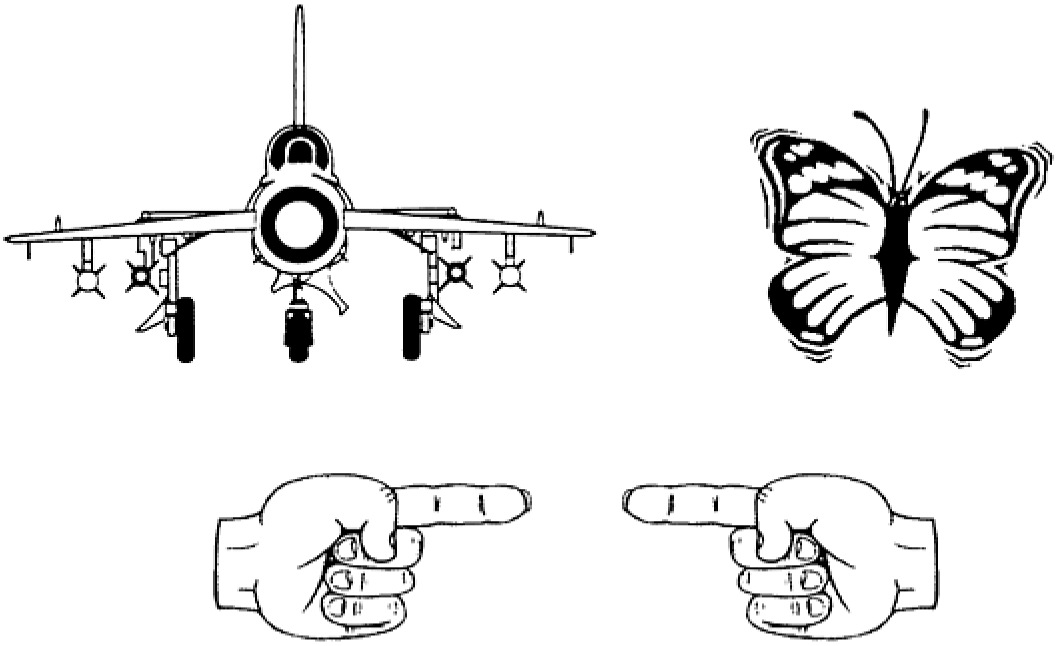

Fig. 14 Objects with bilateral symmetry

Rotational symmetry exists when a fundamental part of the structure spans 360°/n where n is an integer. Figure 15 shows objects that are rotationally symmetric: a stool, a marine propeller, and a fan blade. *Dihedral symmetry* is a special case of rotational symmetry. It occurs when the fundamental region to be rotated is itself bilaterally symmetric. Note that the stool in Fig. 15 has dihedral symmetry (three fundamental regions, each of which has bilateral symmetry), while the other two objects do not. *Axisymmetry* is another special case of rotational symmetry. Every cross section through the axis of rotation of an axisymmetric object is identical. Axisymmetry can reduce a three-dimensional problem to a two-dimensional one.

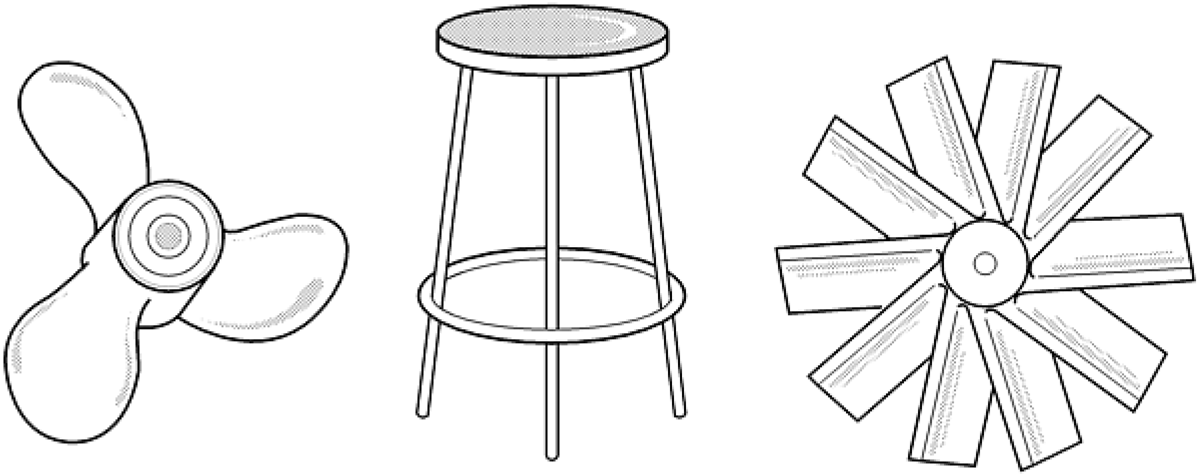

Fig. 15 Objects with rotational symmetry

Translational symmetry occurs when a fundamental unit is translated one or more times. A prismatic structure is a special case of translational symmetry. Often structures comprise a fundamental element that is both translated and rotated, as shown in Fig. 16. Superelement techniques are sometimes useful for such structures.

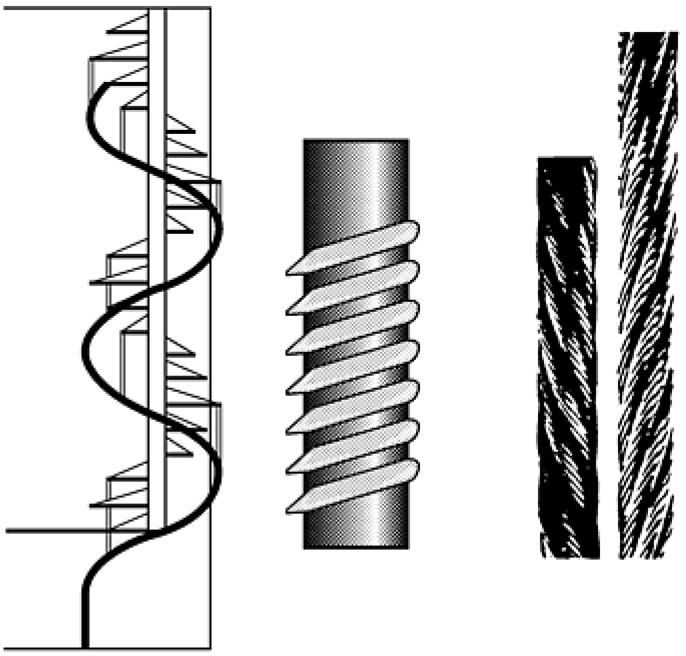

Fig. 16 Objects with translational symmetry combined with rotational symmetry

Discussion so far has been on symmetry in the context of geometry only. When both the geometry and the loads (including the boundary reactions) are symmetric, it is simple to reduce the problem to that of the fundamental region. Consider the example of a bilaterally symmetric beam with symmetric supports and symmetric loads, as shown in Fig. 17. The behavior of the entire structure can be captured by analyzing one-half of the beam. The midpoint load must be divided by two. The boundary conditions on the cut plane are labeled SYMM. This denotes a specific set of boundary conditions. If one imagines a mirror placed at the cut section in such a way as to appropriately reflect the beam half, then the beam cross section should neither rotate away from the mirror nor interpenetrate the mirror surface as the load is applied. This restriction gives rise to two boundary conditions in a two-dimensional problem, and to three boundary conditions in a three-dimensional problem.

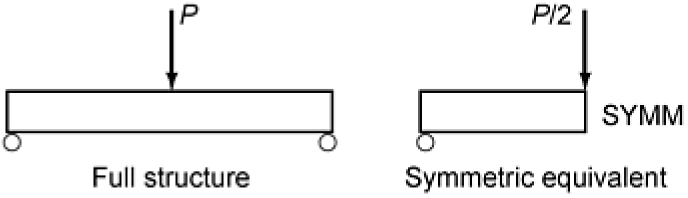

Fig. 17 Symmetric loads. The abbreviation "SYMM" denotes that $u_x = 0$ everywhere on the cross section for continuum elements (e.g., hexagonal and tetragonal elements), or that $u_x = R_y = R_z = 0$ for line elements (e.g., beams).

Antisymmetry refers to symmetry accompanied by a change in some property. For example, a photographic print is antisymmetrical to its negative. In the context of finite element analysis, antisymmetry pertains to a problem whose geometry, loads, and displacement boundary conditions exhibit symmetry, but the sense of whose loads are reversed. In Fig. 18, note that the sense of the forces created by the displacement boundary constraints is also reversed, but because the boundary restraints are bidirectional, it is easier to think of the boundary conditions as symmetric. Note that the boundary conditions at the cut plane are labeled ANTISYMM (antisymmetrical). These boundary conditions are the complement of the SYMM set.

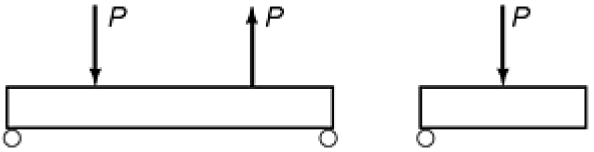

Fig. 18 Antisymmetric loads. The abbreviation "ANTISYMM" denotes boundary conditions that are the complement of the SYMM set, e.g., $u_y = u_z = 0$ everywhere on the cross section for continuum elements.

For linear elastic structures, it is valid to superpose or add the results of multiple solutions. This permits decomposing of loads that do not have symmetry into their symmetric and antisymmetric components and superposing these component loads. This allows modeling a structure with geometrical symmetry as a reduced model, even when the loads are not symmetric (Fig. 19).

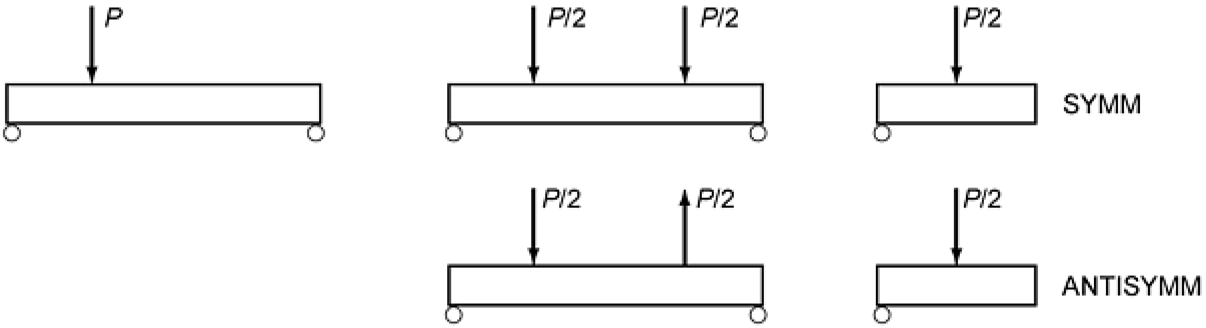

Fig. 19 Superposition of symmetric and antisymmetric loads. The abbreviations "SYMM" and "ANTISYMM" are as defined in Fig. 17 and 18.

Donald L. Dewhirst, Ford Motor Company

Superelements (Substructures)

Several standard techniques exist that improve computational efficiency in special situations. The use of the various forms of symmetry has already been discussed. Another of these techniques is variously known as superelement or substructuring technology. The superelements are individually modeled, and the behavior of their interior nodes is determined as a function of the behavior of their external nodes. The assembly of superelements is then analyzed in a separate run. The original motivation for this technique was to permit the solution of problems too large to be accomplished in a single pass. That is, it was an attempt to get around computer resource limitations. With the startling advances in hardware technology, that motivation has largely disappeared.However there are several situations where superelement technology provides important advantages. These are:

- Iterative redesign of a structure will affect only one or a few of the superelements.
- Analysis of assemblies will be done by analysts in disparate locations, perhaps by individual groups on subassemblies (substructures) with results later integrated into the whole.
- Nonlinear analysis is needed in which one or more superelements retain linear behavior.
- Identical units occur repetitively within the structure.

- Mesh redesign is needed in a critical local region for more accurate results.

There are some potential pitfalls with the technology. Two examples are:

- The bandwidth (or wavefront) may be adversely affected by the substructuring process.
- The mass distribution may be adversely affected for dynamic problems, although no loss of accuracy is experienced for static problems. A technique called *component mode synthesis* attempts to compensate for the altered mass distribution (Ref 1).

Finite Element Analysis

Donald L. Dewhirst, Ford Motor Company

Finite Element Preprocessing

Figure 20 shows the finite element analysis process. *Finite element preprocessing* comprises geometry definition and manipulation, specification of material properties, generation of the finite element mesh, and definition of generalized loads and displacements both at the boundary and distributed through the body (inertia and gravitational loads). Note that material properties may be specified as constant or variable. When variable, they are often input as tables of properties or as mathematical functions, such as exponentials. Finite element preprocessing may consume as much as 80% of the calendar time in the finite element process.

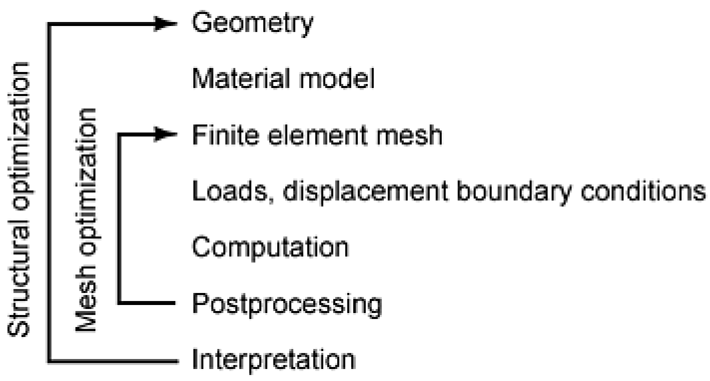

Fig. 20 Typical finite element process

When mesh is obtained by acting upon a definition of geometry, it is sometimes referred to as *top-down.* When the mesh itself is the only definition of the geometry, it may be referred to as *bottom-up.* Top-down meshing is accomplished by one of two methods: *mapped meshing* or *free meshing.* A mapped mesh requires that the geometry be subdivided into canonical shapes, such as quadrilaterals in two dimensions and cuboids in three dimensions. A mesh is then mapped into these regions. This process generally provides for more user control than free meshing, but it is quite time consuming. Free meshing, by contrast, relies on one of several algorithms to fill any arbitrary geometry with elements. In two dimensions, these elements are usually triangles or quadrilaterals. In three dimensions, robust algorithms exist to fill an arbitrary space with tetrahedra. However, robust algorithms to fill an arbitrary space with *hexahedra* are lacking. One of

the contemporary issues in finite elements is the relative performance of these two element types. Because the shape functions of these elements are analogous to those of the triangle and quadrilateral in two dimensions, Fig. 7 implies the superior performance of the low-order hexahedron over the low-order tetrahedron. In practice, high-order tetrahedra are often used to increase accuracy at the expense of increased computational time.

Most finite element preprocessors offer constructs for defining geometry, but it is also desirable that geometry can be imported or exported from/to other software systems. National and international standards organizations have attempted to standardize geometry descriptions toward these ends. Geometry is sometimes described as *clean* or *dirty,* and tools to transform the latter into the former are often needed. Extraneous points or edges must be eliminated. Surfaces or edges smaller than those of the desired finite element size must be blended or eliminated without corrupting the model. Sometimes small features such as fillets and bosses are unimportant for preliminary analyses, but become important as the design matures. For this reason, *feature suppression* is a desirable option.

Another issue to be considered is the number of analysis codes supported. Large organizations often deal with several commercial codes, and the needs of any organization will change with time. Preprocessors are always incomplete with regard to the number of features supported. For example, can seldom-used elements or routines be supported? Can the applied tractions be varied parabolically, sinusoidally, and so on? Can rotation be simulated? Can loads be scaled and superposed?Are contact capabilities supported? Are multiple coordinate systems conveniently supported? Are multipoint constraints supported? What about failure theories? Are composite materials modeled?

It is preferable to define loads and boundary conditions relative to the geometry rather than to the finite element mesh. This permits remeshing of the geometry without the need to redefine loads and boundary conditions. It is also desirable to specify hard points, lines, or surfaces where parts will interact with other parts, so that the interaction (e.g., spot welding, adhesive bonding, etc.) can be properly represented. Those who must create a shell mesh from a solid geometry need a capability called *midsurface extraction* in order to optimally specify the defining surface for plate/shell representation.

Still another function of a preprocessor is the ability to group and categorize various items into convenient sets. Items may be organized geographically (spatially), by material, by a property such as thickness or moment of inertia, by contact pairing, by convection coefficient, or by various other attributes.

Finite element model validation is another capability expected of the finite element preprocessor. Elements need to be investigated for geometric distortion. The traditional criteria (Fig. 6) are aspect ratio, taper, skew, warping, and edge curvature. Because even these traditional metrics are defined differently in different analysis codes, the user needs some control over their definition, their values, or the strategies imposed by the preprocessor for mesh cleanup, mesh smoothing, or element splitting. Still other validation tools are sometimes desirable: the ability to search for duplicate nodes or elements, inconsistent normals in shells, duplicate edges (implying a lack of continuity), missing elements, and so on.

Finally, returning to Fig. 20, it is apparent that the design process is iterative, that both geometry and mesh need to evolve and be updated in an appropriate manner. Macroinstruction capability in a preprocessor can greatly contribute to its usefulness. The ability to be a part of a looping scheme where geometry is modified by the previous iteration in the loop is becoming more and more important.

Finite Element Analysis

Donald L. Dewhirst, Ford Motor Company

Finite Element Postprocessing

Finite element solutions comprise hundreds, thousands, or millions of numbers describing calculated field values. These field values might be scalar, vector, or tensor quantities such as temperature, displacement, or stress states, respectively. Usually, some *postprocessing* operations are necessary to interpret these numbers efficiently. Scalars can be plotted as color contours, vectors as arrows denoting magnitude and direction, and tensors as discrete ellipsoids at various positions. Because color contour plots are so intuitive to interpret and so useful, vector and tensor quantities are often plotted as their scalar components.

Many operations can be performed on finite element data. For example, the stresses from two load cases might be averaged and differenced to determine a mean stress and a stress range for fatigue calculations. Alternatively, fatigue damage might be calculated and summed in a manner proportional to the number of cycles predicted for each load. Such fatigue calculations and their display as color contours are a form of postprocessing.

Error indicators or estimators might be calculated and displayed. Optimization theory might be used to drive changes in size (e.g., thickness, moment of inertia), or shape. Other popular postprocessing operations include various *x*-*y* plots. This might be temperature vs. time, creep displacement vs. time, stress relaxation vs. time, stress vs. load, and so on.

Surprisingly, postprocessing to obtain stress contours is not well standardized. Different schemes exist for where the stresses are calculated, how they are interpolated or extrapolated, and how and whether they are averaged. It is advisable to read your postprocessing manual carefully and/or to compare a postprocessed solution, preferably of a coarse mesh, to a known analytical solution.

Finite Element Analysis

Donald L. Dewhirst, Ford Motor Company

Finite Element Analysis Problems and Applications

This section presents three examples to illustrate types of problems that can be addressed and decisions that must be made when using finite element analysis.

Example 1: Finite Element Analysis of an Engine Block (Large Problem).

The notion of what constitutes a large problem changes from year to year. MacNeal (Ref 8) has defined a large problem as one that crosses the threshold of "pain," and a medium-sized problem as one that merely crosses the threshold of "discomfort." Figure 21 is his notion of where these two thresholds have moved over the years. Note that a large problem can be large (painful) for a variety of reasons, principally the size of the model, a large number of time-steps needed for successful simulation, and/or nonlinearities such as large deformation, material nonlinearity, or contact.

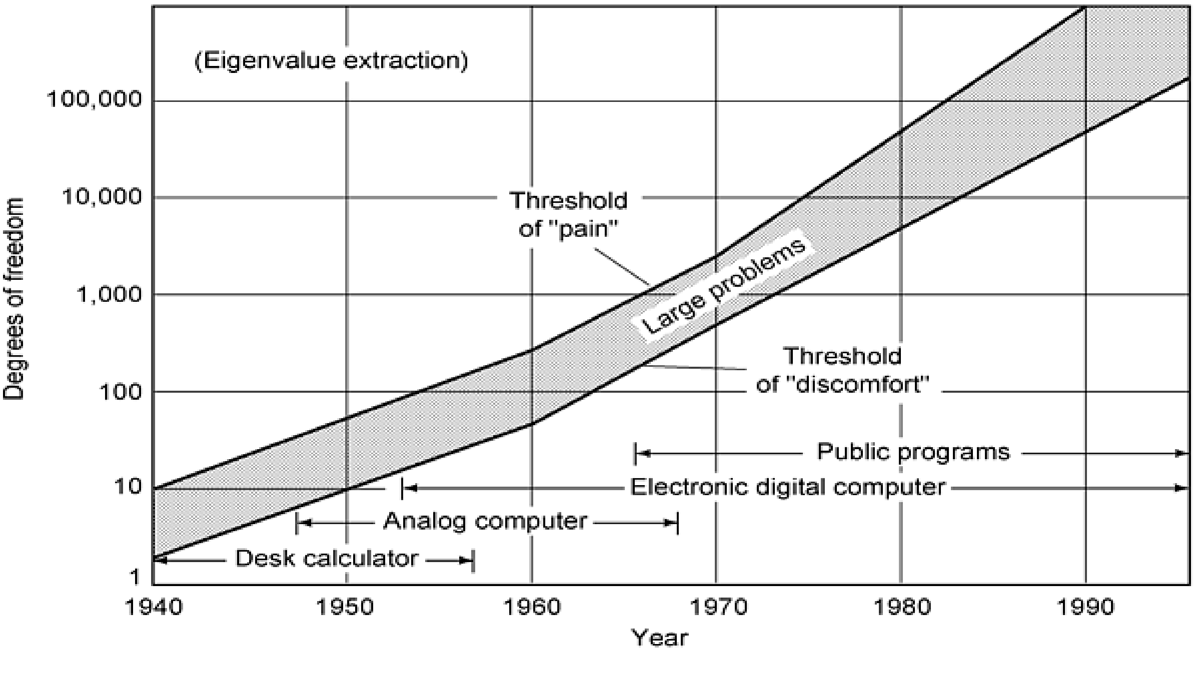

Fig. 21 The changing definition of a large problem. Source: Ref 8

Figure 22 depicts a solid model of a V-6 automotive engine block. Unimportant geometrical details are intentionally omitted or suppressed. The corresponding finite element model of the block is shown in Fig. 23. The mesh consists of 640,000 nodes and 1.9 million DOF. By 1996 standards, this is clearly a large problem. It required communication with the systems analyst who tends the Cray C90 supercomputer, on which it ran, to obtain access to the appropriate memory and disk resources. Solving for all modes of vibration below 3000 Hz required 23 h on a Cray C90 using a direct (as opposed to an iterative) solver.

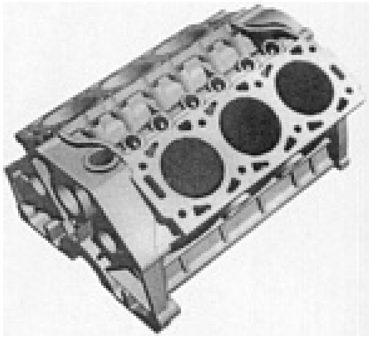

Fig. 22 Solid model of an engine block

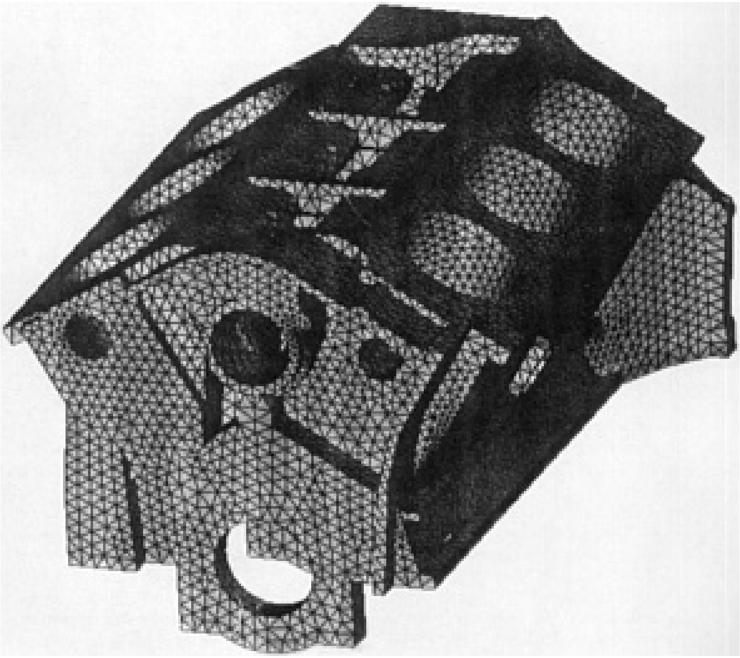

Fig. 23 Finite element model of an engine block

This engine block can be modeled by alternative methods. Given sufficient preprocessing time, it can be map meshed with low-order hexahedron elements, which are more efficient than high-order tetrahedra. However, map meshing an engine block requires weeks or months of preparation time. As a compromise, the solid model of the engine block can be regioned into subgeometries such that the complex portions are free meshed with tetrahedra and the simple portions are map meshed with hexahedra. Because these elements are incompatible, constraint equations (multipoint constraints) should be generated to prevent the faces and edges of these elements from separating or interpenetrating. This compromise approach trades off computer resources against human resources.

Assembling this block with its cylinder heads would increase the size of the problem such that superelement or substructuring techniques would likely be necessary. This would be especially recommended if the nonlinear behavior of the gaskets were to be represented. That kind of static analysis is sometimes performed in order to predict cylinder bore

distortion as a function of the tightening pattern of the head bolts. A nearly perfect cylinder bore minimizes emissions and maximizes performance.

Example 2: Finite Element Analysis of a Connecting Rod (Levels of Complexity).

A typical automotive connecting rod is shown in Fig. 24. A connecting rod is a link that transmits power from the piston to the crankshaft. The rod rotates at its lower end and reciprocates at its upper end. For this reason, engineers are especially concerned to obtain a minimum weight design of the upper end of the rod. The following discussion of its analysis illustrates that finite element models of widely varying fidelity and cost may be appropriate at different stages of analysis and design.

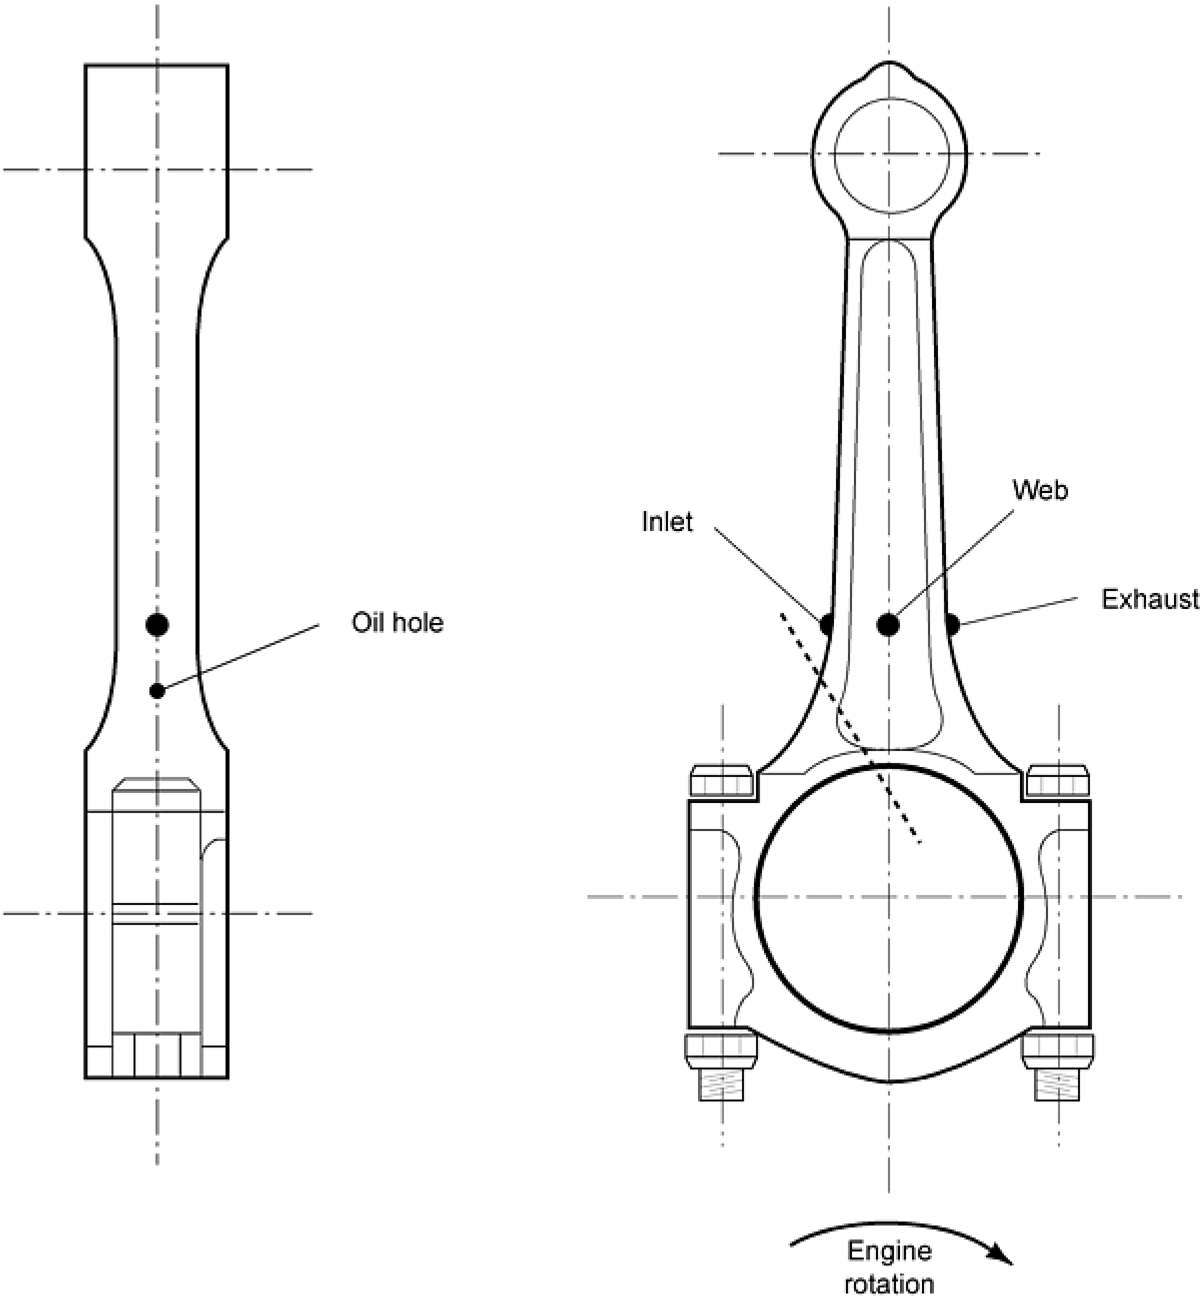

Fig. 24 Automotive connecting rod

A connecting rod undergoes millions or billions of cycles during its lifetime. Therefore, the problem is not one of determining maximum stress, but of ensuring that the high-cycle fatigue life is sufficient. For fatigue failure analysis of

the rod, the *difference* in stress states everywhere in the structure is required. (Von Mises stresses are awkward for this sort of analysis because of the loss of sign; i.e., they are always positive by definition.)

The rod undergoes a continuously varying load during the four-stroke cycle that covers 720° of crankshaft revolution. Therefore, it is sometimes prudent to step the rod through its incremental positions to obtain the neighborhood of those positions in the cycle that produce the maximum and minimum stresses. Furthermore, it may be desirable to consider three or more load cases, say peak torque, peak horsepower, and peak rpm. Because so many analyses are required, a simple two-dimensional model of the rod may be appropriate at the preliminary design stage. The purpose of these analyses is to screen the loads to be used ultimately for the full three-dimensional model.

A second level of modeling might consider the full three-dimensional geometry of the structure, but might apply the loads in some assumed fashion. For example, the pin loading at either end might be arbitrarily spread in a sinusoidal manner over 180° (or less) of arc, at both the upper and lower ends of the rod.

A third level of modeling might explicitly consider all of the contact pairs that occur in the problem. These contact pairs include the two surfaces at the split of the big end of the rod, the crankpin-to-rod interface, the piston-pin-to-rod interface, and the rod bolts at the lower end. Contact problems are nonlinear and therefore computationally expensive. Additional analysis that should be considered is for the buckling of the rod, or of its flanges, due to peak compressive load. This would typically be done as a linear eigenvalue problem for a rod with low loads and long life. Conversely, for a rod intended to be used in a racing engine, where loads are extremely high, a nonlinear buckling model would be more appropriate.

Example 3: Finite Element Analysis of Brake Assemblies (Multidisciplinary Problem).

Brake assemblies for all forms of transportation have been analyzed by finite elements. Assume that the temperature distribution of a brake disk at the end of a panic stop from high speed is to be determined. This problem might be treated strictly as a thermal problem in which the kinetic energy of the vehicle is converted into heat generated by friction at the brake pad/brake disk interface. It might be assumed that the heat input is ramped (decreasing with time) into the disk in a spatially uniform way across the pad. The heat transferred to the atmosphere during the panic braking might be ignored because of the short time duration. If the heat transfer to the atmosphere is to be considered, then a set of values for *convection coefficients* (energy/unit area/unit time) at the disk surface is calculated or assumed. In either case, this would be a transient thermal problem with one degree of freedom, namely temperature, at each node.

However, let us assume that interest is specifically in changing the wheel design to promote brake cooling or in adding an aerodynamic device to augment cooling (as in racing). Here we consider not a single panic stop, but a series of stops or a continuous drag down a grade. A decision might be made that modeling by means of assumed convection coefficients is insufficiently accurate. In that case, a finite element model of both the fluid (i.e., the moving air surrounding the disk) and the solid might be built, wherein the boundary between the solid and the fluid is interior to the model. Analyzing the problem this way is known as *conjugate heat transfer analysis.* This analysis is inherently more costly (many more DOF and many more elements) than the method that employs the assumed convection coefficients. The feasibility of doing this large transient conjugate heat transfer problem might depend upon the ability to invoke a simplifying assumption, as, for example, cyclic symmetry.

Alternatively, if the primary concern is the smoothness of operation of the brake, this problem could be viewed as a coupled mechanical-thermal problem. The heat generated at the surface of the disk is a function of the frictional force and, therefore, the pressure distribution of the brake pad on the disk. Then thermal expansion due to temperature would influence the friction distribution and, therefore, the heat input distribution at the boundary. This coupled problem would have four DOF per node: one temperature and three displacements.

As computers get still faster and cheaper, and as software becomes increasingly sophisticated, multidisciplinary problems will no doubt be attacked more and more frequently.

COMPUTATIONAL FLUID DYNAMICS (CFD) is one discipline falling under the broad heading of computer-aided engineering (CAE). Computer-aided engineering together with computer-aided design (CAD) and computer-aided manufacturing (CAM) comprise a mathematical-based approach to engineering product and process design, analysis, and fabrication. In this overview of CFD for the design engineer, the purposes are three-fold:

- To define the scope of CFD and motivate its utility for engineering
- To provide a basic technical foundation for CFD
- To convey how CFD is incorporated into engineering product and process design

Computational Fluid Dynamics

Peter J. O'Rourke, Los Alamos National Laboratory; Daniel C. Haworth and Raj Ranganathan, General Motors Corporation

Introduction

Computational fluid dynamics has as its objective the numerical solution of fluid-flow equations. The calculus problem of solving a coupled system of nonlinear partial differential equations (PDEs) for the variables of interest (e.g., velocity,

pressure, and temperature) is transformed into an algebra problem of solving a large system of simultaneous linear equations for discrete unknowns that represent the state of a thermal-fluids system; the latter is amenable to numerical solution on a digital computer.

This is a somewhat abstract description of CFD, but it is necessary to speak in general terms when introducing a subject that encompasses such a wide variety of solution techniques. This overview discusses finite difference, finite volume, finite element, spectral, and some computational particle methods. The emphasis is on the first three, as these are the methods that are primarily used in contemporary CFD codes for engineering design.

In this article, the terminology "computational fluid dynamics" is reserved for computationally intensive three-dimensional simulations of thermal-fluids systems where nonlinear momentum transport plays an important role. It does not encompass all branches of numerical analysis as applied to fluid-dynamics problems. In particular, consideration of zero- or quasi-dimensional analysis of fluids systems (Ref 1, 2) and linear heat conduction or potential flow problems (Ref 3, 4) has been excluded.

The practice of CFD began with the advent of computers; indeed, the first computer was developed, in part, to solve fluid-flow equations. It was recognized by the developers of the atomic bomb at Los Alamos National Laboratory that many fluid-dynamics problems were impossible to solve by analytic means. What was needed was a machine that could perform the massive number of calculations necessary to solve the flow equations by simple finite-difference methods. The ENIAC computer began operating shortly after World War II, and its first calculations were to test various configurations for a hydrogen bomb (Ref 5). Ensuring the safety and reliability of modern nuclear weapons remains a major impetus for the development of more powerful computers and more efficient numerical techniques for solving the fluid-flow equations (Ref 6).

Initially, most numerical solutions were limited to flows that could be approximated as spatially one- or two-dimensional; the time and expense of performing three-dimensional calculations remained prohibitive. Over the last fifteen years, however, CFD calculations of three-dimensional flows have become more common. This has heightened enormously the interest in CFD among engineers, as most real flows are three dimensional. In fact, most fluid-flow problems encountered in industry are so complex that the *only* method of analysis to which they are amenable is CFD. Thus, although use of CFD began only fifty years ago, it is difficult to find problems in fluid dynamics to which computer solution has not been brought to bear.

The capability to perform three-dimensional CFD has resulted primarily from the availability of faster computers with larger memories (Fig. 1) (Ref 7). The development of parallel and massively parallel computers promises to further improve the speed and extend the applicability of CFD. A recent simulation of the oceans (Ref 8, 9) serves to illustrate the problem size and computational requirements that have been realized in modern applications. This problem was run on a 512-node massively parallel computer, requiring ten gigabytes of memory (giga = billion, one byte = eight bits). It ran at a computational speed of four gigaflops ("flops" = floating point operations per second) and required 80 days of computer time. A plot of ocean surface temperature obtained in this simulation is shown in Fig. 2. Computers with maximum performance at one teraflop (tera = trillion) are now becoming available, and petaflop computers (peta = 1000 trillion) are being planned for the next decade (Ref 10).

Fig. 2 Ocean surface temperatures from a recent CFD simulation of the North Atlantic Ocean. Source: Ref 8

At the same time, improved numerical methods have yielded higher computational efficiency, that is, fewer operations and/or less memory for a given accuracy. Among the most important of these advances has been the development of faster methods for solving implicit difference approximations (see the following section). A third enabler for three-dimensional CFD has been the formation of improved finite-volume and finite-element methods that better accommodate the complex geometrical boundaries that characterize engineering flows. Examples of engineering applications are given later in this article.

The advent of three-dimensional calculations has increased the engineering relevance of CFD, but many obstacles remain to be overcome before CFD realizes its full potential as an engineering design tool. Foremost among these is spatial resolution. Most flows of practical interest have features whose relevant spatial and temporal scales span many orders of magnitude. For example, in an automotive four-stroke-cycle spark-ignited internal-combustion engine operating at 2000 rev/min, hydrodynamic scales range from 0.01 mm (0.0004 in.) (the turbulence microscale) to 100 mm (4 in.) (the bore diameter); flame thickness (stoichiometric, undiluted reactants) is in the range 0.01 to 0.10 mm (0.0004 to 0.004 in.); and spray droplets issuing from a typical port-fuel injector have diameters as small as 0.10 mm (0.004 in.) (Ref 11). Computers do not exist, and will not exist in the foreseeable future, that can store all the numbers required to fully resolve these phenomena. Thus, the effects of small-scale, unresolvable features on the large-scale, average flow features of interest are "modeled" through modifications to the governing PDEs. Examples of models include turbulence models, combustion models, and multiphase flow models. All models necessarily introduce imprecision, and an ongoing goal of research is to improve the accuracy of these models.

Other issues for three-dimensional engineering CFD include geometry acquisition and grid generation, numerical accuracy, and diagnostics to extract the physical information of interest from the computations. Modeling and other issues are discussed further in subsequent sections.

Fundamentals of Computational Fluid Dynamics

The governing equations of fluid dynamics and an introduction to the CFD techniques for their solution are given in this section. Also, basic terminology used by practitioners of CFD is introduced. Readers who are not interested in the technical foundation of CFD can proceed to the next section in this article, "Computational Fluid Dynamics for Engineering Design."

Governing Equations

The equations of fluid dynamics can be derived from kinetic theory or continuum points of view (Ref 12, 13, 14), each of which complements the other. Kinetic theory regards the fluid as made up of molecules subject to collisions and intermolecular forces. Kinetic theory derivations are valid only for dilute gases, but give detailed information about how such transport phenomena as stresses and heat fluxes arise from molecular fluctuations, which in turn are related to the average molecular properties for which the fluid equations solve. Continuum derivations regard the fluid as a continuous medium and show the applicability of the fluid equations to a much broader class of media than dilute gases, but do not give detailed information about transport phenomena.

The Equations of Continuous, Compressible Media. Three basic physical principles, applicable to any continuous medium, are used in continuum derivations:

- Conservation of mass
- Newton's second law that force equals mass times acceleration
- The first law of thermodynamics, which states that total energy, in all its forms, must be conserved

These three principles lead to the following three equations of motion: the mass, or continuity, equation:

$$\frac{\partial \rho}{\partial t} + \frac{\partial \rho u_i}{\partial x_i} = 0 \qquad \textbf{(Eq 1)}$$

the momentum equation:

$$\frac{\partial \rho u_i}{\partial t} + \frac{\partial (\rho u_i u_j)}{\partial x_j} = \frac{\partial \Sigma_{ij}}{\partial x_j} + \rho F_i \qquad \textbf{(Eq 2)}$$

the total energy equation:

$$\frac{\partial \rho E}{\partial t} + \frac{\partial (\rho E u_j)}{\partial x_j} = \frac{\partial (\Sigma_{ij} u_j)}{\partial x_i} - \frac{\partial Q_j}{\partial x_j} + \rho F_i u_i \qquad \textbf{(Eq 3)}$$

These equations are written in Cartesian tensor notation (Ref 15), according to which the subscripts i and j take the values 1, 2, or 3 corresponding to the three Cartesian coordinate directions. A subscript that appears just once in a term takes on one of the three values 1, 2, or 3; repeated subscripts in a term denote a summation of that term over all three coordinate directions. The other notation in Eq 1, 2, and 3 is defined in Table 1.

Table 1 Computational fluid dynamics nomenclature

Symbol	Definition
C_p	Specific heat at constant pressure
C_v	Specific heat at constant volume
e	Internal energy
E	Total energy
F	Body force per unit mass
h	Enthalpy
K	Turbulent kinetic energy
p	Pressure
Q	Heat flux
R	Universal gas constant
S	Rate of deformation
t	Time
T	Temperature
u	Velocity
W	Molecular weight
x	Spatial location
δ	Kronecker delta function

ε	Dissipation rate of turbulent kinetic energy
κ	Heat conductivity
λ	Second coefficient of viscosity
λ'	Bulk viscosity
μ	First coefficient of viscosity
ρ	Mass density
Σ	Stress

The total energy *E* is the sum of the local flow kinetic energy and its internal energy *e:*

$$E = e + \frac{1}{2} u_i^2 \qquad \textbf{(Eq 4)}$$

Alternative energy equations for *e* and for enthalpy $h = e + p / \rho$, where *p* is the pressure, can easily be derived using Eq 1, 2, and 3. Computational fluid dynamics codes often solve internal energy or enthalpy equations, in place of Eq 3, when calculating compressible flows.

The above equations are expressed in *Eulerian* form; that is, the time derivative is taken at a fixed point in space. This contrasts with the *Lagrangian* form, in which the time derivative is taken following a fluid element (Ref 14). Although the Eulerian form of the equations is most often used in CFD, there are CFD methods that approximate the Lagrangian equations.

When completed with constitutive relations appropriate for fluids, these are the basic equations of compressible fluid dynamics. In practice, one often encounters applications in which extensions of these equations are necessary. Among the most common are extensions to multicomponent and chemically reactive flows (Ref 16), to magnetohydrodynamic flows (Ref 17), and to flows with radiative heat transfer (Ref 18). It is beyond the scope of this overview of CFD to give these extended equations, and the reader is referred to the above references for this information.

Constitutive Relations of Fluid Flow. To complete these equations the stress Σ_{ij} and heat flux Q_i need to be expressed in terms of known fluid variables and their derivatives. These expressions are known as constitutive relations. A fluid is a medium for which the nonhydrostatic part of its stress depends only on its rate of deformation S_{ij}. The quantity S_{ij} is given by:

$$S_{ij} = \frac{1}{2}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) \qquad \textbf{(Eq 5)}$$

Thus a fluid has no memory of its previous configurations. This fact, together with the assumption of an isotropic medium in terms of its microstructure, allow the expression (Ref 14) of the full stress as:

$$\Sigma_{ij} = 2\mu S_{ij} + \lambda S_{kk}\delta_{ij} - p\delta_{ij} \qquad \textbf{(Eq 6)}$$

where δ_{ij} is the Kronecker delta function (Ref 15). Fluids with this form of stress tensor are called Newtonian fluids. The thermodynamic pressure p and the first and second coefficients of viscosity μ and λ, depend only on the local thermodynamic state of the fluid. Often the second coefficient of viscosity in Eq 6 is replaced by the bulk viscosity λ', defined by:

$$\lambda' = \lambda + \frac{2}{3}\mu \qquad \textbf{(Eq 7)}$$

The heat flux Q_i depends on gradients in temperature. Again assuming an isotropic fluid Q_i can be written:

$$Q_i = -\kappa \frac{\partial T}{\partial x_i} \qquad \textbf{(Eq 8)}$$

This is Fourier's heat conduction law, and κ is called the heat-conduction coefficient or simply the heat conductivity. Its value depends on the local thermodynamic state of the gas. When one substitutes Eq 6 for the stress tensor and Eq 8 for the heat-flux vector into Eq 1, 2, and 3, the resulting equations are called the compressible Navier-Stokes equations.

The fluid equations are completed by the specification of the quantities p, e, μ, λ, and κ in terms of the local fluid temperature T and density ρ. The equations specifying p and e are referred to as thermal and caloric equations of state, respectively. For a so-called ideal gas, these are given by:

$$p = \rho \frac{R}{W} T \qquad \textbf{(Eq 9)}$$

and

$$e = \int^{T} C_v(T)\, dT \qquad \textbf{(Eq 10)}$$

where the specific heat at constant volume C_v is a function of temperature. Alternatively, the enthalpy h is given by:

$$h = \int^{T} C_p(T)\, dT \qquad \textbf{(Eq 11)}$$

where, from the definition of h and the thermal equation of state Eq 9, the specific heat at constant pressure C_p is given by:

$$C_p = C_v + \frac{R}{W} \qquad \textbf{(Eq 12)}$$

Values of C_v and C_p versus temperature are given in Ref 19 and 20.

The quantities μ, λ, and κ are called transport coefficients. How they are related to the local thermodynamic state of the fluid and its molecular properties are given in Ref 21. Given an expression for the viscosity μ, the heat conductivity κ can frequently be approximated by:

$$\kappa = \frac{\mu C_p}{Pr} \qquad \textbf{(Eq 13)}$$

where Pr is the Prandtl number, whose value is nearly constant and often of order unity.

Simplifications of the Fluid-Flow Equations. For certain flow situations, considerable computer time can be saved by solving simplified forms of the compressible flow equations. In this section, the steady-state, inviscid, and incompressible approximations are introduced, and the circumstances under which they may be used are described.

The steady-state approximation is obtained simply by dropping the time-derivative terms in Eq 1, 2, and 3. While solving the steady-state equations can often save computer time, sometimes CFD-solution techniques for the steady-state equations have what are called convergence difficulties, and steady-fluid-flow solutions are more reliably obtained by calculating the long-time limits of solutions to the unsteady equations (Ref 22).

The inviscid, or Euler, equations are obtained by neglecting the viscosity and heat-conduction terms in the preceding equations. A necessary condition for the applicability of the Euler equations is that the Reynolds number *Re* be much greater than one, where *Re* is defined by:

$$Re = \frac{\rho u L}{\mu} \qquad \textbf{(Eq 14)}$$

In Eq 14 ρ, u, and $\mu$are characteristic values of the density, velocity, and visocity, respectively, of the fluid, and L is a characteristic distance over which the velocity changes appreciably, also called a gradient length. In a flow to which the Euler equations apply, L is typically the dimension of the apparatus that bounds the flow. The Reynolds number is approximately the ratio of the magnitude of the advective terms to that of the viscous terms in the fluid momentum equation, Eq 2. Thus, when *Re* is large the viscous terms may sometimes be neglected. When fluid Prandtl numbers are of order unity, smallness of the viscous terms also implies smallness of the heat-conduction terms relative to the advection terms in the energy equation.

There are many high Reynolds number flows, however, where neglect of the viscous and heat-conduction terms is not justified. Sometimes fluid flows have broad regions over which the inviscid equations apply, coupled with thin regions (e.g., boundary layers and shocks) in which the viscous and heat-conduction terms are important. In addition, as *Re* is increased many flows become turbulent, and the velocity then varies over a range of length scales L. At the smallest of these length scales, *Re* is of order unity, and viscosity is important because it is responsible for the dissipation of turbulent kinetic energy into heat. (See the section on turbulence below.)

An incompressible flow is one in which the divergence of the velocity field is identically equal to zero:

$$\frac{\partial u_i}{\partial x_i} = S_{ii} = 0 \qquad \textbf{(Eq 15)}$$

A necessary, but not sufficient (see Ref 14), condition that a flow be incompressible is that the Mach number M be much less than one, where M is defined by:

$$M = \frac{u}{c} \qquad \textbf{(Eq 16)}$$

In Eq 16, u and c are characteristic values of the velocity and sound speed of the fluid.

In combination with the continuity equation Eq 1, Eq 15 implies that:

$$\frac{D\rho}{Dt} = \frac{\partial \rho}{\partial t} + u_i \frac{\partial \rho}{\partial x_i} = 0 \qquad \textbf{(Eq 17)}$$

D/Dt is the time derivative following a fluid element, and Eq 17 states that the density of each element of fluid remains a constant along its trajectory. Usually, a more restrictive assumption is made that the density of the whole fluid is equal to a constant ρ_0. In this case, the momentum equation, Eq 2, becomes:

$$\frac{\partial u_i}{\partial t} + \frac{\partial (u_i u_j)}{\partial x_j} = \frac{1}{\rho_0}\frac{\partial \Sigma_{ij}}{\partial x_j} + F_i \qquad \textbf{(Eq 18)}$$

The great simplification of incompressible flow equations is that the energy equation is decoupled from the momentum equation and need not be solved. This is the so-called primitive-variable form of the incompressible flow equations. Another formulation that is used in CFD calculations of two-dimensional, incompressible flows is the stream function and vorticity formulation, which can be found in Ref 3.

Turbulence and Other Models. As has been stated in the introduction, there are many flow situations in which flows have changes in their properties, such as their velocities, with superimposed size scales or time scales that differ by many orders of magnitude. Examples are the seemingly chaotic motions in a turbulent flow or in a multiphase flow such as a liquid spraying into a gas. Classical theories of turbulence predict that the ratios of the largest to the smallest fluctuation length scales of turbulent flows are approximately equal to $Re^{0.75}$, where, in this case, *Re* is based on the velocity and size scales of the largest turbulent eddies (Ref 23). Even a low value of Re = 10,000 gives fluctuation length scales varying over three orders of magnitude. For such cases it is impossible to resolve the detailed flow fluctuations with CFD methods, and fortunately one usually is not concerned with these detailed fluctuations. The average flow behavior is of interest, however, and it is important to account for the effects of the fluctuations on average flow variables.

There are many ways to define averaged, or filtered, flow variables. In general, space- and time-averages can be defined using a filter function $K(x_i, t)$ whose integral over all space and time is unity. In terms of K, the average of a fluid variable q, denoted by $\bar{q}$, is defined by:

$$\bar{q}(x_i, t) = \int\int\int\int q(y_i, t')K(y_i - x_i, t' - t)\, dy_i dt' \qquad \textbf{(Eq 19)}$$

For example, for pure time averaging, one can take $K(x_i, t) = \delta(x_i)\,\Psi_T(t)/T$, where:

$$\Psi_T(t) = \begin{cases} 1 & \text{if } |t| < T/2 \\ 0 & \text{otherwise} \end{cases} \qquad \textbf{(Eq 20)}$$

and $\delta(x_i)$ is the Dirac delta function. Then the average q is defined by:

$$\bar{q}(x_i, t) = \frac{1}{T}\int_{t-T/2}^{t+T/2} q(x_i, t')\, dt' \qquad \textbf{(Eq 21)}$$

and the filter size is said to be *T.* In addition to space- or time-averaging, one can also use ensemble averaging. This is defined by averaging over an imagined large set of realizations of a fluid experiment. Sometimes ensemble-averaging is combined with space- or time-averaging. In any case, the fluctuation of quantity q from its mean value is denoted by q':

$$q'(x_i, t) = q(x_i, t) - \bar{q}(x_i, t) \qquad \textbf{(Eq 22)}$$

There are two approaches to calculating average flow fields. In the first, called Reynolds averaging because it was first proposed by O. Reynolds (Ref 24), one is interested in predicting *the* average flow field and uses ensemble averaging or a filter size that is large compared to the scales of fluctuations. Thus, the average of the fluctuating part of q is zero:

$$\overline{(q')} = 0 \text{ (Reynolds averaging)} \qquad \textbf{(Eq 23)}$$

In contrast, subgrid-scale turbulence models use filters with as small a size as possible, typically comparable to the grid size in the CFD calculation. Thus, one attempts to calculate flow fluctuations with scales larger than the filter, or grid, size and to model only subgrid-scale fluctuations. In a subgrid-scale model, the average of the fluctuation part of q is in general nonzero:

$$\overline{(q')} \neq 0 \text{ (subgrid model filtering)} \qquad \textbf{(Eq 24)}$$

Once the method of averaging is chosen, then equations for the averaged flow variables can be obtained by averaging the equations of the preceding sections, or simplified forms of these. In deriving the averaged equations, one finds that the rates of change of average flow variables depend on averages of the products of two fluctuating quantities, also called second-order correlations. The values of these are unknown, and if one tries to close the system of equations by deriving transport equations for the second-order correlations, it is found that these depend on third-order correlations, or averages of three fluctuating quantities. Continuing in this way, one finds that it is impossible to obtain a closed system of equations using either Reynolds-averaging or subgrid-scale-averaging (Ref 25). By using physical and dimensional reasoning and empirical information, the unknown correlation must be expressed (the word "modeled" is also used here) in terms of average flow variables that are known.

A very important example of a second-order correlation and its modeling arises when averaging the incompressible flow momentum equation (Eq 18). The Reynolds-averaged form of this equation is:

$$\rho_0\left(\frac{\partial \bar{u}_i}{\partial t}+\frac{\partial \bar{u}_i\bar{u}_j}{\partial x_j}\right)=\frac{\partial \bar{\Sigma}_{ij}}{\partial x_j}-\frac{\partial}{\partial x_j}\left(\rho_0\,\overline{u'_i u'_j}\right)+\rho_0\bar{F}_i \qquad \textbf{(Eq 25)}$$

The second-order correlation $-\rho_0\overline{u'_i u'_j}$ on the right-hand side of this equation is called the Reynolds stress. The most popular turbulence models in engineering design calculations are the so-called two-equation models, in which the Reynolds stress is, with some theoretical justification (Ref 25, 26), taken to have the form:

$$-\rho_0\,\overline{u'_i u'_j}=2\mu_T\,\bar{S}_{ij}-\frac{2}{3}\rho_0 K\,\delta_{ij} \qquad \textbf{(Eq 26)}$$

In this expression μ_T is the turbulent viscosity and K is the turbulent kinetic energy:

$$K=\frac{1}{2}\,\overline{(u'_i)^2} \qquad \textbf{(Eq 27)}$$

By substituting Eq 26 into Eq 25, one finds that the momentum equation for turbulent flow closely resembles the momentum equation for laminar, or nonturbulent, flow. This is also the case for other averaged fluid equations, and this resemblance allows the same numerical techniques for CFD to be applied to both laminar and turbulent flows.

In two-equation turbulence models, transport equations are solved for the turbulent kinetic energy K and one other scalar that gives a local length or time scale of the turbulence. A popular choice for this second turbulence quantity is the turbulence kinetic energy dissipation rate ε. In terms of K and $\varepsilon$the turbulent viscosity is given by:

$$\mu_T=c_\mu\rho_0\frac{K^2}{\varepsilon} \qquad \textbf{(Eq 28)}$$

where c_μ is a dimensionless constant. The K-ε turbulence model is described in more detail in Ref 26, which also describes the use of wall functions to calculate wall heat and momentum losses in conjunction with the K-ε model. Descriptions of many two-equation turbulence models, and their relative advantages, can be found in Ref 27.

Numerical Solution of the Fluid-Flow Equations

This section introduces some common techniques for discretizing the fluid-flow equations and methods for solving the discrete equations.

Discretization of the Fluid Equations. In the process of discretization a continuously varying fluid flowfield, which has an infinite number of degrees of freedom, is represented by a finite set of data. This section introduces the

discretization techniques used by finite-difference, finite-volume, finite-element, spectral, and some particle methods, and associated concepts of numerical stability and accuracy. The discrete equations of the finite-difference, finite-volume, and finite-element techniques all look similar and are referred to generically as "difference approximations." This introduction to CFD can only scratch the surface of each method. For more in-depth information, the reader should consult Ref 3, 28, 29, 30, 31, and 32.

Finite-Difference Methods (FDM). In FDMs the entire fluid region of interest is divided into nonoverlapping cells, and approximate values of the fluid variables are stored in each cell. This subdivision is called a grid or a mesh. Derivatives are approximated by taking differences between the variable values in neighboring cells, using the idea of a Taylor-series expansion. Consider the simple one-dimensional example of finite-difference solution of the linear advection equation:

$$\frac{\partial q}{\partial t} + u\frac{\partial q}{\partial x} = 0 \qquad \textbf{(Eq 29)}$$

in the spatial interval $a \leq x \leq b$. This interval is subdivided into cells of equal size $\Delta x = (b - a)/N$, where N is the total number of cells, and q_i^n denotes the approximate value of q at the center of cell i, which lies at the location, or grid point, $x_i = a + (i - \frac{1}{2})\Delta x$, at time $t = n\Delta t$, where Δt is the computational timestep. (In this section, the subscript i represents a cell number, rather than a coordinate direction.) All the values of q_i^n, $1 \leq i \leq N$, for a particular time $t = n\Delta t$ are stored in computer memory, and values can be computed at time $t = (n + 1)\Delta t$ by using a finite-difference approximation to Eq 29.

To approximate the spatial derivative in Eq 29, q_i^n is considered to be the value at x_i of a differentiable function $q(x, t)$ that can be expanded in a Taylor series about any grid point. Thus the value of q at a neighboring grid point can be expressed in terms of the value of q and its derivatives at grid point i by:

$$q_{i+k}^n = q_i^n + \left(\frac{\partial q}{\partial x}\right)_i^n k\Delta x + \left(\frac{\partial^2 q}{\partial x^2}\right)_i^n \frac{(k\Delta x)^2}{2} + O(\Delta x^3) \qquad \textbf{(Eq 30)}$$

where $O(\Delta x^m)$ represents the fact that the remaining terms in this expansion have as their lowest-order term one in which Δx is raised to the power m. Now the value of the spatial derivative in Eq 29 can be approximated by any finite combination that satisfies:

$$\sum_k a_k q_{i+k}^n = \left(\frac{\partial q}{\partial x}\right)_i^n + O(\Delta x^m) \qquad \textbf{(Eq 31)}$$

when one substitutes from Eq 30 for the q_{i+k}, where a_k are coefficients that depend on Δx. In the approximation Eq 31, m is said to be the order of accuracy of the approximation and all terms containing Δx to some power are said to be truncation errors. As long as $m > 0$, the approximation is said to be consistent. Examples of consistent approximations are the centered-difference approximation:

$$\frac{q_{i+1}^n - q_{i-1}^n}{2\Delta x} = \left(\frac{\partial q}{\partial x}\right)_i^n + O(\Delta x^2) \qquad \textbf{(Eq 32)}$$

which is second-order accurate, and the one-sided approximations:

$$\frac{q_i^n - q_{i-1}^n}{\Delta x} = \left(\frac{\partial q}{\partial x}\right)_i^n + O(\Delta x) \qquad \textbf{(Eq 33a)}$$

and

$$\frac{q_{i+1}^n - q_i^n}{\Delta x} = \left(\frac{\partial q}{\partial x_i}\right)_i^n + O(\Delta x) \quad \textbf{(Eq 33b)}$$

which are first-order accurate. If the advection speed *u* in Eq 29 is positive, then the approximation Eq 33a is called an upwind approximation and Eq 33b a downwind approximation.

Order of accuracy is one measure of the accuracy of an FDM. To test the accuracy of a finite-difference solution, one can refine the grid by reducing the cell size Δx. When Δx is reduced by a factor of two, numerical errors will be reduced approximately by a factor of four when using a second-order method, but only by a factor of two with a first-order method. It may thus seem to be desirable to use only methods with a very high order of accuracy. In practice, however, it is difficult to define high-order methods near boundaries and often numerical solutions using high-order methods have oscillations in regions of steep gradients. Because of these difficulties, most modern FDMs have second- to fourth-order accuracy and sometimes drop to first-order accuracy in regions of steep gradients.

Returning to the example of the linear advection equation, the time derivative can be approximated in much the same way as the spatial derivative. Because one usually only stores the value of q_i at a single time-level in order to save computer storage, the time derivative is most often approximated by the one-sided finite-difference formula:

$$\frac{q_i^{n+1} - q_i^n}{\Delta t} = \left(\frac{\partial q}{\partial t}\right)_i^n + O(\Delta t) \quad \textbf{(Eq 34)}$$

When Eq 34 and one of the finite-difference formulas Eq 32, 33a, or 33b is used to approximate the time- and space-derivatives in Eq 29, one obtains a consistent approximation to the linear advection equation that is first-order accurate in time.

When these finite-difference equations are used to advance the numerical solution for *q* in time, one finds that, in contrast to solutions to the differential equation, solutions to the finite-difference equations using Eq 32 or the downwind approximation Eq 33b are subject to catastrophic numerical instabilities, and solutions using Eq 33a are only stable if a certain condition is met. This condition, the so-called Courant condition, is that the Courant number $C = (u\Delta t)/\Delta x$ be less than one. The origin of these numerical instabilities was first discovered by J. von Neumann (Ref 33), who devised a method for analyzing the stability of linear finite-difference equations based on examining the behavior of each Fourier component of the solution.

The finite-difference approximations presented so far are explicit in the sense that the solution for q_i^{n+1} can be explicitly found by solving only the finite-difference equation at grid point *i.* All explicit methods, if they are stable, are subject to Courant conditions to ensure their numerical stability. Intuitively, this condition arises because when using an explicit method, information can only propagate at a speed proportional to $\Delta x/\Delta t$. In order for the numerical solution to approximate the physical solution, the numerical propagation speed must be at least as great as the physical speed. For the simple advection Eq 29, the only physical propagation speed is *u.* For the fluid equations there are several physical, or characteristic, speeds. The largest of these is $u + c$, where *c* is the fluid speed of sound, and the Courant condition in explicit CFD calculations is based on the speed $u + c$. To overcome the Courant condition one uses implicit FDMs, in which solution for the value of q_i^{n+1} is implicitly coupled to the solution for q^{n+1} at other grid points. An example of an implicit finite-difference approximation to the linear advection Eq 29 is:

$$\frac{q_i^{n+1} - q_i^n}{\Delta t} = -u\,\frac{q_{i+1}^{n+1} - q_{i-1}^{n+1}}{2\Delta x} \quad \textbf{(Eq 35)}$$

which can be shown to be unconditionally stable. The disadvantage of implicit methods is that they usually require costly iterative solution. Some iterative solution techniques for implicit equations will be introduced below.

Finite Volume Methods (FVM). As in FDMs, FVMs subdivide the computational region into a mesh of cells, but finite-volume cells can be arbitrary quadrilaterals in two dimensions, hexahedra in three dimensions, or indeed any shape enclosed by a set of corner points. In contrast, FDMs are defined on grids that are obtained using orthogonal curvilinear coordinate systems. Thus, FVMs have much more geometric flexibility than FDMs.

Finite-volume methods approximate forms of the fluid equations that are integrated over these cells, which are also called control volumes. An example is the finite-volume approximation of the integrated form of the mass equation, Eq 1. After integrating Eq 1 over control volume *V* and applying the Reynolds transport and divergence theorems (Ref 14) one obtains:

$$\frac{d}{dt}\iiint_V \rho \, dv + \iint_S \rho u_i n_i da = 0 \qquad \textbf{(Eq 36)}$$

The quantity $\rho u_i n_i$ is the mass flux (mass per unit area and time) through surface *S* with unit normal n_i, and Eq 36 is a statement that the time-rate-of-change of the total mass in volume *V* is equal to the sum of the fluxes, times the areas, through the surface *S* of the volume. Thus mass is conserved in the sense that there are no internal mass sources. Commonly, the time derivative term in Eq 36 is approximated by:

$$\frac{d}{dt}\iiint_V \rho \, dv \approx V_\nu \frac{\rho_\nu^{n+1} - \rho_\nu^n}{\Delta t} \qquad \textbf{(Eq 37)}$$

where ν is the index of finite-volume cell and V_ν is its volume, and the surface integral is approximated by:

$$\iint_S \rho u_i n_i \, da \approx \sum_\alpha \rho_\alpha (u_i)_\alpha (n_i)_\alpha A_\alpha \qquad \textbf{(Eq 38)}$$

where the sum is over all faces α of control volume ν; ρ_α and $(u_i)_\alpha$ are approximations to ρ and u_i, respectively, on face α; $(n_i)_\alpha$ is an average unit normal vector to face α pointing out of volume *V*; and A_α is the area of face α.

Using finite-volume methods one can easily construct discrete approximations that have the conservative property; that is, the discrete approximations can mimic the physical laws from which the fluid equations were derived by conserving properties such as computed mass, momentum, and energy. To be more precise, consider the approximation to the mass equation above. A conservative approximation has the property that if ν and μ are two cells that share face α, then when one sums the finite-volume approximations to the change of mass in cells ν and μ, the contributions due to fluxes through common face α cancel each other. This will be true if ρ_α and $(u_i)_\alpha$ are defined the same way in the finite-volume approximations at nodes ν and μ, because the unit outward normal to face α relative to cell ν is minus the outward normal relative to cell μ. Conservative difference approximations have many desirable accuracy properties. For example, it can be shown that difference approximations that conserve mass, momentum, and energy will calculate the correct jump conditions across shocks without having to resolve shock structure (Ref 3).

A problem with FVMs is that it is difficult to formulate higher-order FVMs. When a FVM is specialized to a finite-difference grid, the difference approximations look very much like finite-difference approximations, and one can perform Taylor-series expansions and determine the order of accuracy of the method. When more general meshes are used, however, it is unclear whether the same accuracy can be expected.

Finite element methods (FEMs) (Ref 28) use a consistent spatial interpolation when evaluating all the spatial derivative terms in the fluid dynamics equations. These methods have long been popular in stress-analysis problems and have recently been gaining popularity in CFD problems because of advances in the methodology. As in FVMs the computational domain is subdivided into nonoverlapping cells that in three dimensions are either arbitrary hexahedra or tetrahedra (Fig. 3, 4). Finite-element terminology is different, however, in that the cells are called elements, and the vertices of the cells are called nodes. A function $q(x_i,t)$ is represented by an expansion of the form:

$$q(x_i, t) = \sum_{\nu} q_{\nu}(t) b_{\nu}(x_i) \quad \textbf{(Eq 39)}$$

where the sum is over all the nodes ν in the computational domain. The b_{ν} (x_i) are called basis functions and have finite support, meaning that they vanish outside of some neighborhood of the node ν location $(x_i)_{\nu}$. They also have the properties that:

$$b_{\nu} ((x_i)_{\mu}) = \delta_{\nu\mu} \quad \textbf{(Eq 40)}$$

where $\delta_{\nu\mu}$ is the Kronecker delta function, and:

$$\sum_{\nu} b_{\nu} (x_i) = 1 \quad \textbf{(Eq 41)}$$

for all x_i. Linear (for tetrahedra) or trilinear (for hexahedra) basis functions give rise to second-order numerical methods in the following sense: When the finite-element grid is refined in such a way that the dimensions of elements are reduced by a factor of two, then the difference between the computed and exact solutions, as measured by a global integral of this difference, is reduced by a factor of four. Higher-order FEMs can be constructed by adding midside nodes to the elements and using nonlinear basis functions that have properties Eq 40 and Eq 41 (Ref 28). Because of Eq 40, the coefficient $q_{\nu}(t)$ is the value of q at location $(x_i)_{\nu}$ at time t.

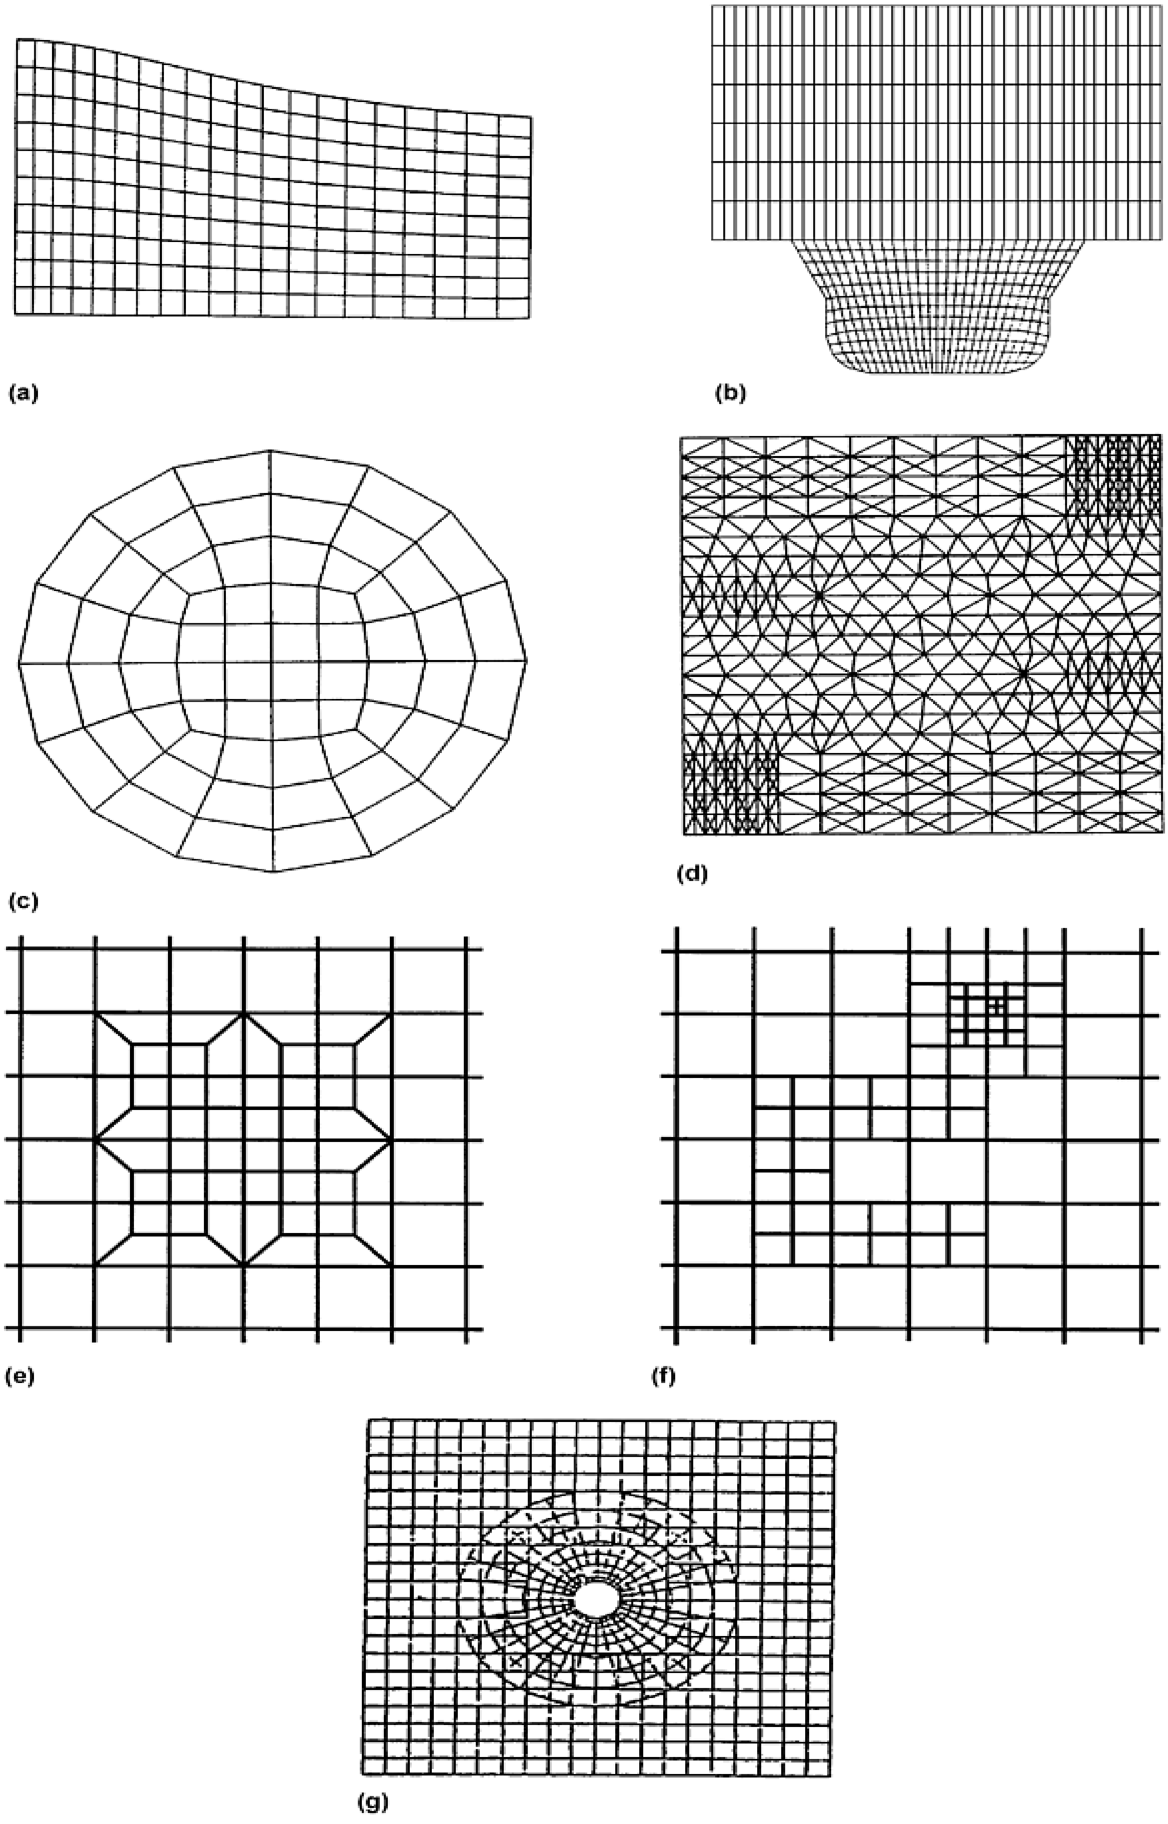

Fig. 3 Examples of grids used in CFD calculations. Two-dimensional examples are shown for clarity. (a) A structured grid. (b) A block-structured grid. (c) An unstructured hexahedral (quadrilateral) grid. (d) An unstructured tetrahedral (triangular) grid. (e) Local mesh refinement via a transition region on an unstructured

hexahedral grid. (f) Local mesh refinement via cell splitting on an unstructured hexahedral grid. (g) A chimera grid

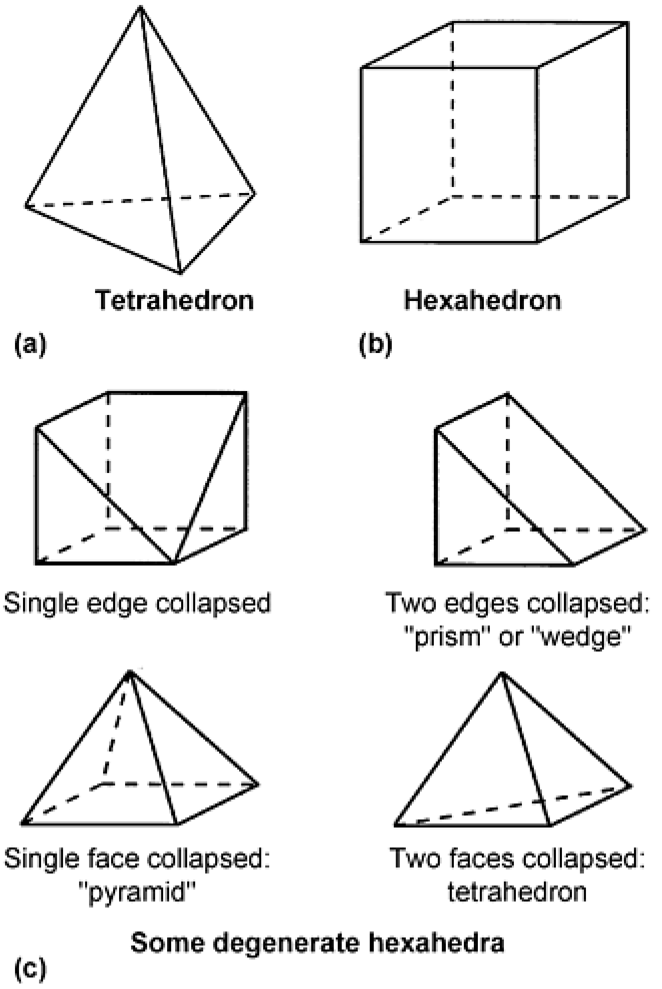

Fig. 4 Principal cell or element types for CFD. (a) Tetrahedron: there are four vertices or nodes, four faces, and six edges for each element. (b) Hexahedron: there are eight vertices or nodes, six faces, and twelve edges for each element. Hexahedral elements generally must remain convex (angles formed by edge and face intersections must remain smaller than 180°). (c) A sampling of possible edge and/or face degeneracies for hexahedral elements

Although there are many possibilities for determining q (t),the most common method is that of the Galerkin finite-element method (GFEM). In GFEM, one substitutes expansions of the form Eq 39 for each function in the fluid equations. To obtain the discrete equations associated with node , one multiplies the resulting expanded equations by basis function b (x_i) and integrates over the entire computational domain. This gives rise to a coupled system of ordinary differential equations for the functions q (t). Standard numerical methods for ordinary differential equations can then be used to solve for the q (t). These ordinary differential equations involve coefficients that are integrals of products of the basis functions and their derivatives. Evaluating these coefficients can be a costly step in obtaining a GFEM solution.

Spectral Methods. Like FEMs, spectral methods (Ref 28) represent a function $q(x_i, t)$ by a finite sum:

$$q(x_i, t) = \sum_n c_n(t)\, b_n(x_i) \qquad \textbf{(Eq 42)}$$

but unlike FEMs the basis functions b_n (x_i) are typically orthogonal functions with respect to some weight functions $W(x_i)$; that is:

$$b_n\,(x_i)\;b_m\,(x_i)\;W\,(x_i)\;dx_i = \quad_{nm} \qquad \textbf{(Eq 43)}$$

There is no grid in a spectral method. The $c_n(t)$ are no longer the values of q at nodes, but simply the coefficients of the function q in an orthogonal function expansion. Ordinary differential equations for the $c_n(t)$ are obtained by a method that is similar to that of GFEM: one substitutes the expansion Eq 42 into the fluid equations and then multiplies the resulting expanded equation by $b_n\,(x_i)\;W\,(x_i)$ and integrates over the computational domain.

Spectral methods are most often used in situations where suitable basis functions can be found that satisfy the boundary conditions of a problem. When this is the case, spectral methods are very efficient for solving fluid-dynamics problems. For example, direct simulations of turbulence with periodic boundary conditions invariably use Fourier series expansions (Ref 34) because of their high accuracy. Because of the difficulty of finding suitable basis functions that satisfy boundary conditions in complex geometries, spectral methods are usually used only for simple geometries.

Computational Particle Methods. Computational particles have long been used for many purposes in CFD calculations (Ref 35). At the simplest level they are used to follow the motion of Lagrangian fluid elements for flow-visualization purposes. At the other extreme, in some particle methods the fluid is completely represented by particles, each of which is endowed with a certain amount of mass, momentum, and energy. This is the case for particle-in-cell (PIC) methods (Ref 36, 37) and for the newer smoothed-particle-hydrodynamics (SPH) methods (Ref 38). The great advantage of the latter two methods is their Lagrangian nature. Because the Lagrangian equations are solved, numerical truncation errors are avoided that arise from finite-difference approximations to the advection terms. These are often the largest errors in approximations of the Eulerian equations. When carefully formulated, PIC and SPH method solutions can also be Galilean invariant and conserve angular momentum (Ref 37).

A disadvantage of particle methods lies in the difficulty of calculating interactions among fluid particles--which give rise, for example, to the pressure gradient terms in the momentum equation. This difficulty manifests itself, particularly in low Mach number calculations, in particle bunching and consequent fluctuations in advective transport. Possibly because of this difficulty, very few commercially available CFD codes use particle methods. An exception is a class of commonly used fluid/particle methods for calculating dispersed, two-phase flows (Ref 39, 40), such as occur when a liquid sprays into a gas. In these methods, computational particles represent the dispersed phase entities and only interact with each other weakly, if they do so at all.

Solution of Implicit Equations. When solving difference approximations to the steady fluid equations or when solving implicit approximations to the unsteady equations, one must solve a large number of coupled algebraic equations for the unknown values of the fluid variables. When the equations are linear, an equation corresponding to the ith cell or node can be written in the form:

$$\sum_j a_{ij}\, q_j = s_i \qquad \textbf{(Eq 44)}$$

where a_{ij} are constant coefficients and s_i is a known source term. The q_j are the unknowns to be solved for; in an unsteady problem $q_j = q_j^{n+1}$. For example, for the implicit approximation Eq 35 to the one-dimensional linear advection equation, one can take $a_{ii} = 1.0$, $a_{ii+1} = u \quad t/(2 \quad x)$, $a_{ii\text{-}1} = -u \quad t/(2 \quad x)$, and $s_i =$. Equation 44 is usually written:

$$\mathbf{Aq} = \mathbf{s} \qquad \textbf{(Eq 45)}$$

where $\mathbf{A} = (a_{ij})$ is an $N \times N$ matrix of coefficients, N being the number of unknowns; $\mathbf{s} = (s_i)$ is a known source vector; and $\mathbf{q} = (q_j)$ is the vector of unknowns. Because the difference approximation in cell i only depends on the values of q in cell i and a small number of neighbors of cell i, only a small number of elements of the ith row of matrix **A** will be nonzero, and for this reason **A** is referred to as a sparse matrix. The basic problem of implicit fluid dynamics is to solve Eq 45 for the vector of unknowns, given a sparse matrix **A** and source vector **s.**

Only for problems with small N can the matrix problem Eq 45 be solved directly by Gaussian elimination. This is because although the matrix **A** is sparse, and therefore does not require much computer storage for its nonzero elements, when

Gaussian elimination is used to solve Eq 45, one finds that it is generally necessary to store in computer memory approximately N^2 nonzero coefficients, which is impossible in problems with a large number of cells.

Thus, iterative methods are usually used to solve the matrix problem, Eq 45. Iterative solution methods calculate a sequence of approximations $\mathbf{q}^k$ that converge to the solution **q.** The exact solution is not obtained, but one stops calculating $\mathbf{q}^k$ when either the difference between successive iterates $\mathbf{q}^{k+1} - \mathbf{q}^k$, or the residual $\mathbf{Aq}^k - \mathbf{s}$, is acceptably small. In the past, popular iterative methods have been point-successive relaxation, line-successive relaxation, and methods based on approximate decomposition of matrix **A** into a product of lower and upper triangular matrices that can each be easily inverted (Ref 30). Recently, these methods have largely been supplanted by two methods that have greatly reduced the computer time to solve implicit equations and thereby have made implicit methods more attractive. These more recent methods are conjugate-gradient methods (Ref 41) and multigrid methods (Ref 42).

When nonlinear finite-difference equations are solved, the above iterative methods can be used in conjunction with Newton's method (Ref 43). A nonlinear difference approximation can be written:

$$\mathbf{F}(\mathbf{q}) = \mathbf{O} \qquad \textbf{(Eq 46)}$$

where **F** is a vector-valued function of the vector of unknowns **q.** If $\mathbf{q}^k$ is the approximation to the solution **q** after *k* Newton-iteration steps, then $\mathbf{q}^{k+1} = \mathbf{q}^k + \quad \mathbf{q}$ is obtained by solving the matrix equation:

$$\frac{\partial \mathbf{F}}{\partial \mathbf{q}} \delta \mathbf{q} = -\mathbf{F}(\mathbf{q}^k) \qquad \textbf{(Eq 47)}$$

The matrix $\partial \mathbf{F}/\partial \mathbf{q}$ is called the Jacobian matrix. Equation 47 is of the form of Eq 45 and can be solved by one of the iterative methods for linear equations. Thus solution for **q** involves using an iteration within an iteration. As in the solution of nonlinear equations for single variables, convergence is sometimes accelerated by under-relaxation; that is, one takes $\mathbf{q}^{k+1} = \mathbf{q}^k + \quad \mathbf{q}$ where $\quad \mathbf{q}$ is the solution to Eq 47 and is an underrelaxation factor whose value lies between zero and one.

Newton's method is sometimes used to solve systems of coupled difference equations arising in CFD (Ref 44), but it is often more economical for this purpose to use the simple-implicit method for pressure-linked equations (SIMPLE) method (Ref 45). In the SIMPLE method, a system of coupled implicit equations is solved by associating with each equation an independent solution variable and solving implicitly for the value of the associated solution variable that satisfies the equation, while keeping the other solution variables fixed. As is implied by the acronym SIMPLE, pressure is chosen as an independent variable, and special treatment is used to solve for pressure (Ref 45). The equations are solved sequentially, and repeatedly, until convergence of all the equations is obtained. The SIMPLE method is more efficient if the difference equations are loosely coupled, or if some independent linear combinations of the equations can be found that have little coupling.

Grid Generation for Complex Geometries

Before applying most of the CFD methods outlined above, a computational grid must be generated that fills the flow domain and conforms to its boundaries. For complex domains with curved or moving boundaries, or with embedded subregions that require higher resolution than the remainder of the flowfield, grid generation can be a formidable task requiring more time than the flow solution itself. Two general approaches are available to deal with complex geometries: use of unstructured grids and use of special differencing methods on structured grids.

Unstructured Meshes. Figure 3 shows examples (in two dimensions) of several possible grids arrangements for CFD. In a structured three-dimensional grid (Fig. 3a), one can associate with each computational cell an ordered triple of indices (i, j, k), where each index varies over a fixed range, independently of the values of the other indices, and where neighboring cells have associated indices that differ by ±1. Thus, if N_i, N_j, and N_k are the number of cells in the i-, j-, and k-index directions, respectively, then the number of cells in the entire mesh is $N_i N_j N_k$. Additionally, it is seen that each interior vertex in a structured grid is a vertex of exactly eight neighboring cells.

In an unstructured grid (Fig. 3c and d), on the other hand, a vertex is shared by an arbitrary number of cells. Unstructured grids are further classified according to the allowed cell or element shapes (Fig. 4). In the case of finite-volume methods

in particular, an unstructured CFD code may require a mesh of strictly hexahedral cells (Fig. 4b), hexahedral cells with degeneracies (Fig. 4c), strictly tetrahedral cells (Fig. 4a), or may allow for multiple cell types. In any case, the cells cannot be associated with an ordered triple of indices as in a structured mesh.

Intermediate between structured and unstructured meshes are block-structured meshes (Fig. 3b), in which "blocks" of structured grid are pieced together to fill the computational domain.

There are three advantages of unstructured meshes over structured and block-structured meshes. First, unstructured meshes do not require that the computational domain or subdomains be topologically cubic. This flexibility allows one to construct unstructured grids in which the cells are less distorted, and therefore give rise to less numerical inaccuracy, compared to a structured grid. Second, local adaptive mesh refinement (AMR) is naturally accommodated in unstructured meshes by subdividing cells in flow regions where more numerical resolution is required (Fig. 3e, f). Such subdivisions cannot be performed in structured meshes without destroying the logical (i, j, k) indexing. Third, in some cases, particularly when the cells are tetrahedra, unstructured grid generation can be automated with little or no user intervention (Ref 46). Thus, generating unstructured grids can be much faster than generating block-structured grids.

On the other hand, unstructured-mesh CFD codes generally demand higher computational resources. Additional memory is needed to store cell-to-cell and vertex-to-cell pointers on unstructured meshes, while this information is implicit for structured meshes. And, the implied connectivity of structured meshes reduces the number of numerical operations and memory accesses needed to implement a given solution algorithm compared to the indirect addressing required with unstructured meshes.

The relative advantages of hexahedral verses tetrahedral element shapes remain subjects of debate in the CFD community. Tetrahedra have an advantage in grid generation, as any arbitrary three-dimensional domain can be filled with tetrahedra using well-established methodologies (Ref 46). By contrast, it mathematically is not possible to tessellate an arbitrary three-dimensional domain with nondegenerate six-faced convex volume elements. Thus, each of the various automatic hexahedral grid-generation approaches that have been proposed (e.g., Ref 47, 48) either yields occasional degeneracies or shifts the location of boundary nodes, thus compromising the geometry.

Specialized Differencing Techniques. In a second general approach to computing flows in complex geometric configurations, the onus of work is shifted from complexity in grid generation to complexity in the differencing scheme (Ref 49, 50, 51). Structured and block-structured grids are used, but one of three numerical strategies is used to extend the applicability of these grids. The first strategy is to use so-called chimera grids (Ref 49) that can overlap in a fairly arbitrary manner (Fig. 3g). Solutions on the multiple grids are coupled by interpolating the solution from each grid to provide the boundary conditions for the grid that overlaps it. This is a very powerful strategy that handles naturally problems in which two flow regions meet at a boundary with a complicated shape or where one object moves relative to another. The second numerical strategy is to use so-called embedded boundaries (Ref 50). Again, structured meshes are used, but the complicated boundary of the computational domain is allowed to cut through computational cells. Special numerical methods are then used in the partial cells that are intersected by the boundary. In the third strategy, local AMR is allowed by using a nested hierarchy of grids (Ref 51). The different grids in the hierarchy are structured and have different cell sizes, but the cells in the more finely resolved grids must subdivide those of the coarser grids.

Although the second general approach affords simplicity in grid generation, it generally is less mature than the various unstructured-mesh approaches. Much development remains before these specialized differencing techniques have the robustness, generality, and efficiency to deal with the variety of problems presented in engineering applications. For the near future, then, the use of various unstructured-mesh approaches is expected to dominate in engineering applications of CFD.

Computational Fluid Dynamics for Engineering Design

This section discusses the process by which the above formalisms are used by the industrial design engineer. Because the use of CFD in engineering design is proliferating rapidly in the 1990s, some of this information, particularly that citing specific software, unavoidably will rapidly become dated. The authors believe that the benefits of providing concrete examples to the reader outweigh the concern of premature obsolescence.

Computational fluid dynamics is one of the tools available to the engineer to understand and predict the performance of thermal-fluids systems. It is used to provide insight into thermal-fluids processes, to interpret experimental measurements, to identify controlling parameters, and to optimize product and process designs. It is the use of CFD as a design tool that is the principal focus here. In the course of a design program, an engineer typically will perform multiple CFD computations to explore the influence of geometry (hardware shape), operating conditions (initial and boundary conditions), and fluid properties. For CFD to be fully integrated into the design process, it must satisfy ever-tightening demands for functionality, accuracy, robustness, speed, and cost.

At present, most engineering CFD using commercially available software can be characterized as having high geometric complexity (domain boundaries are complex three-dimensional surfaces) and moderate physical complexity. The majority of flows considered are steady, incompressible, single-phase, and nonreacting. A common physical complexity encountered in engineering situations is turbulence, as engineering flows typically are characterized by high Reynolds number. Turbulence is modeled using a two-equation model (standard *K*- or variants, Ref 27) in most cases. Applications to transient flows with additional physical complexity and/or more sophisticated models (e.g., compressibility, multiphase, reacting, higher-order turbulence models) are increasing.

The CFD Process

Idealized component design processes are shown schematically in Fig. 5. There the left-hand-side flowchart depicts a hardware-based design process, while the right-hand side represents an analysis- or math-based process. Although CFD is the single analysis tool under consideration here, the right-hand side applies equally well to other mathematical/computational tools (e.g., finite-element structural analysis) that together fall under the heading of CAE.

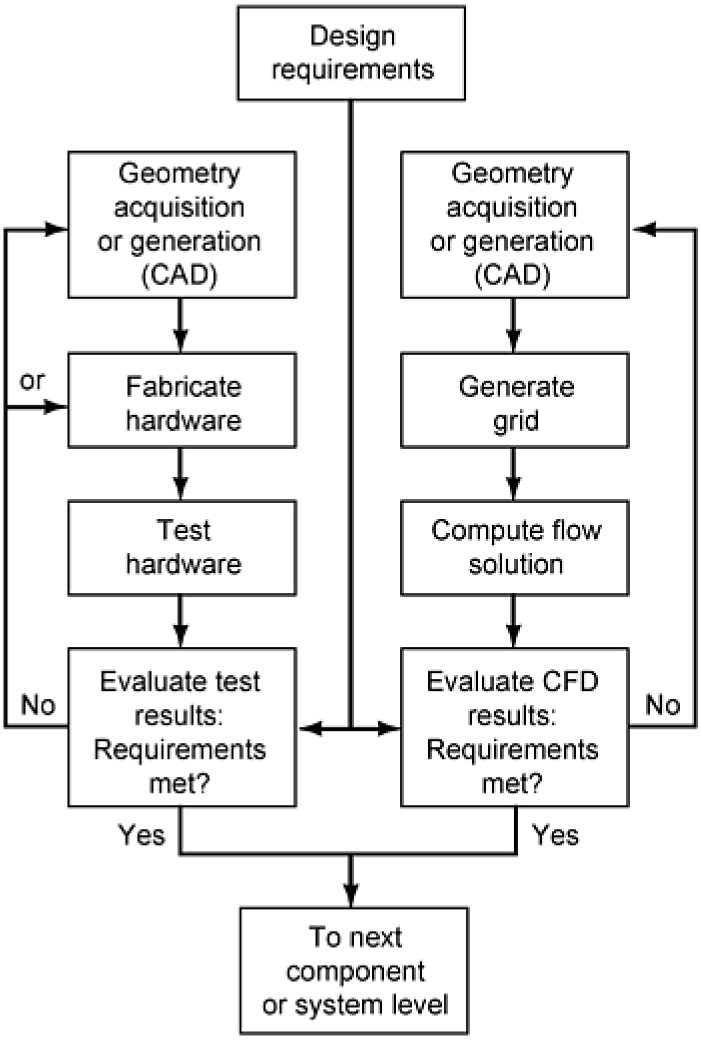

Fig. 5 Engineering component design processes. Left-hand side depicts a hardware-based approach; right-hand side is an analysis- (CFD-) based approach.

Both the hardware- and analysis-based processes require the generation or acquisition of geometric data, and the specification of design requirements. Here it is assumed that a three-dimensional CAD geometry model is the preferred method for geometric representation. A hardware approach then proceeds with fabrication of prototypes, followed by testing of prototypes, and evaluation of test results. Design iterations are accomplished either by direct changes to the hardware or by modification of the CAD data set and refabrication, until the design requirements are satisfied. At that point, the original CAD data must be updated (in the case of direct hardware iterations), and the design proceeds to the next component or system level where a similar process is repeated.

Analysis-based design (here, CFD) is not fundamentally different. Mesh generation replaces hardware fabrication, computer simulation substitutes for experimental measurement, and postprocessing diagnostics are needed to extract relevant physical information from the vast quantity of numerical data. To the extent that relatively simple design criteria are available and the component lends itself to a parametric representation, the design-iteration loop can be automated using numerical optimization techniques (Ref 52). Automated computer optimization with three-dimensional CFD remains a subject of research; in most engineering applications, determination of the next design iteration remains largely a subjective, experience-based exercise.

Analysis-based design can be faster and less costly compared to hardware build-and-test. If this is not yet the case in a particular application, it most likely will be true at some point in the future. Thus, analysis affords the opportunity to explore more design possibilities within specified time and budget constraints. Advances in rapid prototyping systems (Ref 53) and other fabrication technology mitigate this advantage to some extent.

A second advantage of analysis is that more extensive information can be extracted compared to experimental measurements. Computational fluid dynamics yields values of the computed dependent variables (e.g., velocity, pressure, temperature) at literally thousands or even millions of discrete points in space and (in time-dependent problems) in time. From this high density of information can be extracted qualitative and quantitative pictures of flow streamlines and three-dimensional isopleths of any computed dependent variable. For time-dependent problems, animation or "movies" reveal the time evolution of physical processes. Application-specific "figures of merit" including total drag force, wall heat flux, or overall pressure drop or rise can be computed. Examples are given in the case studies that follow. Experimental measurements, on the other hand, traditionally have been limited to global quantities or to values of flow variables at a small number of points in space and/or time. Thus in principal, much more complete information is available from CFD to guide the next design iteration. An important caveat is that this additional information is useful only to the extent that it accurately and reliably represents the actual hardware under the desired operation conditions. In most applications of CFD today, there are sufficient sources of uncertainty that abandonment of experimentation is unwarranted. Recent progress in two- and three-dimensional experimental diagnostics (e.g., particle-image velocimetry for velocity fields, Ref 54; laser-induced fluorescence for species concentrations, Ref 55) is enabling higher spatial and/or temporal measurement densities in many applications.

In Fig. 6, the CFD process is modeled as a four-step procedure: (1) geometry acquisition, (2) grid generation and problem specification, (3) flow solution, and (4) postprocessing and synthesis. Depending on the level of integration in the software selected, four (or more) distinct codes may be needed to accomplish these tasks. Some vendors offer fully integrated systems. For the purpose of exposition, we treat each separately.

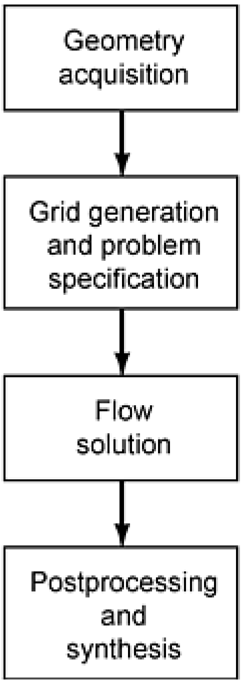

Fig. 6 The CFD process. Examples of available software are given in Table 2.

Table 2 Examples of CFD software available in the United States

This partial listing was extracted from information maintained by several computer hardware and software companies on the Internet early in 1997. Further information on each company and/or code can be found by initiating a network keyword search. Additional information is provided for some companies in Table 3.

Geometry Acquisition (CAD). The principal role of CAD software in the CFD process is to provide geometric definition of the bounding surfaces of the three-dimensional computational domain. The computational domain of interest in CFD generally is everything *external* to the solid material; this conveniently might be thought of as the negative of a finite-element structural solid model. Several CAD packages are available commercially; examples are listed in Table 2. These codes are designed primarily with the design and fabrication of three-dimensional solids in mind and have considerable functionality that is not of direct relevance for CFD (Ref 56).

The various CAD packages use different internal representations for curves (one-dimensional objects), surfaces (two-dimensional objects), and solids (three-dimensional objects). The surfaces needed for CFD, for example, may be represented using one of several tensor-product polynomial or spline representations in a two-dimensional parametric space (Ref 57, 58). Any of these representations generally suffice for CFD; most FDM, FVM, and FEM solution methodologies in current engineering CFD codes require at most linear interpolation between the discrete points (nodes or vertices) representing the surface. However, spectral-element methods (Ref 59) and some other high-order orthogonal basis function expansions require a level of surface definition that generally is not available from current commercial CAD systems; this limits the application of such methods to simple geometric configurations at present.

The need to move geometry models among different CAD systems having different internal representations led to the establishment of standards for external geometric data exchange. An early standard supported by most CAD software is the initial graphics exchange specification (IGES, Ref 60). Most CAD-to-CFD interfaces today operate by extracting the outer surfaces and writing an IGES file of "trimmed" B-spline surfaces. Newer standards such as standard for the exchange of products model data (STEP) are merging with IGES and supplanting it; existing standards are evolving rapidly, and new standards are developed as needed. Other external data formats commonly used in the CAD/CAE arena include stereo lithography (STL), where surfaces are processed into a set of triangular facets, cloud-of points (a set of random points in three-dimensional space), and DES (a set of piecewise linear curves describing a surface).

The set of raw surfaces extracted from the CAD model usually requires additional processing before it is suitable for CFD grid generation. The extracted surfaces may not define a closed three-dimensional domain (gaps), there may be more than one surface at a physical location (overlaps), and there simply may be too much geometric detail to be practical for CFD. Modern CAD and grid-generation systems provide fault tolerance and a variety of tools to "clean up" the extracted surfaces prior to grid generation. This cleanup step is labor intensive and often is the single most time-consuming element of the CFD process.

Grid Generation and Problem Specification. The second step in the CFD process is to generate a computational mesh. This might be accomplished using the same software as for geometry acquisition, or a separate code. The grid must satisfy three general requirements:

- It must be compatible with the selected flow solver
- It must be sufficiently fine to satisfy accuracy requirements
- It must be sufficiently coarse to satisfy computational resource limitations

For an unstructured mesh, the minimum information that must be provided from the grid-generation step is the location of each node or vertex, and a description of connectivity among the vertices. A complete problem prescription for CFD requires in addition the specification of initial and boundary conditions for all flow variables (e.g., velocity, pressure, temperature), fluid properties, and any model and numerical parameters. Other code- and application-specific information also may be needed. Because both geometry and grid information are available at the grid-generation stage, this is the most natural time to tag volumes for initial conditions and material properties and surfaces for boundary conditions (e.g., specify which surfaces represent walls, inflow boundaries, etc.). Specific initial values for each dependent variable at each interior cell or vertex, boundary values for each boundary element face or vertex and fluid properties may be set either in the grid-generation software itself or in a separate "preprocessor" provided for the specific CFD code. For present purposes, the preprocessor is considered to be part of the flow solver. Model constants and numerical parameters are specified to the flow solver directly.

Fully automatic tetrahedral-mesh generation is available in a number of commercial and public-domain codes (Ref 46, Table 2). Early generations of automated hexahedral, hexahedral-with-degeneracies, and hybrid hexahedral/tetrahedral strategies (requiring varying levels of manual intervention) also are available at the time of this writing (Ref 47, 48; Table 2). However, a high level of manual intervention still is required to generate high-quality meshes for CFD. This is particularly true in the case of tetrahedral meshes in the vicinity of solid walls. A "high-quality" mesh is defined here as one that yields high numerical accuracy for low computational effort (memory and CPU time). This is quantified by performing multiple computations of a single flow configuration using different meshes, and computing the error in each with respect to a benchmark numerical or experimental solution. Discussions of modern mesh-generation techniques for CFD can be found in Ref 32 and 61.

Regardless of the specific methodology used to generate the mesh, it is important that any grid-generation software for CFD maintain separate data structures for geometry definition and for the computational mesh. This ensures that design changes (modifications to CAD surfaces) can be made without redoing the domain decomposition, that boundary conditions can be reset without regenerating the grid, and that mesh density and distribution can be changed independently of the geometry.

Flow Solution. Most contemporary CFD solvers available to the industrial design engineer use either finite-volume or finite-element discretization, with SIMPLE-like iterative pressure-based implicit solution algorithms. Unstructured meshes of primarily hexahedral elements (with limited degeneracies) have been prevalent in most finite-volume formulations to date, although the grid-generation advantages of tetrahedra are leading to an increase in the usage of that element type.

Default or recommended values of numerical parameters are provided by each flow solver. New and/or unusual applications often require experimentation in selecting values of numerical parameters to obtain a stable, converged solution. For the solution methodologies commonly used today, parameters include choice of advection scheme (e.g., the degree of upwinding), convergence criteria for linear equation solvers and pressure iterations, time-step control (for transient problems), mesh adaptation (where available), and other method-specific controls. For this reason, the CFD practitioner needs to have a working knowledge of the information covered in the "Fundamentals" section of this article. With these caveats, flow solution is the step requiring the least manual intervention. The engineer can monitor the solution as it progresses using the available diagnostics, which are discussed next.

Postprocessing and Synthesis. Viewing and making sense of the vast quantities of three-dimensional data that are generated in CFD is a challenging task. Many software packages have been developed for this purpose, both for structured and unstructured meshes (Table 2). All provide considerable flexibility in setting model orientation, in passing cutting planes and/or lines through the computed solution, and in displaying the computed vector and scalar fields. Postprocessors have varying levels of "calculator" capability for computing quantities not supplied directly from the CFD solution, such as vorticity or total pressure. Many allow transient animation to accommodate time-dependent data. Most

modern packages provide both a graphics-user interface (GUI) and a save file/read file capability, the latter to allow the user to replicate a particular view of interest for multiple data sets.

Such direct inspection of the computed fields provides detailed insight into flow structure in the same sense as a high-resolution flow visualization experiment. In this respect and others, it had been argued that CFD is more akin to experiment than to theory. Features such as an undesirable flow separation, for example, might provide the engineer with sufficient information to guide a modification to the device geometry for the next design iteration. The connection between device performance or design requirements and the full three-dimensional flow field often is not obvious, however; considerable effort may be required to extract meaningful figures-of-merit from the numerical solution.

Judicious development of diagnostics is necessary to advance CFD from a sophisticated flow-visualization tool to a scientifically based design tool. Quantitative information of direct relevance to the designer is needed to drive design changes toward satisfaction of the design requirements. Such diagnostics are application-specific and have received relatively little attention by CFD researchers and code developers. Examples of diagnostics to extract physical insight and to assess numerical accuracy can be found in Ref 62.

Examples of Engineering CFD

Application areas that have been particularly active in their use of CFD include aircraft and ship design, geophysical fluid flows, and flows in industrial devices that involve energy conversion and utilization. A comprehensive list of the applications of CFD would be difficult to compile, and no attempt to do so is made here. Instead, specific case studies are cited with several purposes:

- To illustrate the scope and state-of-the-art in engineering CFD
- To highlight issues that arise in engineering applications of CFD
- To introduce some specific CFD software that is widely used in industry

Internal Duct Flow. Many internal flows of engineering interest can be broadly categorized as complex duct flows. The principle physical complexity is turbulence, particularly as it influences flow separation. A related numerical issue is mesh resolution, especially in the vicinity of walls. Flow losses (pressure drop and separations), flow distribution among multiple branches, mixing, and heat transfer may be important in such configurations.

Two examples of steady, incompressible CFD simulations are given in Fig. 7 (Ref 63, 64). Figures 7(a) and 7(b) show a simplified automotive heating, ventilation, and air-conditioning (HVAC) duct. This is taken from a validation study (Ref 63) where experimental measurements also are available. Results of this kind have allowed engineers to identify flow separations and poor flow distribution among branches; optimized designs for lower pressure drop and more favorable flow distribution are identified using CFD prior to hardware fabrication.

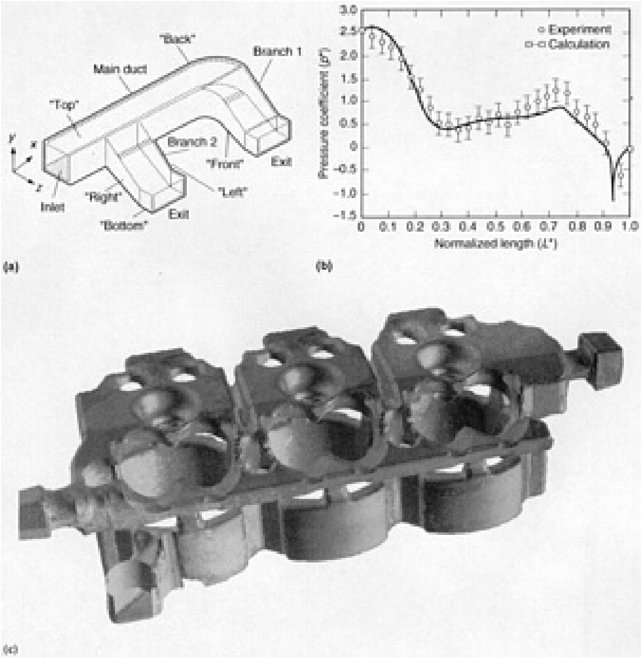

Fig. 7 Examples of internal flow CFD. (a) A simplified automotive HVAC duct (Ref 63). (b) Measured and computed static pressure distributions along the "Top" surface of the main duct and Branch 1 (Ref 63). (c) Computed surface heat trans coefficients for a production automotive engine block (Ref 64)

A second internal flow configuration (Fig. 7c) illustrates the geometric complexity that often arises in engineering applications. There, surface heat transfer coefficients from computations of flow in the coolant passages of a production automotive engine block are shown. Such results are used to identify potential "hot spots" and to modify flow passages for more uniform cooling.

External Aerodynamics. External flows comprise a second broad category of engineering interest. This includes flows around immersed bodies such as aircraft, ships, submarines, and automobiles. Bluff-body aerodynamics is particularly challenging; the accurate computation of separation, which may be highly unsteady, is key to predicting lift and drag.

Examples of computations and measurements for idealized three-dimensional bluff bodies are shown in Fig. 8(a) and 8(b) (Ref 65, 66, 67, 68). A computational challenge is to capture the sudden drop in drag coefficient at a slant angle of about 30° (Fig. 8b). Computations of flow over realistic vehicle shapes also are feasible using modern CAD/grid generation tools (Fig. 8c) (Ref 69). In all cases shown here, the flows have been computed as steady and incompressible using standard Reynolds-averaged turbulence models to account for unsteadiness.

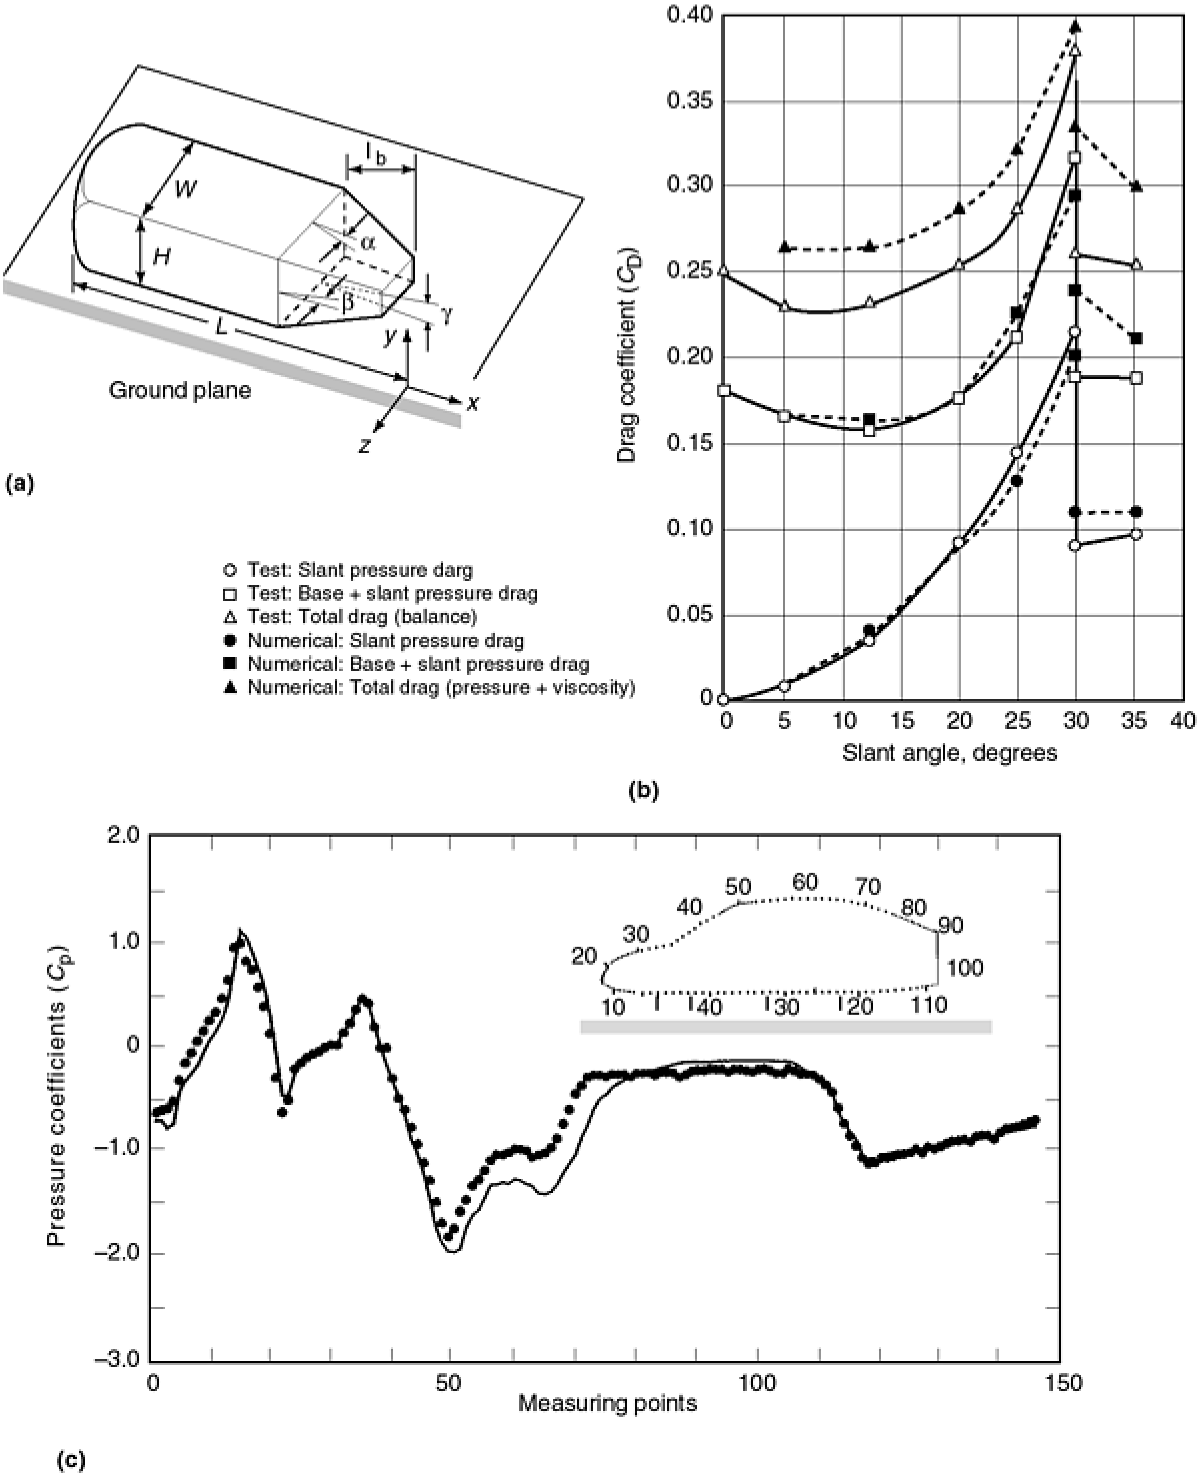

Fig. 8 Examples of external flow CFD. (a) Generic three-dimensional bluff body for validation studies (Ref 65). (b) Computed drag coefficient versus slant angle (angle) (Ref 66). (c) Measured and computed pressure coefficients along a production car body (Ref 69)

Manufacturing Processes. Increasing attention is being focused on the design and analysis of engineering processes. Heat transfer accompanied by melting and solidification occurs in manufacturing processes including casting, injection molding, welding, and crystal growth. In such applications, heat conduction in the solid is coupled to convective heat transfer in the fluid. The solid-liquid interface moves with time, and its location needs to be tracked as a propagating three-dimensional surface in the CFD solution. Also, fluid properties may be highly temperature dependent and non-Newtonian, including phase changes. Metal casting is cited as one example of such an application.

Casting is a process in which parts are produced by pouring molten metal into a cavity having the shape of the desired product. Figure 9(a) is a schematic of a typical sand-casting configuration. Once the two halves of the mold have been made, they are carefully aligned, one over the other, with the aid of pins and bushings in the sides of the molding boxes, to create the complete mold. Aside from the casting cavity itself, other features are also incorporated into the finished mold such as the pouring basin, downsprue, runners, and ingates that conduct the molten metal into the casting cavity. Risers, or reservoirs of molten metal that remain molten longer than the casting, are needed with most metals and alloys that undergo liquid shrinkage as the casting solidifies. These are placed at critical locations in the mold, generally at heavier sections and areas remote from the ingates. Once the casting has been poured and allowed to cool, and after it has been withdrawn from the sand mold, these appendages are removed before the casting undergoes various finishing operations.

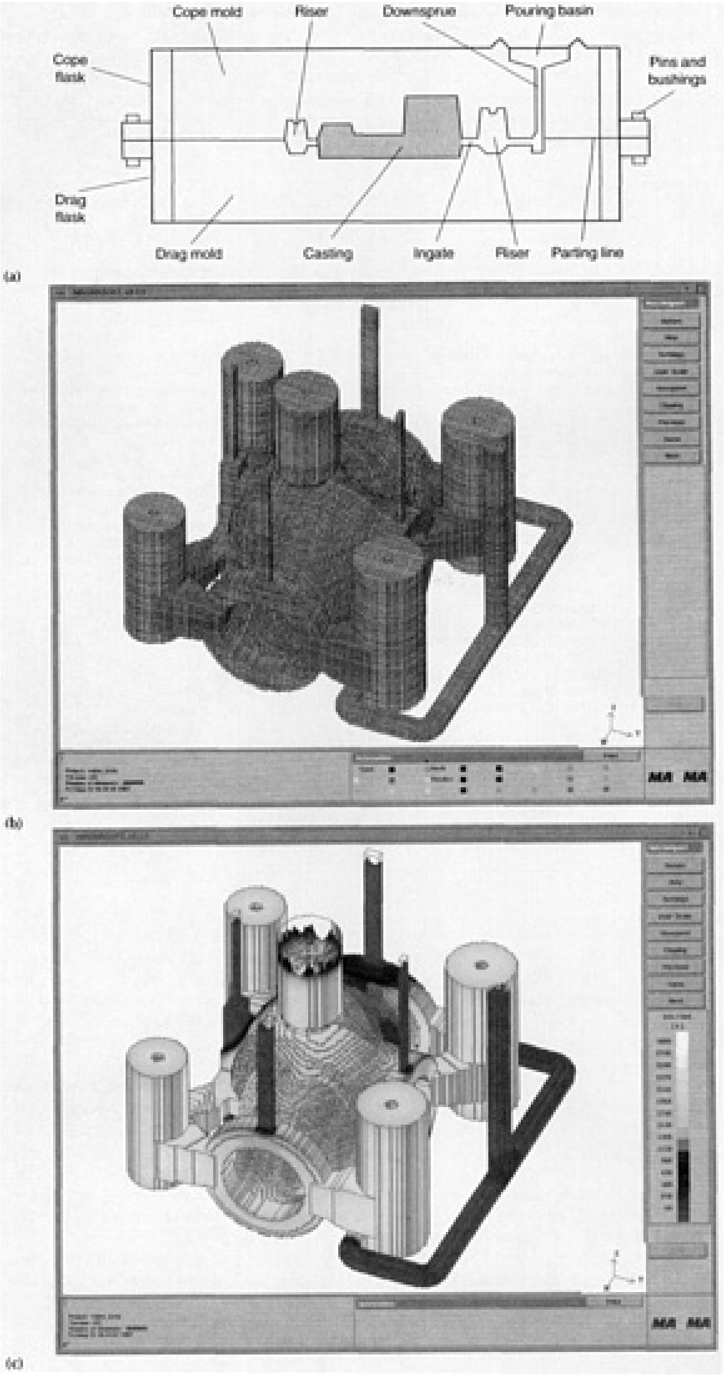

Fig. 9 A metal casting simulation. (a) Typical sand-casting configuration. (b) Automatically generated mesh (five million elements) for casting and cooling channels (Ref 71). (c) Computed local solidification times, which range from 1 to 3000s (Ref 71)

Fluid flow plays two important roles in the casting process. First, and most obviously, the flow of molten metal is necessary to fill the mold. Second, and less obvious, are the effect of convective fluid flow during solidification of the casting. It is the task of the foundry engineer to design grating and riser systems (Fig. 9a) that ensure proper filling and solidification, and CFD is playing an increasingly important role in this field. Proper designs result in lower scrap and less casting repair at the foundry. An example of a computational mesh and computed solidification times is given in Fig. 9(b) and 9(c). One CFD package that has been developed specifically for the modeling of flow and thermal phenomena in casting applications is Magmasoft (Ref 70). Recent references from the literature give ample evidence of the vast amount of CFD activity that is taking place in this area (Ref 71, 72).

Building Interiors. Figure 10 shows an example of CFD applied to building HVAC design. In this case, the geometric configuration is relatively straightforward. The computational domain represents the interior of the Sistine Chapel at the Vatican. The purpose of the analysis was to determine the placement and angles of air-conditioning ducts to minimize deposition of contaminants on the newly restored surface of Michelanglo's frescos. The creation of two separate recirculation cells for the configuration shown in Fig. 10 was deemed to be favorable for isolating traffic-borne particles from chapel visitors in the lower half from the fresco surfaces along the upper walls and ceiling.

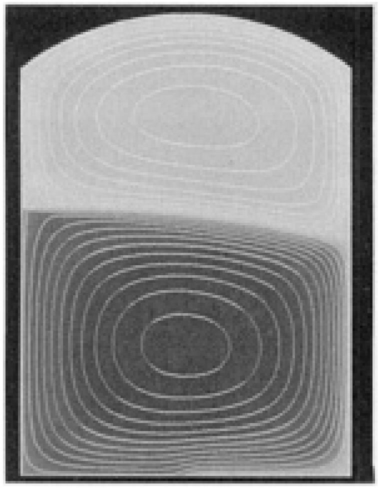

Fig. 10 Flow in the interior of the Sistine Chapel for one possible air-conditioning system configuration. Calculations were done using the FIDAP finite-element CFD code (Ref 73).

Environmental flows include natural phenomena such as atmospheric weather patterns and ocean currents (Fig. 2) and flows of molten rock beneath the crust of the earth. Engineering design issues arise in the extraction of fossil fuels and other materials from the earth, in bridge and building design, and in the treatment and dispersal of wastes from electrical utilities, transportation systems and vehicles, and industrial manufacturing plants. Such problems typically are characterized by a coupling of natural convection (resulting from temperature and/or concentration gradients) with other forces, in many cases including the rotation of the earth.

Internal Combustion Engine. The final example shows a few results from transient computations of flow, fuel spray, and combustion in a reciprocating internal combustion engine (Fig. 11) (Ref 74, 75). This application includes geometric complexity (complex internal flow passages, moving boundaries--piston and valves), physical complexity (turbulence, combustion, multiphase flow), and numerical challenges (deforming mesh, large density and fluid property variations, coupled Eulerian/Lagrangian algorithms). This represents an application area of CFD that lies at the frontier between research and engineering application.

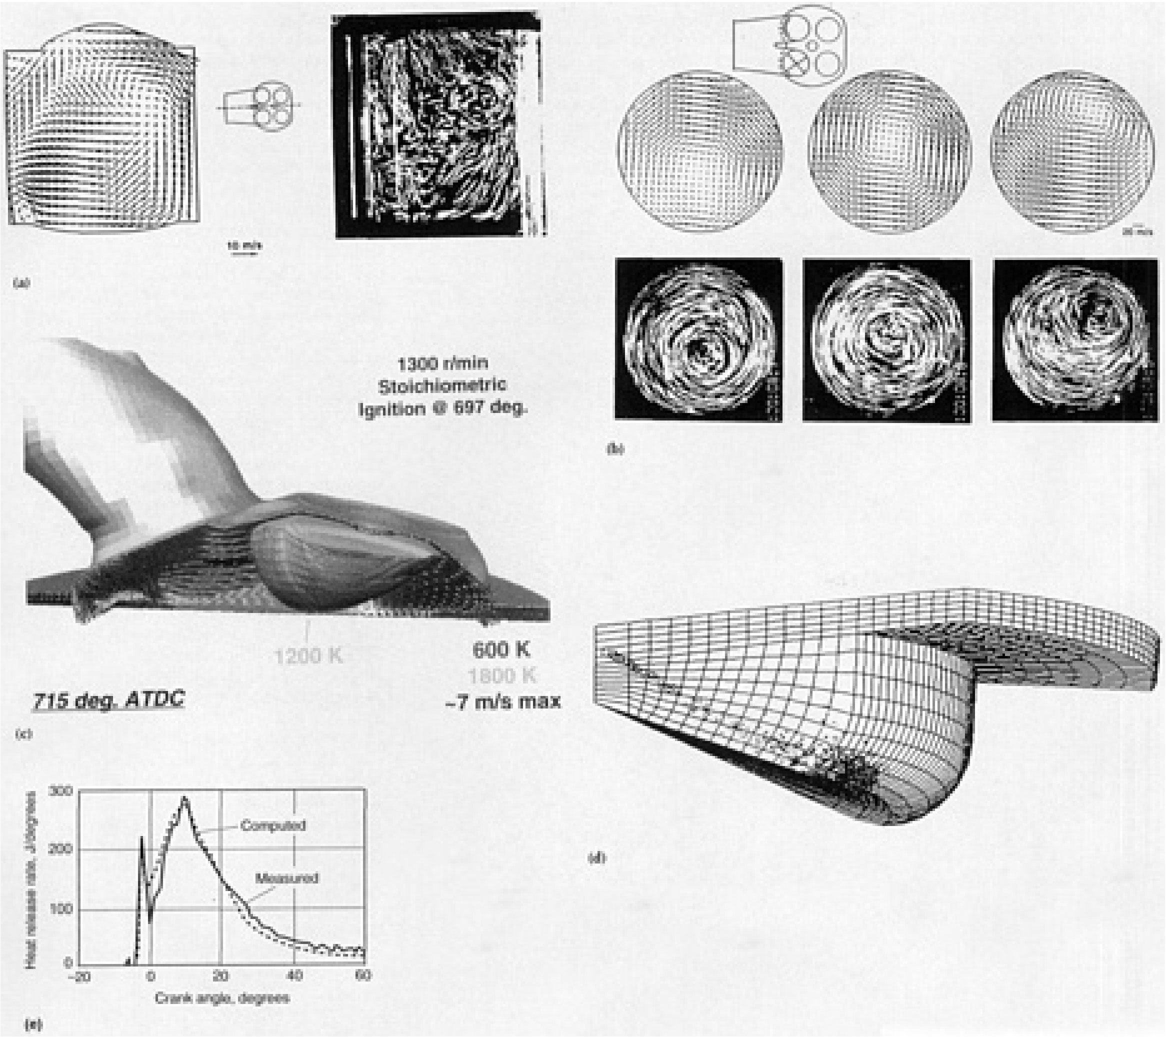

Fig. 11 Examples of CFD for in-cylinder processes reciprocating IC engines. (a) Instantaneous computed and measured induction flow at piston bottom-dead-center for a port and chamber configuration yielding weakly structured in-cylinder flow (Ref 74). (b) Instantaneous computed and measured induction flow at piston bottom-dead-center for a port and chamber configuration yielding a highly structured in-cylinder flow (Ref 74). (c) Instantaneous computed velocity field and flame propagation near piston top-dead-center for a production four-valve-per-cylinder engine. (d) Instantaneous computed fuel spray for a direct-injection diesel engine (Ref 75). (e) Computed and measured heat release for a direct-injection diesel engine (Ref 75)

Of particular interest in a homogeneous-charge spark-ignited engine is the trade-off between flow losses and in-cylinder flow "structure." Flow losses (induction system pressure drop) reduce the quantity of air that can be drawn into the cylinder, lowering engine peak power. A coherent large-scale in-cylinder flow structure tends to yield higher combustion efficiency, but generation of highly structured flow (e.g., a large-scale swirl about the cylinder axis) generally implies a pressure-drop penalty. These trade-offs can be quantified and optimized using CFD (Ref 74). The computations of Fig. 11(a) and 11(b) were performed on unstructured meshes of up to 250,000 predominantly hexahedral cells; computation through one crankshaft revolution required about 150 equivalent single-processor Cray YMP CPU hours.

Flame propagation for a production four-valve-per-cylinder automotive engine is shown in Fig. 11(c). Flame shapes and burn rates are tailored by changing the intake port, intake valve, and combustion chamber geometry. A good design generally is one having favorable spark-gap conditions and a flame that propagates uniformly outward to reach all solid walls at the same instant.

Direct-injection diesel and gasoline engines, wherein liquid fuel is injected directly into the combution chamber, are of interest for their high fuel economy potential. Here mixing and fuel stratification are key issues affecting combustion performance; CFD is one tool that is being used to explore the influence of flow structure, injector placement, and injection characteristics on engine combustion performance (Fig. 11d, e) (Ref 75).

Computational Fluid Dynamics

Peter J. O'Rourke, Los Alamos National Laboratory; Daniel C. Haworth and Raj Ranganathan, General Motors Corporation

Issues and Directions for Engineering CFD

Geometric fidelity between hardware and the computational mesh is crucial to obtaining accurate results. It is characteristic of the highly nonlinear flow equations that small geometric perturbations can result in large changes to the flowfield. One example is shown in Fig. 12 (Ref 76). There, significantly different flow structure and mixing result when the fraction-of-a-millimeter gap between piston and cylinder liner (the "top-ring-land crevice") is included in the mesh compared to when it is ignored. With a top-ring-land crevice, the flow entering the cylinder attaches to the cylinder wall and flows parallel to the wall for an extended time; in the absence of a top-ring-land crevice, the entering flow quickly adopts the port angle on entering the cylinder. This highlights the importance of maintaining a consistent three-dimensional representation of the hardware at all stages of design, analysis, and fabrication. The CFD practitioner should be wary of compromising the geometry in favor of grid-generation expediency, particularly in applications where he or she has little previous experience.

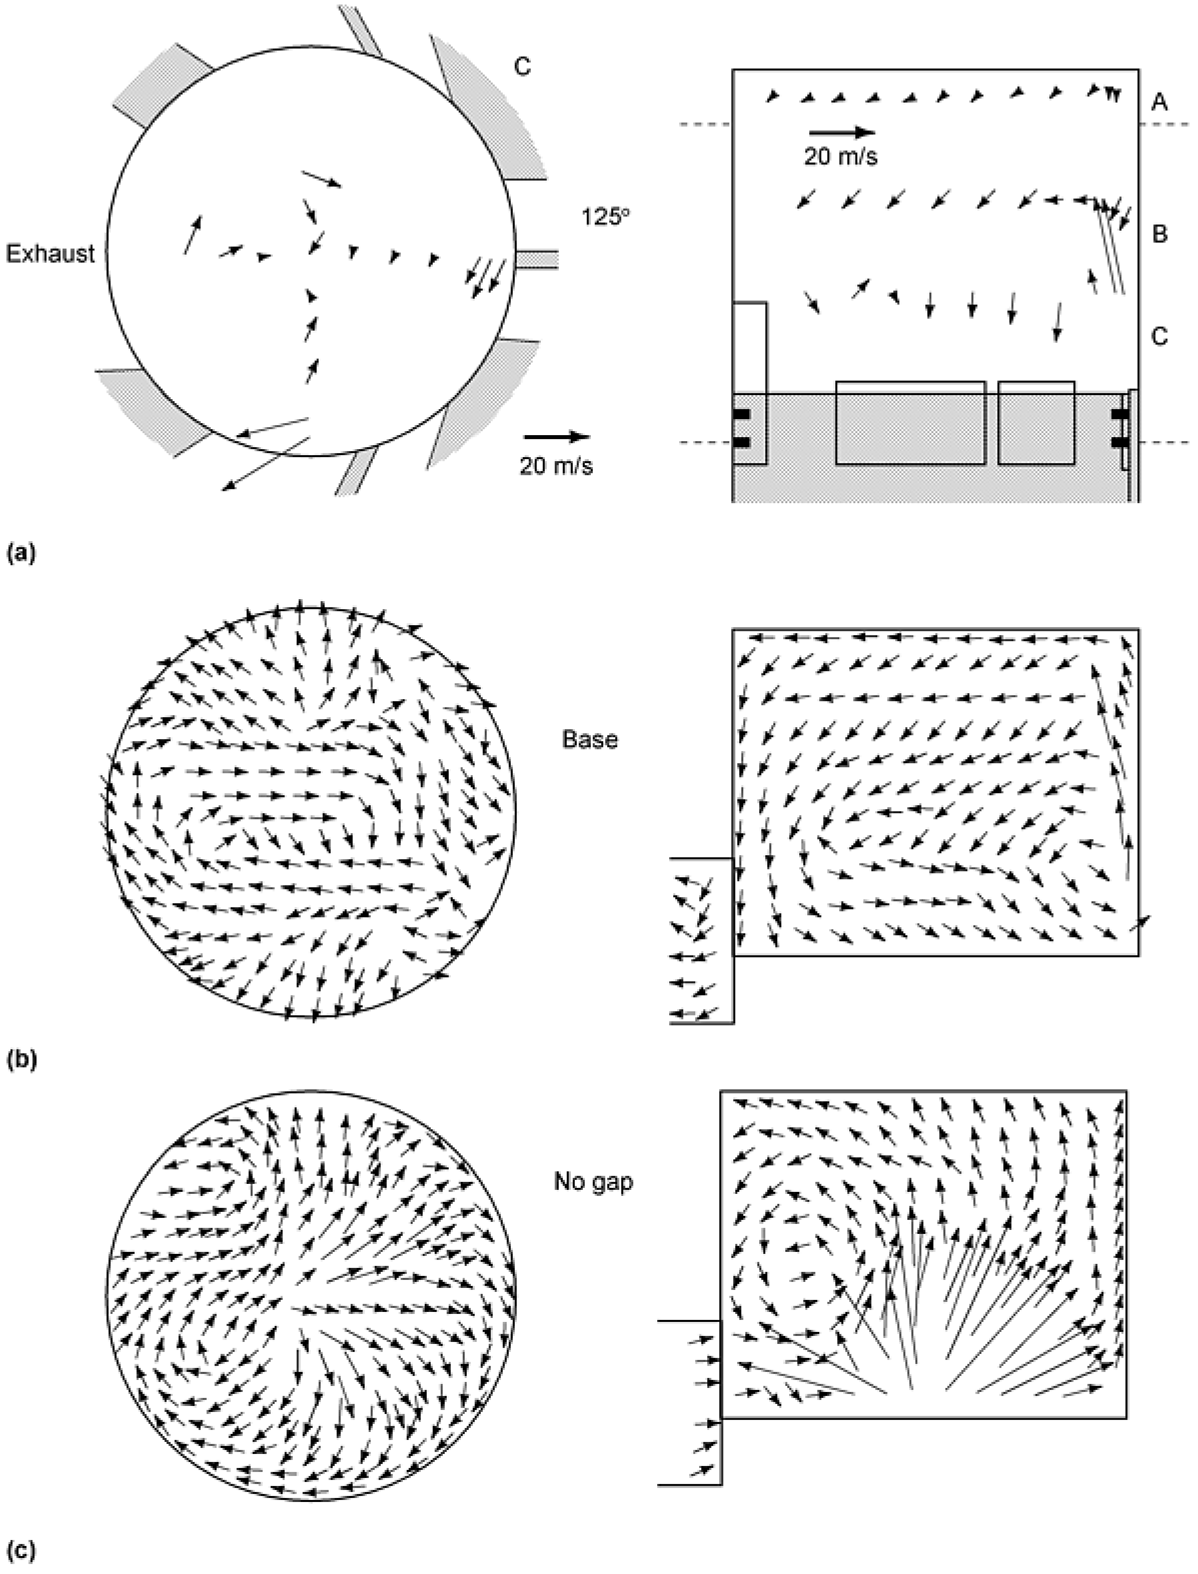

Fig. 12 Computed and measured ensemble-mean velocity fields on two-dimensional cutting planes at 125° after piston top-dead-center for a ported two-stroke-cycle engine. Computational results with and without a top-ring-land crevice are shown. (a) Measured. (b) CFD with top-ring-land crevice. (c) CFD without top-ring-land crevice

Numerical Inaccuracy. Meshes of hundreds of thousands of computational cells are common in transient engineering applications of CFD today, and several millions of cells are being used in steady-state computations. Even so, numerical inaccuracy remains an issue for three-dimensional CFD. A mesh of 1 million cells corresponds to just 100 nodes in each

coordinate direction in a three-dimensional calculation. With the low-order numerics that characterize engineering CFD, this is sufficient to resolve a dynamic range of about one order of magnitude (a factor of 10) in flow scales.

Rapid progress is being made both in discretization schemes for tetrahedral meshes, and in automated grid generation for (primarily) hexahedral meshes; it is unclear at this time which will become dominant in engineering CFD.

The physical models used to represent turbulence, combustion, sprays, and other unresolvable phenomena are a third source of uncertainty in CFD. Turbulence modeling, in particular, is an issue that affects nearly all engineering applications. Research toward improved models continues. Much new physical insight into turbulence is itself being derived from large-scale numerical simulations (Ref 77).

In many high-Reynolds-number engineering applications where the instantaneous flow is highly transient and three-dimensional, turbulence models can be used to reduce the problem to one of steady flow, provided that the *mean* quantities of interest are time independent. This reduces the computational requirements considerably and provides results of acceptable accuracy in many cases. However, as engineering design requirements tighten, there is an increasing number of problems that demand a full three-dimensional transient treatment. Models still are needed to account for scales smaller than those that can be resolved numerically, but subgrid-scale turbulence models are used instead of Reynolds-averaged models. The resulting three-dimensional time-dependent simulations in this case are referred to as large-eddy simulations (LES) (Ref 78). The use of LES in engineering design is expected to proliferate rapidly. Examples of current applications of interest include acoustics and aerodynamic noise (Ref 79) and in-cylinder flows in engines (Ref 80).

Each of these three sources of uncertainty can in principle be isolated and quantified in simple configurations where a second source of data (e.g., experimental measurements) is available. It is more difficult in engineering applications of CFD to isolate and to quantify these errors to obtain meaningful estimates of error bounds. Early in the history of three-dimensional CFD, discrepancies between CFD and experiments generally were attributed to the turbulence model. The importance of the other sources of uncertainty and numerical inaccuracy in particular, has been more widely acknowledged recently (Ref 62, 81, 82). In the authors' experience, most discrepancies between computations and measurements for single-phase nonreacting flows in complex configurations are traced to geometric infidelity or to inadequate mesh resolution (in cases where they have been traced at all).

User Expertise. Computational fluid dynamics codes generally require more experience on the part of the user than other, more mature, CAE tools (e.g., linear FEM structural analysis). "General-purpose" CFD software provides a large number of numerical parameters and problem-specification options. In steady-flow problems, results should be independent of the choice of initial conditions, but different initial conditions may lead to different steady solutions when time-marching to the steady state. The choice of computational domain and specification of boundary conditions always are important, both for steady and time-dependent flows. Minimal user experience may suffice to obtain a reliable solution for steady incompressible flow in a benign geometric configuration, but considerable expertise is needed in problem specification and in results interpretation for complex flows.

CFD and Experimental Measurements. The engineering and scientific community typically accepts measurements from experiments as being more reliable than similar information generated by a CFD calculation. This is the reason for the strong emphasis placed by the profession on "validating" CFD results. While it is true that there are many sources of uncertainty in CFD, the same is true of experiments, particularly for complex systems (e.g., the in-cylinder flow in the last example). When comparing CFD results with measurements for such complex engineering problems, it is more appropriate to approach the exercise as a "reconciliation" rather than a "validation," as the latter implies that the experiment provides the "correct" value.

Interdisciplinary Analysis. In this overview, CFD has been considered as an isolated analysis tool. This is satisfactory only to the extent that one can reasonably prescribe boundary conditions that are independent of the flow solution itself.

For example, in the coolant-flow analysis of Fig. 7(c) temperature boundary conditions might be prescribed from a separate finite-element structural analysis, but the temperature field in the solid depends on the coolant flow itself. One can alternate through a sequence of CFD and thermal structural analyses, taking the most recent boundary conditions available at each step, to obtain a solution that effectively is coupled. A single direct computation of the coupled solution would be more satisfactory, however. In this case, a coupled fluid/heat conduction analysis is feasible as many CFD codes provide conjugate heat transfer capability.

More difficult are cases where fluids and solids interact in a manner that changes the shape of the flow domain. Flow/structure interactions including deformations are important, for example, in some aircraft design problems or in applications where there is significant thermal distortion. Interdisciplinary analysis tools are becoming available for these problems and will see more widespread use in the future.

Future of Engineering CFD. Most contemporary commercial CFD codes start from a discretization of the continuum equations of fluid mechanics and require a computational mesh of discrete cells or elements. An alternative is to approach CFD from a kinetic theory point of view. In Ref 83, for example, an (essentially) grid-free Lagrangian-particle method has been developed and implemented. It is too early, at the time of this writing, to speculate on the future of this approach for engineering design. Computations have been reported for configurations including external flow over simplified and realistic vehicles.

Active research areas for CFD include automated mesh generation, numerical algorithms for parallel computer architectures, linear equation solvers, more accurate and stable discretization schemes, automatic numerical error assessment and correction, improved solution algorithms for coupled nonlinear systems, new and enhanced physical models, more sophisticated diagnostics, interdisciplinary coupled structures/fluids analysis, optimization algorithms, and coupling of three-dimensional CFD into systems-level models.

In the ideal math-based design process, CFD is one part of a multidisciplinary CAE approach, and the full system (versus isolated component) is considered. Grid generation is fully automated to ensure a high-quality (initial) mesh. The flow solver selects all numerical parameters and provides automated solution-adaptive mesh refinement to a specified level of error or allowable computational resource (time or cost). Solution diagnostics provide information of direct relevance to the design requirements. Automated design optimization through modifications to the geometry and/or operating conditions proceeds until design requirements are met.

While much work remains to realize this ideal, CFD already is being used with considerable success in engineering design. Its utility and applicability will increase as the outstanding issues are resolved.

Sources for Further Information. Many references to specific topics have been cited throughout this chapter. General CFD texts include Ref 3, 28, 31, and 32. At all stages of the CFD process (geometry acquisition, grid generation, flow solution, and postprocessing), a broad array of commercial, public-domain, and in-house proprietary codes are being used in engineering design. A small sampling of the software currently available to the design engineer has been mentioned herein. For more comprehensive and up-to-date listings, the reader can consult several sources. Computer hardware companies maintain lists of software that has been ported to their platforms; software vendors maintain lists of codes with which their own products are compatible. Table 3 has been extracted from one such list (Ref 84). General (Ref 85) and industry-specific engineering periodicals often provide reviews of available software. And, a wealth of timely information can be found on the Internet (Ref 86). Given the rapid pace at which CFD technology is evolving, this last source is particularly valuable. In addition to lists and descriptions of the available software, user evaluations and direct comparisons of alternative codes and methodologies can be found there.

Table 3 A partial listing of CFD data formats supported by one software vendor

This provides a snapshot in time (late 1996) of the wide variety of commercially available, public domain, and proprietary CFD software used for engineering design and analysis.

Format/code name(s)	Company
FLUENT/UNS, FLUENT-V4, RAMPANT-V2 and V3, NEKTON, TGRID	Fluent Inc., Lebanon, NH

FLOTRAN	Swanson Analysis Systems Inc., Houston, PA

Source: Ref 84

CFD is at a relatively early stage of development compared to other areas of CAE such as linear FEM structural analysis. No single code covers all areas of application equally well. While "general-purpose" CFD has been emphasized here, specialized application-specific numerical methods and software often are needed. Specialized experience and expertise can be found within university engineering departments, U.S. national laboratories, and engineering consulting firms; again, the Internet provides a good vehicle for exploring these possibilities.

Computer-Aided Electrical/Electronic Design

Shaun S. Devlin, Ford Motor Company

Introduction

DESIGN AND ANALYSIS of electrical/electronic systems and components tends to be different from the corresponding process for most mechanical and hydraulic systems, for one key reason. In most systems, the components interact with each other along a small number of relatively ideal paths (conductors) that have relatively ideal behavior (linear and almost conservative) via two scalar variables (voltage and current). This has led to a greater use of simulation and modeling in all phases of the process and has allowed very complex systems to be modeled, before they were built, with remarkable fidelity. Daniel Whitney (Ref 1) concludes that some of the idealizations that electronic design has employed are becoming less accurate in submicron design. These and other difficulties of the electrical simplifications are described below in contrasting the lumped circuit model and the situations where it is not applicable.

It is useful to think of electrical design following through three overlapping phases: functional, electrical, and physical.

The functional phase involves describing very carefully what the circuit or component is supposed to do (i.e., how do the outputs depend on the inputs). These are the behavioral requirements. If these descriptions can be simulated, we gain increased confidence that the behavioral requirements are correct. Some description techniques support synthesis (nearly automatic translation, usually with the inclusion of library or process technology information) into a full electrical or physical description. This phase of the design is sometimes conducted by the customers (of the design) in order to get the correct requirements in the context of a larger system design.

The ability to synthesize a design from a behavioral description will eliminate many detailed human design steps, thus reducing error, but will require more detail and precision in the behavioral and nonbehavioral requirements. The limitations of the languages and the lack of synthesis tools (except for digital integrated circuits) has limited the automation of this phase. It *is* appropriate to capture at this point any nonelectrical requirements and constraints that the implemented component/system must meet, because the information will be useful in the later implementation stages. Examples are power dissipation (waste energy to be disposed of), size and weight, and any chemical, thermal, or radiation (electromagnetic or nuclear) conditions in the environment that must be met.

The electrical phase is where most designers start describing a design whose desired behavior they often know only informally. The design is often described as a graph of interconnected blocks. The lines or arcs are assumed to be ideal signal conductors and only the blocks have "interesting" explicit behavior. The overall behavior is governed by the individual blocks and their interconnections. The expressive power of these schematic diagrams and their robust mapping to analytical representations such as graph theory and Kirkoff's laws have made these techniques important for many years (Ref 2).

The physical phase is where specific available components are chosen (or requirements for new components are defined and the new component is designed) and descriptions of their electrical and mechanical assembly are elaborated. The electrical interconnections dominate the electrical engineering considerations. The size, strength, reliability, and heat dissipation requirements help in determining the choice between electrically equivalent available parts. The assembly description must provide a geometrical arrangement of conductors (e.g., wires, circuit board traces, silicon metallization), functional elements (e.g., motors, integrated circuit chips, registers), and appropriate physical/geometrical relationships.

Many details of the process, the design tools, and the analysis depend on the physical scale (e.g. chip, board, or systems) and the power levels. These will be discussed at the appropriate places. This article does not discuss any of the commercial tools because of the large number and the high rate of change of these products. The trade publications *Electrical Engineering Times (EETimes)* and *EDN* are recommended for current information about commercial design and analysis tools.

Functional Phase

The process of collecting requirements is essentially informal. There is enormous range of rigor in "writing" the requirements. The more rigorous the expression of the requirements, the more likely that the conformance of the final product to those requirements can be determined with little additional judgment or other human effort. VHDL (Ref 3) and VERILOG (Ref 4) at the behavioral level can be used to express the desired digital behavior. At this time there is no accepted (national, international, or consortium) standard language for describing continuous analog behavior, but there is active work to extend VHDL in this direction. SPICE, which was originally developed at the University of California at Berkeley, is a de facto standard both as a language and a simulator. There are a number of proprietary versions of it (PSPICE, HSPICE) as well as unrelated languages such as the MAST language for Saber (Analogy Corp., Beaverton, OR). Each language is associated with a particular simulator.

Electrical Phase

This discussion begins with the tools that were developed early and are still the most commonly needed and then moves on to more recent and often less needed capabilities. The discussion cannot possibly be complete but will give the reader a feeling for current capabilities, the difficulties in using more than one tool, and the directions of current development.

Schematic Capture

Although there were many design description and analysis tools before graphic computing, the design description techniques (structured text) were not natural for most designers. They were often rigid in syntax and aimed at easy processing into board layout information or simulation. They rarely did both. Graphic schematic capture tools allow designers to draw and interconnect the symbols they are used to drawing on paper. The modification and revision process becomes much easier. Most systems have an internal representation that not only captures the graphics aspect (how the design should be presented on screen or paper) but also "understands" some of the electrical function. If the tool is to be used for simulation, then each symbol must have a simulation model associated with it. The meaning of a line on the screen connecting ports (pins) on two cells (components) has to be stored in such a way that the electrical connection can be understood in the simulator. Alternately, if the design information is to be used for board or chip layout, then the symbol information has to be associated with geometrical information about packages and the physical placement of pins, or (in the case of an integrated circuit) the standard cells (a useful collection of transistors in a controlled library).

To gain user acceptance, the schematic capture tool must provide many of the services of a general-purpose graphic editor and not unduly constrain design creativity with the need to be electrically accurate. For example, many graphic editors force the connection of a line to an adjacent box when the grid feature is turned on. When an electrical schematic editor is used, it should be easy to connect a line to a pin (port) on a symbol, and the editor should not allow a connection at an arbitrary place that does not have electrical significance.

The capability to move symbols around while preserving the connections already drawn ("rubber banding") is very useful. It allows the user to make layout changes to improve the understandability of a diagram after many modifications without altering the essential connectivity. It is usually important to represent a design as either flat (all elements visible on one logical sheet) or hierarchical (blocks or symbols can contain groups of blocks or symbols that may be made visible by some special action on the symbol, often by double clicking). Some tools provide ways of toggling between the two representations.

Even when hierarchical techniques are used, a design may be too large to represent on one sheet of whatever size paper is available. It is then necessary to break the design up into multiple "pages" with indications of how conductivity (lines) on one page are related to connectivity on another. Most systems provide for "off-page connectors" that provide logical linking between pages. These presentation features should not affect the ease or accuracy of simulation. Users must understand that off-page connectors are a notational convenience with no electrical or physical properties, while a real connector certainly has size and weight and may have significant electrical properties.

Figure 1 is a screen image of a session with Viewlogic's Viewdraw, a modern schematic capture package. It can only hint at the capability and usability of such a product.

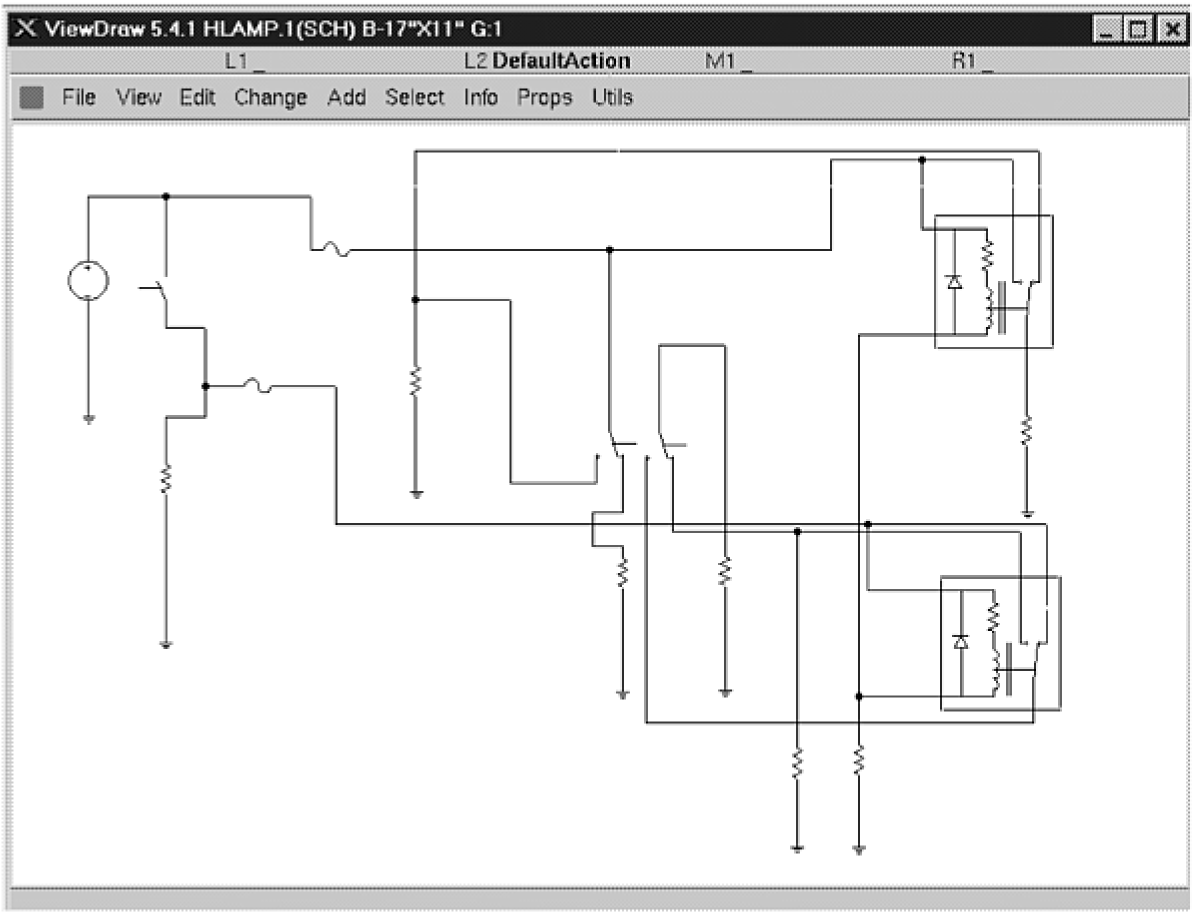

Fig. 1 An electromechanical circuit drawn with a schematic capture tool

This is a good time to emphasize the difference between two types of requirements for the outputs of a schematic editor: those that are based on the limitations of human vision and the available printer/plotter sizes, and the need to represent the underlying connectivity that must be manufactured or simulated. There is often a tension between the ease of

drawing/annotating and human understandability on one hand and providing a robust "carrier" for the underlying behavioral and/or assembly information. For example, in the author's opinion, a sufficiently complete symbol library with associated simulation models and/or component geometric information is more important than having a variety of fonts or a large number of colors.

Simulation and Testing

Simulation allows the designer to evaluate some of the behavior of a design before any physical parts are built. To perform a simulation the designer must have the design described in a language understandable to the simulation engine ("the simulator"), a simulation engine, and usually a set of time-varying signals (test vectors) that provide inputs to the circuit to be simulated. This set must be carefully chosen to represent the normal and abnormal (but possible) signals that the circuit is likely to experience in practice. These signals can be constructed from recorded data, obtained from simulations of the environment that drives the system under consideration, constructed with the toolkit that is provided with most simulators, or constructed with some combination of these techniques. At the later stages of the design, it is important that these test vectors cause every portion of the design to be exercised. It is also necessary to have a way of recording and displaying the outputs of the design (the results). It is very desirable to have some reasonably concrete ideas about what the "correct" results should be for a certain set of time-varying input signals. Very specific results can be obtained by using the output of a simulation of the behavioral design that has been subjected to the same input sets as are to be used in the physical test.

Simulation engines tend to be optimized for two distinct classes of problems: discrete signal (digital) and continuous signal (analog). The digital simulators are concerned with discrete time changes among a small set of discrete values (low, high, unknown, undetermined, etc.). The simulator is optimized to propagate these changes from the element causing the change to all affected elements and to determine how these changes will generate future changes. In large systems where only a modest fraction of the signals are changing at any given time, minimizing calculations of "no-change" is the best way to improve simulation speed. The currents are rarely evaluated. Analog simulators normally calculate both the voltage and the currents, because the currents drawn by the load often significantly lower the voltages at the driving terminal. In other words, the conservation of current and energy must be considered in the simulation. Because digital circuits are designed to be insensitive to modest changes in the voltage signal and the loads tend to be similar, detailed loading effects are simulated less often and problems are avoided with design rules (e.g., connect fewer than N loads to a source whose "fanout" is N). In contrast, in digital systems the power transmitted between macro design elements is small compared to that dissipated in internal switching and is only modeled during design stages where heat removal and packaging are considered.

Analog simulators must evaluate continuous changes in values in continuous time. The analog simulation engine must solve systems of simultaneous (usually nonlinear) differential equations. There will be one equation for each voltage node or current branch in the circuit. The equations represent the application of Kirkoff's laws to circuits with time-varying voltages and currents. The challenge for modern electrical simulators is to choose the form of the mathematical models of each circuit element and a general integration technique such that the time evolution of the circuit voltages and currents can be expressed to suitable accuracy with a minimum number of computational steps. A capability for reducing "waste time" on slowly changing signals can lead to considerable speedup. The SPICE simulator and model description language (Ref 5) pioneered demonstration of these techniques for circuits involving transistors. All the commercially available simulators and languages were influenced by it. The SPICE simulator is in the public domain and is a good starting point, but there are a wide variety of simulators with a broad range of capabilities and costs (e.g., PSPICE, HSPICE, Saber).

Most electrical simulators and models assume that the spatial extent of the component or system does not inherently affect its behavior. More precisely, it is assumed that the delay due to the finite speed of electrical signals in conductors is negligible compared to other delays in the design. An equivalent assumption is that the system is small compared to the electrical wavelength of the frequencies of concern. This is known as the "lumped circuit" approximation, and it allows the dynamics to be described with ordinary differential equations, primarily in time with no spatial definitives, due to the effects of electromagnetic field propagation.

There is a class of problems where this is not a good approximation. Most examples are from high-frequency design (e.g., microwave) where the wavelength of the electrical signals *is* comparable to the dimensions of the circuit elements, including conductors and their spacings. These are best described by partial differential equations in space and time, rather than by the ordinary differential equations in time that are satisfactory for discrete circuits. These partial differential equations cannot be solved analytically for most geometrical situations of interest. Hence, the continuous spatial variation is approximated by three-dimensional meshes of lumped circuit elements whose property variation in space approximates the true variation. This is the finite element method, which has been used in mechanical problems for many years and is

now used to calculate the properties of microwave circuit boards, evaluate the magnetic field generated by time-varying currents in motors and transformers, and calculate the electrical response of a piezoresistive strain sensor element to a nonuniform strain field. Of course, within a single transistor, or sometimes between adjacent transistors, the full three-dimensional flow of current carriers must be analyzed, but this is normally the concern of the semiconductor device designer and very specialized tools are used.

The digital simulation engines, in contrast, must solve a set of coupled finite state equations (Ref 6). Each equation predicts the next state (one of a small set of discrete values) as a function of all the current state values and the value of any discrete input signals. In synchronous systems, the prediction is for the next clock signal transition, which occurs at a known time in the future. Hence, for each clock transition, the simulator must obtain the current state variables and the input variables and use them to evaluate the set of state values that will be true at the next clock transition. Since there may be thousands or millions of state variables in a modern digital circuit, the simulator must efficiently evaluate these equations and in particular recognize equations that predict no change. In synchronous systems, that time interval may be set by any element of the circuit and hence can occur at a time unknown. In a mixed analog digital system, simulation is much more complicated. For example, if an analog integration must start when a particular logical value becomes true, that fact must be communicated from the digital simulator to the analog simulator at the appropriate simulated time. The analog simulator must be prepared to act on this signal, presumably like any other external input. Likewise, if the time at which that integrated value crosses a threshold is an event required in the digital simulation, it must be transmitted back. Few commercial simulators do this well enough to simulate large mixed systems.

The primary initial use of simulation is to help the designer confirm that the design performs its intended function, however completely that is defined. Once the design is frozen, simulation can generate expected results files for test systems. A very wide range of input signal descriptions, designed to exercise all "important" circuits in a design, must be created. Tools exist for creating input signals (test vectors) that can exercise every state that is achievable in a finite number of clock steps. Some states may not be tested in practice because too many steps (and hence prolonged simulation time) are required to reach them. Each organization must make a decision for each product about what fraction of the possible states will not be tested. In systems where 100% test coverage is essential, sometimes extra circuitry (which does not contribute to the base function) is introduced that can read/or set the value of states that would otherwise be costly (in the time sense) to read or set.

Other Analysis

Simulators often perform other analyses on the circuit before the primary simulation begins. In digital simulation, these may include finding circuit elements whose inputs or outputs are unconnected. Additionally, checks may be made to ensure that no output is required to drive more inputs than it is capable of driving (fanout). Checks are also made for locating two or more outputs connected together, which will lead to ambiguous results for most digital technologies. Even in logic families where such connections are allowed and the results are unambiguous, they are normally a small fraction of the connections, and it is useful to highlight them to ensure that they are intentional and not due to a design error.

Another class of errors may occur when designers who are accustomed to conventional electronic logic design use relays or transmission gates to implement logic functions. These errors arise because in conventional electronic logic the signal can only propagate "forward" through gates, while in relays and transmission gates the signal can propagate both ways. Consider these original requirements:

- Load1 (the brake lights) shall be ON if switch1 (ignition switch) and switch2 (brake switch) are both ON.
- Load2 (radio) shall be ON if switch1 (ignition switch) is ON.

Later an additional requirement is added:

- Load1 shall be ON if switch1 (ignition switch) and switch2 (brake switch) are both ON OR if switch3 (hazard switch) AND switch4 (flasher module) is ON.

These are trivial requirements if they arrived at the same time. Let us assume the existing circuit to be modified meets the two original requirements and the designer is asked to make a modification to meet the new requirement. The resulting

design, shown in Fig. 2, meets the requirements if it is interpreted colloquially. If the requirement is "Load2 shall be ON *if and only if* switch1 is ON," then the design indicated is wrong because load1 can also be ON if switch2 and switch3 and switch4 are ON. This is a trivial example of an error due to a "sneak path." Today most requirements are not stated with the precision that distinguishes "if then" from "if and only if then." Because the requirement is often ambiguous, the circuit paths that implement the "if then" form can be highlighted by a heuristic "sneak" error detection process or tool as a *possible* error to be examined more closely by the designer. A circuit in Fig. 2 is an example of a common sneak pattern, which occurs when two initially independent circuits of switches and loads are drawn near each other on the page, sharing a common power source at the top and a common power return at the bottom, and then a design change introduces a switched path between these previously independent circuits. This is called an "H" pattern because of its resemblance to a letter "H." Errors like these are easy to make in large electromechanical systems with incremental requirements and numerous switches and relays.

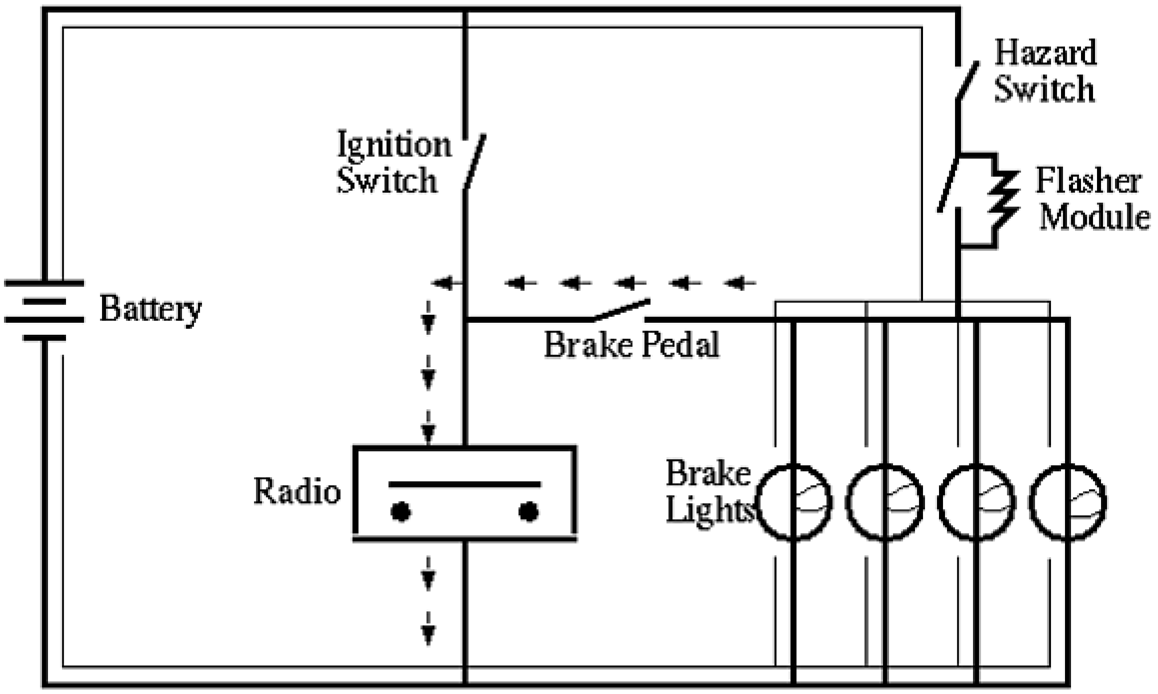

Fig. 2 An automotive example of a "sneak path"

Design errors of this kind can be detected by formal methods where both the requirements and the design are described in languages with semantics that are very well defined. An algorithmic process can then be used to prove whether or not the design requirement is met by the design. This algorithmic process can be automated. There is some progress in this area, but it has been difficult to express requirements in a language that is both precise enough to be mechanically compared to the design and clear enough to discuss with the customer. Likewise, the design language must be precise while not interfering with the creativeness inherent in most good design.

Physical Phase

Printed Circuit Board Layout

The determination of the placement of components and the routing of conductors between them is one of the most important computer-aided capabilities available to the engineer. The algorithms to make the process more automatic have been studied for many years. The process has a blend of electrical and mechanical/geometric aspects, and there are several logical steps.

Choice of Board Material, Outline, and Number of Layers. Most printed circuit boards are made of phenolic. However, unusual requirements of temperature range, thermal dissipation, strength, or dielectric constant may indicate other materials. Although the temperature range may be known a priori, the details of the other considerations may require that the material be chosen before the corresponding analysis is made. For example, the magnitude and location of heat-generating components on a board is known only after placement and simulation. Likewise, the contribution of the conductor to the spreading of heat is determined by the layout. Hence, it may be necessary to run a thermal analysis of the board with all components on it and in an enclosure for several choices of board material. Differential thermal expansion has caused reliability problems, particularly with surface-mounted components. The board size and outline are determined by the size of the circuit to be mounted but are often constrained by the size of the enclosure and the connector arrangement. If the circuit is too large to fit on one board in the chosen enclosure and the partitioning of circuit elements is not obvious (i.e., dictated by a bus architecture), then computer aids are sometime used to allocate the circuit to multiple boards, minimizing the interconnect.

The cost of a board rises steeply with the number of layers. Hence, it is desirable to try to lay out the board with a low number of layers and then increase the number of layers if it is not feasible to route. Feasibility is conditional on how much manual routing is acceptable in the local engineering process. A layout tool that can minimize the need to try several alternatives is very desirable.

Placement of components must account for conductor lengths, thermal dissipation, insertion feasibility, and many other factors. Each of these considerations may be the subject of analysis, and while an optimal set of locations can be calculated for one criterion, no tools take into account multiple considerations. A layout system must first have a library of the "footprints" (a projection of the part outline, including pins on the board, and preferably with recommended pad geometry and drill hole patterns) for each part in the proposed design. A comprehensive layout system provides predesigned drill hole patterns and corresponding electrical pads for each component in the design library. A more comprehensive library will also include the constraints on intercomponent spacing imposed by the insertion process, whether automatic or human.

The library system must certainly allow the addition of new components. It is desirable but much more difficult to be able to add new aspects or attributes of the components when those design attributes become important. For example, if the current library system provides for storing only part shapes that are parameterized by three or four numbers (e.g., cylinders, parallelepipeds, and pyramids), it may be difficult to extend it to be able to describe more complex shapes such as transformers, heat sinks, and other shapes requiring many more parameters, if they can be described parametrically at all. Similarly, a library of component models of geometry for manufacturing and electrical/thermal simulation may be difficult to extend for use with a vibration analysis of a populated board. Hence these possibly future needs should be considered when acquiring a new computer-aided electrical design system.

Routing of Conductors. The conductors must be routed between the appropriate pins on the placed components according to the intent expressed in the netlist (the set of sets of interconnected components and connector pins) but subject to the constraints of the size of the board, minimum widths and spacings, and the number of layers available. Routing of the conductive strips is both the most tedious hand process and the one most investigated theoretically (Ref 7). The netlist provides the connectivity desired. The router attempts to provide that connectivity subject to the constraints of the number of layers and the kind of vias (interlayer connections) that the manufacturing process allows. Interlayer connections should be minimized because they tend to be expensive. Modern routing tools can fully route average boards but may require manual assistance with particularly large designs (large number of component pins per unit area). All tools allow manual routing of difficult or special cases.

Systems Interconnected with Wire and Cable. Electrical/electronic equipment often requires wiring to interconnect circuit boards and other electrical equipment (sensors, switches, motors, etc.). If the equipment in which the electronics is housed is mass produced, the wiring is prebuilt and installed with the electronic boards or modules in the larger system. Examples include a complete computer workstation, a telephone switch, or an automobile. If the product is manufactured in low volume, the wiring is usually installed wire by wire and connectors are attached during the installation process. These two applications have many design similarities but the manufacturing techniques are very different.

Large electrical/electronic systems often consist of printed circuit boards interconnected by more or less organized wiring within a cabinet, vehicle, building, or larger complex. The process of using the netlist as the expression of the desired connectivity is common. The process of determining the routing of the wiring in three-dimensional space is subject to many nonquantifiable constraints related to installation and serviceability. The physical problem of routing individual wires or bundles of wires in three-dimensional space is very similar to the problem of routing piping. In fact, several systems simplify the problem to routing conduits (pipe to protect wiring) or channels (imaginary conduit). Initially only the centerline of the channel path is determined, and the diameter is determined after the number of wires and their diameter are fixed. The capability to use the lengths, spacings, and curvatures defined in the routing process in a calculation of the resulting "parasitic" remittances, capacitances, and inductances is not available in any commercial product in a manner that can be used easily in simulation. In principle, there is an interaction between the routing and the diameter (if there is a voltage drop constraint), but it rarely causes an experimental router to iterate.

Simulation. The metal foil interconnect between a set of pins is not a perfect conductor. Its geometry and the dielectric properties of the board material can lead to (usually) undesired parasitic remittances, and to interconductor capacitance and inductance. For most circuits to operate as intended, these must be below some acceptably low level, determined by the current and frequency levels and the desired function of the circuit. These levels can normally be reached by following the spacing rules that the router uses. Parasitic extraction is the process of calculating the values of these stray parameters from the geometry of the conductors and the parameters of the material and calculating the equivalent lumped circuit elements (resistance, capacitance, inductance) and inserting them in the original netlist. This new actual netlist with the calculated parasitic parameters can now be resimulated to ensure that the circuit meets its requirements. At very high frequencies (>110 MHz), the parasitics are treated not as lumped circuit elements but as transmission lines, and the tailoring of their properties is an essential part of the design process.

Test Design

A stimulus file and the results of a simulation with that stimulus should be usable as an expected results file. The physical design can be verified by subjecting it to a stimulus file in real time and comparing the measured electrical outputs with those predicted by simulation. The detailed physical design files of the unit being tested can be used to help design the mechanical fixtures and electrical probes for the test system.

Standards

It should be clear from this discussion that it is unlikely that a single computer-aided tool (or family of tools) will provide all the electrical/electronic design, manufacturing engineering, and test engineering functions required in a complex enterprise. Standards of representation of the product design and behavior are aimed at providing vendor-neutral file formats or other mechanisms of transferring the required information from one computer system or another. Modern standards of data representation should have a careful definition of the semantics of their terms so that a developer of an application who writes a product description has a clear understanding of the meaning of each term and so that the developer of a reader will have the same understanding. Many standards use the language Express for that purpose (Ref 8). The STEP family of standards developed by ISO TC184-SC4, "Industrial Data," is the most ambitious. It is an evolving series of standards, of which ISO 10303-210, "Electronic Design and Assembly" (AP210) (primarily printed circuit boards and assemblies), and ISO 10303-212 (AP212), "ElectroTechnical Plants," may be of interest to electrical engineers and computer-aided tool developers. The languages VHDL and VERILOG for the description of the behavior and structure of digital systems are now U.S. standards, and VHDL is now an International Electrotechnical Commission (IEC) standard. The EIA/EDIF series of standards (Ref 9) have evolved from a pure netlist standard to include schematics and printed circuit boards with multichip modules.

There is vigorous ongoing work in this area, and it is becoming more important as design and supplier relationships become global and organizations can no longer depend on a single supplier. The process of review required in establishing a national or international standard helps clarify any ambiguities in the meaning of a standard and helps ensure that it will allow description of product aspects that are larger than the scope of any one tool.

Design Optimization

Douglas E. Smith, Ford Motor Company

Introduction

ENGINEERING DESIGN involves the reallocation of materials and energy to improve the quality of life. This occurs in all fields of engineering, including civil, mechanical, electrical, and so forth, and often involves trade-offs based on the requirements of each application. The idea of design optimization suggests that for a given set of possible designs and design criteria, there exists a design that is the best or optimal.

Optimization is a part of everyone's life, either consciously or subconsciously. It is our nature to optimize. Investors want the largest return with the least investment or risk. Marathon runners adjust their pace to achieve the best overall time. This article discusses tools that provide a method for systematic optimization of engineering designs. The primary focus here is on the practical application of optimization technology in a computer-aided engineering (CAE) environment.

The role of the CAE simulation tool is very important in CAE-based design optimization. Computer-aided-engineering-based design optimization does in fact turn CAE *analysis* tools into CAE *design* tools by replacing traditional trial-and-error design approachs with a systematic design-search methodology. Thus, CAE computations that quantify the performance of a particular design are enhanced with information on how to modify the design to better achieve important performance criteria.

It is impossible to cover in detail the broad field of optimal design in this short article. The goal here, therefore, is to acquaint the reader with CAE-based design optimization and to provide direction on where to find additional information on the topic. Although CAE-based optimal design is applicable to a wide array of engineering design problems, much of its development has focused on structural optimization. This fact reflects the greater emphasis devoted to structural optimization in this article. Background in numerical optimization is discussed, and emphasis is placed on identifying specific challenges that are encountered when computing optimal designs with traditional CAE analysis tools. Trends in optimal design for CAE applications are also considered through a discussion of emerging technologies in this area. The interested reader is encouraged to consult the cited and Selected References at the end of the article for more information. Other approaches to engineering design that also seek the best design solution can be found elsewhere (see, for example, Taguchi methods in the article "Robust Design" in this Volume).

Douglas E. Smith, Ford Motor Company

Numerical Optimization Methods

A key component of CAE-based design optimization is the numerical optimization algorithm. These algorithms solve optimization problems with mathematical programming techniques independent of the physical application. Better designs are computed based on the design definition and the performance measures that evaluate the goodness of a design. This section focuses on numerical optimization algorithms and is intended to provide some background on how these algorithms make decisions when searching for the optimal design. The interested reader is encouraged to find more information in Ref 1, 2, 3, 4, 5.

The Nonlinear Constrained Optimization Problem

To formulate the design-optimization problem, the notion of having *design parameters* (often referred to as design variables) and *performance measures* is first considered. Design parameters define the process or structure of interest and thus provide a means for changing it to improve its performance. Performance measures that are defined as functions of the design parameters quantify the effectiveness of a given design and enter the optimization problem through the objective function (sometimes referred to as the cost function) and the constraints. The goal when solving an optimization problem is to determine the design parameters that give more desirable objective function and constraint values.

The most general single objective optimization problem is one that minimizes or maximizes an objective function F defined over the N design parameters b_i, $i = 1, 2, \ldots, N$ while satisfying both equality and inequality constraints. In mathematical terms, find:

$$\mathbf{b} = \{b_1, b_2, \ldots, b_N\}^T$$

To minimize or maximize $F(\mathbf{b})$ such that

$$\begin{aligned} &g_j(\mathbf{b}) \leq 0 \quad j = 1, 2, \ldots, n_g \\ &h_k(\mathbf{b}) = 0 \quad k = 1, 2, \ldots, n_h \\ &b_i^{\mathrm{L}} \leq b_i \leq b_i^{\mathrm{U}} \quad i = 1, 2, \ldots, N \end{aligned} \qquad \textbf{(Eq 1)}$$

where superscript T indicates the transpose. Constraint functions g and h are defined that mark the boundaries between which designs are allowed and which are infeasible. These constraints are divided into two groups, n_g inequality constraints g_j, $j = 1, 2, \ldots, n_g$, and n_h equality constraints h_k, $k = 1, 2, \ldots, n_h$. The design parameters are assembled in a vector **b,** and initial values are chosen for each component. Side constraints define the upper and lower bounds for each design variable b_i as b_i^{U} and b_i^{L}, respectively. The set of all possible designs that can be generated by adjusting the design variables between their respective upper and lower limits is called the *design space.*

A simple structural optimization example is given in Ref 1, where the cross-sectional areas of the truss shown in Fig. 1 are adjusted to obtain a design with minimum mass while satisfying constraints on the maximum allowable tension and compression stresses in each member. In this example, the cross-sectional areas A_1, A_2, and A_3 are the design variables and the mass of the structure is the objective function. Inequality constraints are formed to represent the limits on the maximum stress, and side constraints bound the range of cross-sectional areas to be considered. Truss member stresses are computed from a deformation analysis of the structure under the given loads.

Aspects of Numerical Optimization

Many aspects of the optimization problem play a major role in algorithm selection and performance, and ultimately in the success or failure of the optimization process. Below are some considerations which should be addressed when formulating an optimization problem.

The Nature of the Design Parameters. Design parameters define the structure or process being optimized and thus provide a means to alter or change it. They are often classified as *continuous* or *discrete.* Continuous design parameters are permitted to take any value over a predetermined range. A hole or fillet radius, for example, or the location of a joint in a truss structure can take any value over its permissible range. Discrete or integer variables are restricted to a finite set of values. Discrete design variables are required when design components are limited to sizes that are available, such as sheet metal gage thickness or tubing diameter. Material modulus is also a discrete design variable because there is only a finite set of materials and thus moduli that exist.

Commonly used optimization algorithms accept only continuous design variables. Therefore, the discrete variables are often treated as continuous and the discrete value that is closest to the optimal design is selected. This approach works relatively well when the distance between discrete values is small. Otherwise, *integer programming,* which limits the design variables to the predefined finite set, may be required when the distance between permissible values is large, such as when the variable defines the choice of material (Ref 1).

The Nature of the Performance Measures. Performance measures provide a quantitative measure of the goodness of a design. For each set of design parameters, there is a corresponding set of values, one for each of the performance measures. Performance measures may enter the optimization problem as an objective function or as a constraint. As the objective function, the performance measure is either minimized or maximized. For example, one may wish to minimize the mass of a structure. When the performance measure forms a constraint, it is expressed as a limit on a critical value. In structural optimization, for example, mass is commonly minimized while it is specified that the maximum stress remain below the yield value of the structure's material.

The nature of the performance measures is problem dependent. Objective and constraint functions can be linear or nonlinear functions of the design parameters and can be smooth or even discontinuous functions. General nonlinear mathematical programming algorithms are used when the order and/or smoothness of the performance measures is unknown (Ref 3). Alternatively, special algorithms have been developed when the nature of the objective and constraint functions is known. For example, linear programming methods, though applied to nonlinear problems, are very efficient when solving optimization problems where the objective and constraint functions are linear. Other specialized methods exist to efficiently solve least-squares problems that often arise when analytical models are adjusted to match experimental data.

Local and Global Optimum. The minimization problem in Eq 1 may exhibit a single global minimum and possibly many local minima. The goal of solving Eq 1 is to find the global minimum; however, in practice, in the absence of certain convexity conditions (Ref 3), one can only ensure that the solution is a local minimum. Descent search methods

(discussed later in this article) and necessary conditions for an optimum are restricted to values of nearby points, which results in a focus on local or relative minima. In practice, starting with various initial designs alleviates the concern that the global minima is missed; however, local minima are rarely a hindrance to the success of solving practical optimization problems.

Constrained versus Unconstrained Optimization. Optimization problems are classified as constrained or unconstrained. When the range of feasible designs is not restricted, the optimization problem is defined as unconstrained. Alternatively, when limitations are placed on the range of feasible designs through simple bounds on the design variables or with functions of the design variables, the problem is constrained. This distinction plays a significant role in optimization algorithm selection.

Most engineering optimization problems are constrained. Indeed, to minimize the mass of the truss structure in Fig. 1 without constraints on the stress or displacement is of little use. The unconstrained solution is meaningless because all of the areas would simply be reduced to their respective lower bounds. Deformations and stresses in such a design would be well outside their useful ranges, revealing that an ill-defined optimization problem was chosen.

Constraints can significantly affect the computed optimal design because they often force the objective function to assume a higher value. Such constraints are considered to be active because if they were removed, the objective function would decrease in value. It is useful, therefore, to know how a particular constraint influences the value of the optimal objective function value. For smooth, continuous objective functions and constraints, this is accomplished with Lagrange multipliers, which measure the sensitivity of the optimal design to changes in the constraints. Large Lagrange multipliers suggest that even slight changes in the associated constraint limit would result in a significant reduction in the objective function, whereas Lagrange multipliers near zero indicate that the constraint has very little effect on the optimal design.

Multiple- and Single-Objective Optimizations. Many numerical methods have been developed to solve the unconstrained minimization problem given in Eq 1 for a single-objective function F. Often in design, however, there are multiple objectives F_i that may need to be considered. For example, a design may be desired that minimizes both stress *and* weight. Solution techniques for multiple-objective problems, however, have not been developed to the same level as those for single-objective formulations.

Two common methods are used to convert a multiple-objective problem into one that can be solved using single-objective algorithms. The first method defines a new objective function as the weighted sum of each of the individual objectives F_i. Weighting coefficients are selected to reflect the relative importance of each F_i, and care must be taken when using this method because the individual objective with the largest sensitivity always dominates the optimization. The second method chooses the most important F_i as the objective function and defines limits on those remaining, which are then included as constraints in the optimization problem. In the latter, many single-objective optimization problems are typically solved, each with different constraint limits, to understand the behavior of the optimal design.

To a lesser extent, *Edgeworth-Pareto* optimization has been used to solve multiple-objective problems when it is difficult to determine the relative importance of the performance measures (Ref 6, 7). Additionally, compromise programming avoids the sensitivity issues of the weighted objective method by minimizing the difference between each individual objective and its respective target value in a least-squares sense (Ref 8).

Optimization Algorithms

When F is an algebraic function of the design variables, classical methods from elementary calculus can be used to compute the optimal design. For example, when Eq 1 is unconstrained, the design $\mathbf{b}^*$, which satisfies $\nabla F(\mathbf{b}^*) = 0$, and certain criteria on higher-order derivatives comprise the minimum. However, when CAE tools are used to compute the performance of a design, the convenience of having a simple algebraic function is lost because the F is not an explicit function of the design $\mathbf{b}$. Instead, the performance measures are implicitly dependent on $\mathbf{b}$ through a CAE solution. In this case, classical methods may not be applied and iterative schemes that search the design space for the optimal design parameter values must be adopted.

Searching for the Minimum. Most CAE optimal design implementations are based on computationally expensive numerical simulations to evaluate the performance measures and use descent methods to move through the design space. Commonly used descent methods are based on the same underlying structure when systematically adjusting the design variables while searching for a minimum (Ref 3). For unconstrained minimizations, an initial starting design is specified. A search direction is then determined based on some fixed rule, followed by a one-dimensional line search, which

minimizes the function along that direction in the design space. This new minimum serves as a starting point for another iteration, and the process is terminated when the objective function cannot be further reduced. The primary difference between descent algorithms is the rule used to define the search direction and the line search minimization technique. Additional distinctions are made between constrained algorithms based on the manner in which they handle the constraints.

Descent methods iteratively update designs as:

$$\mathbf{b}_{I+1} = \mathbf{b}_I + \alpha_I \mathbf{s}_I \qquad \textbf{(Eq 2)}$$

where I is the iteration number and $\mathbf{s}_I$ and α_I are the corresponding search direction and step length, respectively. The only requirement is that a positive movement along $\mathbf{s}_I$, that is, $\alpha_I > 0$, reduces the value of the objective function. Once the search direction $\mathbf{s}_I$ is selected, α_I is computed from a one-dimensional search that minimizes $F(\mathbf{b}_I + \alpha_I \mathbf{s}_I)$.

The method of steepest descent is one of the simplest unconstrained descent algorithms that provides a satisfactory result. This method is rarely used in practical problems because of its poor performance, but it is discussed here to demonstrate the basics of descent algorithms. Furthermore, more advanced descent methods have been motivated by a desire to improve the steepest descent method. The search direction of Eq 2 for the method of steepest descent is the negative of the objective function gradient, that is:

$$\mathbf{s}_I = -\nabla F(\mathbf{b}_I) \qquad \textbf{(Eq 3)}$$

Note that in this case s_I represents the direction of largest decrease in the objective function F. For each iteration, the objective function F and its gradient $\nabla F = -\mathbf{s}_I$ are evaluated. Multiple-function evaluations are then performed during the one-dimensional line search.

More advanced algorithms use higher-order information to compute search directions. Quasi-Newton methods, for example, are popular because they approximate the matrix of second-order sensitivities (the Hessian matrix) with gradient information, thus avoiding its direct computation. As an example, Fig. 2 shows the iterative solution path for the Broyden-Fletcher-Goldfarb-Shanno (BFGS) quasi-Newton algorithm on Rosenbrock's function (Ref 4).

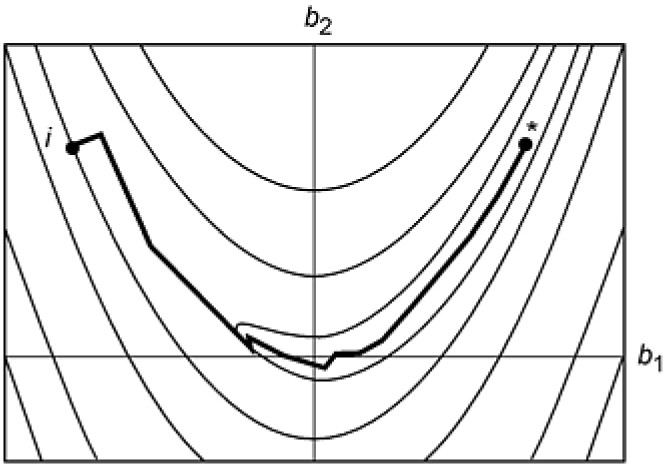

Fig. 2 Unconstrained optimization procedure using BFGS search directions. Shown is the two-dimensional Rosenbrock function $F(\mathbf{b}) = 100(b_2 - b_1^2)^2 + (1 - b_1)^2$, which has a unique minimum at (1,1). *i*, initial design; *, optimal design. Source: Ref 4

In addition to general-purpose optimization algorithms, efficient techniques of limited scope have also been developed for specific applications. The fully stressed design technique (Ref 1), for example, minimizes the mass of truss structures subject to stress constraints alone. New designs are updated based on optimality criteria, which works well in this case for

lightly redundant single-material structures. The limitations of many specific optimization methods render them useless for general applications and thus receive little attention today.

Convergence Criteria. Because numerical optimization is iterative, it is important to know when to stop, that is, when the optimization process has converged to the optimal design. Specifying the maximum number of allowable optimization iterations guarantees that the optimization process terminates; however, it does not ensure convergence is achieved. One convergence criterion is to monitor absolute and relative changes of the objective and constraint functions and the design parameters (Ref 2). Convergence can then be indicated when changes in the performance measures and/or design parameters between successive optimization iterations are within a predefined tolerance. For example, one can choose to terminate an optimization when a new design results in a reduction of mass that is within 1% of the mass for the initial design. Another important convergence criterion is provided by the Kuhn-Tucker necessary conditions for optimality (Ref 1, 2, 3). For unconstrained problems, this criterion simply requires that at the optimal design $\mathbf{b}^*$, the objective function gradient $\nabla F(\mathbf{b}^*)$ is less than a small specified constant. The Kuhn-Tucker conditions generalize for constrained optimization problems where a linear combination of the objective function gradient and the constraint gradients are used to indicate convergence (Ref 2, 3).

Analysis Solutions and Optimization Solutions. The solution of an optimization problem differs significantly from that of a typical CAE simulation. Computer-aided-engineering simulations compute the response or state of a product or process, for example, displacement or temperature; whereas the goal of an optimization solution is to define the product or process itself. Additionally, when analyzing a structure, for example, the displacement solution is almost always guaranteed and under certain conditions, it is unique. On the other hand, the existence and uniqueness of an optimal design is not ensured. Quite possibly, a design may not exist that will merely satisfy the constraints, let alone, be optimal. Furthermore, numerical methods used to solve optimization problems are often sensitive to the initial guess, and solution methods are algorithm dependent. The CAE engineer attempting to optimize his or her design should not be discouraged if the first try is not as successful as expected.

Algorithm Selection. Optimization algorithms are classified by the derivative information that they require to compute $\mathbf{s}_I$ in Eq 2, for example, zero-, first-, and second-order methods. Common unconstrained algorithms include the random search, Powell's conjugate direction, and sequential simplex methods (zero-order); steepest descent, Fletcher-Reeves' conjugate direction, variable metric, Davidon-Fletcher-Powell (DFP), and BFGS methods (first-order); and Newton's method (second-order) (Ref 1, 2, 3, 4, 5). Constrained first-order methods include reduced gradient, feasible direction, and sequential linear and quadratic programming methods (Ref 1, 2, 3, 4, 5). In CAE-based design optimization, efficient algorithms are desired because each iteration requires one or more computationally expensive numerical simulations. Higher-order algorithms are generally more efficient, that is, they require fewer iterations; however, higher-order derivatives may be impractical to evaluate. First-order methods are typically used in CAE-based design optimization because they require far fewer function evaluations than zero-order methods and avoid the Hessian evaluations required for second-order methods. Reference 4 provides further guidance for algorithm selection when solving unconstrained and linearly and nonlinearly constrained optimization problems.

Computer-Aided-Engineering-Based Optimal Design

A general framework for CAE-based optimal design is shown in Fig. 3. In CAE analysis, the response of a system (e.g., the displacement in a vehicle structure) is computed using a numerical simulation. While these results are extremely helpful in determining the state of the current design, they do not indicate what changes are required when design criteria are violated.

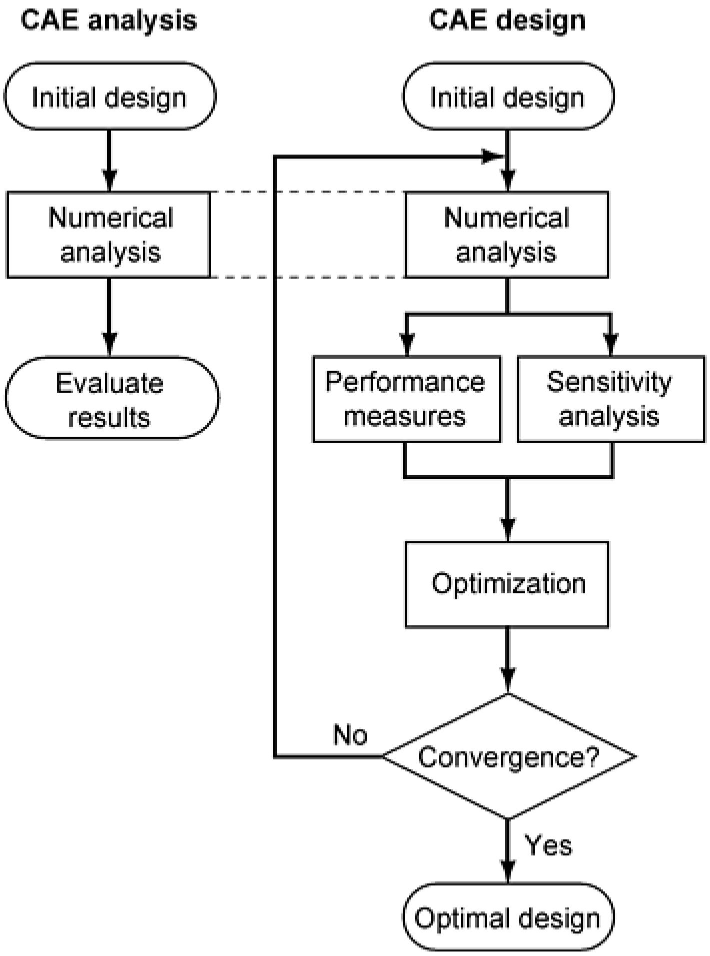

Fig. 3 CAE analysis and CAE design process

In CAE design, the simulation software is included in a loop that iteratively updates the initial design to satisfy design criteria. A CAE simulation is performed on the design, which is followed by a computation of the performance measures and the sensitivity of the performance measures with respect to the design parameters. The optimization algorithm then computes a new design, and the process is continued. To effectively integrate a CAE simulation package into an optimization environment, particular attention must be given to the simulation program, the design parameterization, describing the desired product or process attributes in terms of mathematical statements that form the optimization problem, selection of an optimization algorithm, and performing efficient and accurate design-sensitivity analyses.

Numerical Simulation

Numerical simulation packages exist that are capable of modeling many physical phenomena involving complex material models, a variety of boundary conditions, and quite arbitrary geometries. These programs take the design definition as input and evaluate the performance measures of interest (see the articles "Mechanism Dynamics and Simulation," "Finite Element Analysis," and "Computational Fluid Dynamics" in this Volume).

Most simulation codes solve partial differential equations by using the finite element method (Ref 9), or some other suitable discretization scheme. In linear structural systems under static loading, for example, the governing differential equations are discretized and assembled to form a system of linear algebraic equations of the form:

$$\mathbf{K}\mathbf{u} = \mathbf{f} \quad \text{(Eq 4)}$$

where **u** is the displacement at discrete locations in the model (e.g., nodes in a finite element analysis), **K** is the stiffness matrix, and **f** contains the applied forces.

It is of primary importance that the numerical simulation be robust and accurately represent the physical structure or system being designed. Additionally, because the numerical simulation must be fully automated, leading-edge simulation methods that require significant user interaction such as manual mesh adaptations may not be suitable for design optimization. Furthermore, the accuracy of the numerical result must be maintained over the entire design space. Recall that here merely the model is optimized and not the actual physical product. An optimal design based on an inaccurate simulation may not actually be the best design and it may violate important constraints, or both. Computer-aided engineering optimal design is not immune to the old saying "garbage in, garbage out."

Design Parameterization

The design variables in a CAE-based optimization can parameterize any quantity that serves as input to the numerical simulation. This includes material properties such as density, modulus, or viscosity; boundary conditions such as applied loads or displacements; element properties such as plate thicknesses or beam cross sections; and node point locations.

In structural optimization, a distinction is often made between sizing design variables and shape design variables. This distinction has evolved primarily as a result of implementing optimization algorithms with numerical simulation codes and has little to do with the optimization algorithm itself. Recall that optimization algorithms merely take numerical values of the design variables and performance measures as input and generate an updated design, regardless of the design parameter representation in the numerical simulation. This distinction, however, plays a significant role when transforming the design parameter data into inputs for the numerical simulation and when performing design-sensitivity analysis.

Sizing Design Parameters. A sizing design parameter can be thought of as one that does not alter the location of nodal locations in the numerical model. Material properties, boundary conditions, and element properties (such as a bar cross section or plate thickness) are all sizing design parameters. Including these parameters in the optimization process is often quite straightforward because modified values are easily updated in the numerical simulation input files.

Shape Design Parameters. Shape design parameters describe the boundary position in the numerical model and thus define nodal locations. A simple shape parameterization may define the coordinates of a single node point location (which is usually not recommended). Alternatively, adjusting a shape design variable may require that the entire numerical simulation model be remeshed. Implementing shape design variables is often more complex than that for sizing variables because the relationship between a shape parameter and each of the node locations must be specified prior to each optimization iteration. Two approaches are commonly used in shape optimization: geometry-based mesh parameterization and design basis vectors.

Geometry-Based Mesh Parameterization. In this approach, nodal locations are related to higher-level geometry data such as surface-control points or fillet radii through an automatic mesh generator. The approach has been used with mapped meshes and free meshes (Ref 10, 11, 12). Geometric-based parameterizations are well suited for integration with parametric solid modelers and are quite attractive because the optimal design is described with respect to realistic physical quantities such as hole diameters or length dimensions. The primary disadvantage is that the mesh generator must be included as part of the function and gradient evaluation process to generate new meshes for each optimization iteration. Additionally, the initial numerical simulation mesh must be generated in terms of the shape parameters, which may be a formidable task for large complex models.

The Reduced-Basis Approach. The reduced-basis method starts with a base configuration with a distinct mesh topology (i.e., the element layout and connectivity), which remains fixed during the optimization (see e.g., Ref 2). The mesh is then distorted during the optimization to form the optimal shape. New nodal coordinates are computed from:

$$\mathbf{X} = \mathbf{X}_0 + \sum_{k=1}^{n} b_k \mathbf{V}_k \qquad \textbf{(Eq 5)}$$

where $\mathbf{X}$ and $\mathbf{X}_o$ are the current and original nodal coordinates, respectively, n is the number of shape parameters, and b_k and $\mathbf{V}_k$ are the kth shape parameter and design basis vector, respectively. Each basis vector, representing the design velocity (Ref 13) $\mathbf{V}_k = \mathbf{X}_k - \mathbf{X}_o$, is of length equal to the number of nodes in the finite element model and relates the motion of each nodal coordinate to the design variable b_k. Note that $b_k = 0$, $k = 1,2,. . ., n$ gives the initial design. Numerous methods have been used to generate the design basis vectors (Ref 2, 14, 15), and any procedure that produces linearly independent nodal perturbations may be used. New mesh shapes are efficiently computed with the reduced-basis approach; however, care must be taken to ensure that mesh distortion does not degrade the numerical solution. Figure 4 from Ref 15 illustrates the reduced-basis approach for an automotive lower-control arm with five basis shapes. The optimal design is a linear combination of the initial shape and the basis shapes that minimizes mass subject to stress constraints.

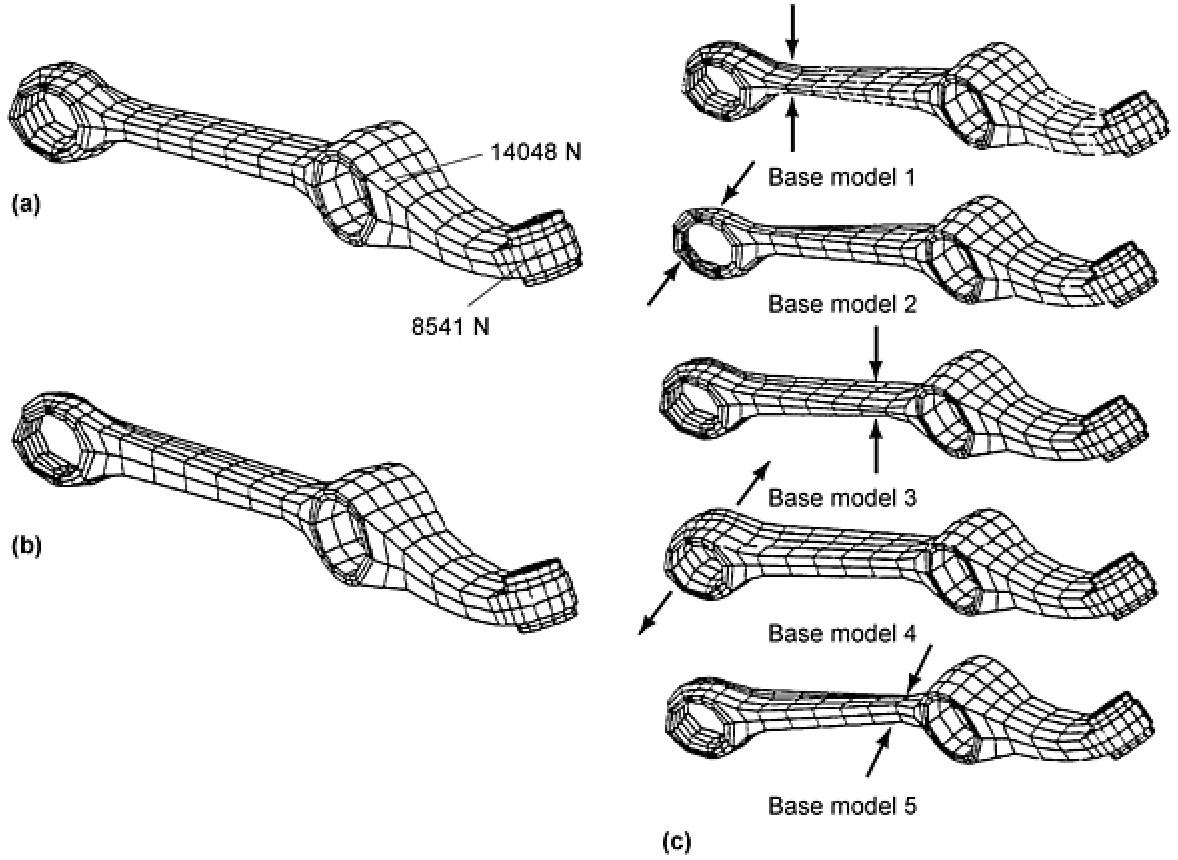

Fig. 4 Basis shapes for structural shape optimization of an automotive lower control arm. (a) Initial design. (b) Optimal design. (c) Five basis shapes of control arm model with arrows that show the location and direction of mesh distortion. Source: Ref 15

Sizing Parameters versus Shape Parameters. From the above definition, it is obvious that material properties and boundary conditions are sizing parameters; however, model geometry variables may or may not be sizing parameters depending on how they are represented in the numerical model. The thickness of a platelike structure, for example, can be parameterized by either a shape or a sizing design parameter. A sizing design parameter can be used to parameterize the element thickness property when plate elements are used in the analysis. Alternatively, when solid brick elements are used to discretize the geometry through the plate thickness, a change in thickness repositions nodal locations. In the latter

case, thickness would not be a sizing parameter. The same is true for beam-type structures whose cross-sectional properties are often represented by area or moment of inertia element constants.

Optimization Problem Formulation

The formulation of the optimization problem often defines the success or failure of a CAE-based design optimization. Even with the most accurate numerical simulation and the best optimization algorithm, the success of the optimization may be in jeopardy if Eq 1 is not properly posed. The objective function and constraints must represent the important performance measures in the product or process design. For example, formulating a structural optimization may merely require the minimization of mass subject to stiffness and stress constraints. However, defining the optimization problem to design a casting operation may not be as straightforward. Care must always be taken to guarantee that all important constraints are included in the optimization.

Design Sensitivity Analysis

As mentioned above, descent algorithms use design-sensitivity information to compute the optimal design. The design sensitivities (or design derivatives) quantify the relationships between design parameters and design-performance measures. Computing design sensitivities with respect to each design parameter must be performed accurately and efficiently so that the CAE-optimization process is feasible.

Finite Difference Approximations. Often the design sensitivity of the function F with respect to the design variable b_i is evaluated by the forward finite difference approximation as:

$$\frac{dF}{db_i} \approx \frac{F(\mathbf{b} + \Delta\mathbf{b}_i) - F(\mathbf{b})}{\Delta b_i} \qquad \textbf{(Eq 6)}$$

where $\Delta\mathbf{b}_i$ is a zero vector with the exception of the *i*th location that contains Δb_i.

Significant disadvantages of the finite difference method exist when it is used with CAE analysis tools, namely, computational expense and lack of accuracy. Performance measures and thus the system response must be evaluated $N + 1$ times to compute the design sensitivity with respect to each of the N design variables. Computer-aided-engineering models for industrial applications typically have thousands of degrees of freedom, often rendering the finite difference method impractical for optimal design because numerous expensive numerical simulations may be prohibitive. Additionally, when F is nonlinear in the design variable b_i, the finite difference approximation depends on the perturbation size Δb_i. When Δb_i is too large, discretization errors occur, and when Δb_i is too small round-off error due to limits in machine precision corrupts the sensitivity calculation. Small but nonzero sensitivities are particularly susceptible to round-off error. Accuracy may be gained at the expense of computational resources by using double precision calculations or central differencing.

Analytical Design-Sensitivity Analysis. Analytical approaches for sensitivity computations avoid costly perturbation methods by differentiating the governing equations of the system with respect to the design parameters (Ref 13, 16). Here only steady-state solution methods are considered. Note that a performance measure in the optimization problem may be an explicit function of the design parameters **b** or it may depend on the response **u,** which is implicitly dependent on **b** through Eq 4. In this case, the performance measure F can be rewritten as:

$$F(\mathbf{b}) = F(\mathbf{u}(\mathbf{b}), \mathbf{b}) \qquad \textbf{(Eq 7)}$$

where both the implicit and explicit dependence of the performance measure F on the design **b** is exposed. Assuming sufficient smoothness, the design sensitivity of F with respect to the design variable b_i, $i = 1,2,\ldots, N$ is calculated from:

$$\frac{dF}{db_i} = \frac{\partial F}{\partial \mathbf{u}} \cdot \frac{d\mathbf{u}}{db_i} + \frac{\partial F}{\partial b_i} \qquad \textbf{(Eq 8)}$$

where $\nabla F = \{dF/d\mathbf{b}\}^T$. The first term in Eq 8 addresses the implicit dependence of F on the design **b** and the last term quantifies the explicit dependence of F on **b.** For example, the mass of a structure does not depend on the displacement

response **u** so that only $\partial F/\partial \mathbf{b}$ is nonzero. Alternatively, when the displacement at a node is the performance measure, $\partial F/\partial \mathbf{b} = 0$, and the design sensitivity only has an implicit contribution.

The explicit derivatives $\partial F/\partial \mathbf{u}$ and $\partial F/\partial b_i$ are readily available once the design engineer parameterizes the design and defines the performance measures. The difficulty in evaluating dF/db_i in Eq 8, however, arises from the presence of the implicit response sensitivity $d\mathbf{u}/db_i$, which is defined through the discretized governing equations (see e.g., Eq 4). Therefore, to compute dF/db_i, the implicit response derivative $d\mathbf{u}/db_i$ must be evaluated using the direct differentiation method or eliminated from Eq 8 with the adjoint method (see e.g., Ref 13, 16).

The Direct Differentiation Method. In the direct differentiation method, a pseudo problem is formed for each design parameter by differentiating Eq 4 with respect to each b_i, which after rearranging gives:

$$\mathbf{K}\frac{d\mathbf{u}}{db_i} = -\frac{d\mathbf{K}}{db_i}\mathbf{u} + \frac{d\mathbf{f}}{db_i} \qquad \textbf{(Eq 9)}$$

Thus computing the response sensitivity $d\mathbf{u}/db_i$ amounts to solving an alternative system of equations that resembles the original analysis of Eq 4. Note that the pseudo problem of Eq 9 must be performed for each b_i where the pseudo load $-d\mathbf{K}/db_i\, \mathbf{u} + d\mathbf{f}/db_i$ replaces the load vector **f** in Eq 4 and the computed response **u** in Eq 4 becomes the pseudo response $d\mathbf{u}/db_i$. The design-sensitivity computation for dF/db_i then follows from Eq 8 where a simple vector dot product and vector addition are performed for any number of performance measures F.

The Adjoint Variable Method. In the adjoint variable method, the implicit response derivative $d\mathbf{u}/db_i$ in Eq 8 is eliminated by first solving the adjoint problem:

$$\mathbf{K}^T\boldsymbol{\lambda} = \left\{\frac{\partial F}{\partial \mathbf{u}}\right\}^T \qquad \textbf{(Eq 10)}$$

for the adjoint variable vector λ and then evaluating the design sensitivity dF/db_i as:

$$\frac{dF}{db_i} = \frac{\partial F}{\partial b_i} - \boldsymbol{\lambda} \cdot \left[\frac{d\mathbf{K}}{db_i}\mathbf{u} - \frac{d\mathbf{f}}{db_i}\right] \qquad \textbf{(Eq 11)}$$

One adjoint variable vector λ is computed for each performance measure F by assembling the adjoint load $\partial F/\partial \mathbf{u}$ and solving the alternative system of Eq 10 that again resembles Eq 4. The design sensitivity dF/db_i is then evaluated with a simple vector dot product computation and a vector addition for each design variable as shown in Eq 11.

Selection and Use of Methods. In contrast to the finite difference method, both the direct differentiation and adjoint methods are efficient and accurate. For example, when the inverted stiffness matrix $\mathbf{K}^{-1}$ (or its transpose $\mathbf{K}^{-T}$) has been stored, the implicit response sensitivity $d\mathbf{u}/db_i$ and the adjoint variable vector λ are efficiently computed from Eq 9 and 10, respectively. Furthermore, when the same discretization method is used in the analysis and the sensitivity analysis, the resulting sensitivities are exact for the numerical problem being considered. Additionally, even though the two methods enjoy quite different derivations, they give identical results (Ref 17). In fact, the same explicit sensitivities (i.e., $\partial F/\partial \mathbf{u}$, $\partial F/\partial b_i$, $d\mathbf{K}/db_i$, and $d\mathbf{f}/db_i$) are required for both calculations. The choice of using one method over the other is an efficiency issue that depends on the optimization problem. When the number of performance measures (including the objective function and all of the constraints) exceeds the number of design variables N, the direct differentiation method is more efficient. Conversely, when N exceeds the number of performance measures, the adjoint variable method is preferred (Ref 16).

Analytical approaches to design-sensitivity analysis are far superior to the brute force finite difference method, especially for large models or when the original simulation is either nonlinear or transient. However, they must be fully integrated into the simulation program to be effective, which will likely be a lengthy implementation and require access to the simulation source code. Variations of these analytical approaches exist, for example, natural frequency and mode shape sensitivities, the semianalytical approach, and continuum sensitivity analysis, which may be used to more efficiently compute design sensitivities in other design problems (see e.g., Ref 1, 12, 13, 18). Automatic differentiation methods

have also been developed that simplify the design-sensitivity computations by differentiating Fortran programs used in the CAE analysis (Ref 19).

Measuring the Performance of the Optimization

The numerical simulations that evaluate each design in a CAE-based optimization are often complex and computationally expensive. Because the correct optimal design needs to be obtained in a reasonable amount of time, the performance of the optimization process, which includes the algorithm itself and the simulation software, should be considered. The performance of the optimization process may be measured in terms of robustness, accuracy, and efficiency.

The robustness of a CAE-based optimization can be defined as the ability of the code to satisfy the convergence criteria within a reasonable number of optimization iterations (Ref 20). To achieve robustness, the optimization problem must be well posed and must employ a robust optimization algorithm.

The optimization is required not only to converge, but it must converge to the correct design. As discussed previously, the accuracy of the CAE simulation must ensure that the optimal simulation results are the optimal reality. However, an accurate CAE model alone does not guarantee that the desired design has been achieved. Incorrect gradients corrupt the design process and improper optimization problem definitions may miss important constraints. In the latter case, what is asked for is achieved, but it may not be what is wanted. The CAE optimization process should be tested on problems with known solutions, and for more complex problems sound engineering judgement should always be used when assessing an optimal design.

One of the most important performance measures of a CAE optimization is the computational effort required to obtain the optimal design. The total number of function evaluations and the number of optimization iterations are both key indicators regarding the success of the optimization process. The final arbiter that often determines if the optimization is efficient enough, however, is the total amount of time required to obtain an optimal design. Schedules and computer resources may render a CAE-based optimization infeasible even though relatively few function evaluations are needed.

Software Packages for CAE Optimal Design

Commercial programs exist, particularly in structural optimization, which integrate simulation, optimization, and design-sensitivity analysis into a single design environment. It is beyond the scope of this article to discuss details of the optimization programs available today; however, Ref 1 discusses some optimization software, including structural optimization programs. Additionally, an extensive discussion of programs for structural optimization developed in Europe (Ref 21) and by North American government agencies and commercial suppliers (Ref 22) is available elsewhere.

Outside of structural optimization, fully integrated optimization packages are rare. To optimize designs that are governed by other physical phenomena, the CAE designer must integrate the appropriate numerical analysis and optimization software. It is common practice to wrap an optimization algorithm around a numerical analysis package that solves the particular problem of interest. For these applications, it is often not fruitful to set out to develop an optimization algorithm or even to write a program that implements an existing algorithm because general computer codes are available that allow the user a variety of choices (see e.g., Ref 8, 23, 24, 25). Function evaluations must avoid user intervention so that the preprocessing, simulation, postprocessing, and design sensitivity analyses must be fully automated. When finite differencing is used for sensitivity evaluation, the integration of one's favorite analysis code with an existing optimization subroutine is straightforward. Alternatively, an extensive implementation may be needed if analytical sensitivities are required.

Approximate Optimization Techniques

When the number of design variables N is small (e.g., less than 10), approximate optimization techniques (also referred to as response surface methods) reduce the number of expensive CAE simulations when compared to direct optimization using finite difference gradients (Ref 2, 26). Approximate techniques use simple expressions such as (Ref 2):

$$F(\mathbf{b}) \approx F(\mathbf{b}^0) + \nabla F(\mathbf{b}^0) \cdot \delta\mathbf{b} + \frac{1}{2}\delta\mathbf{b} \cdot \mathbf{H}(\mathbf{b}^0)\,\delta\mathbf{b} \qquad \textbf{(Eq 12)}$$

to approximate the objective function and the constraints about $\mathbf{b}^0$ where F represents any performance measure in the optimization problem of Eq 1. In Eq 12, ∇F is the gradient vector, $\mathbf{H}$ is the Hessian matrix, and $\delta\mathbf{b} = \mathbf{b} - \mathbf{b}^0$. These

approximations give an overall view of the design space and can be used to smooth otherwise discontinuous performance measures. Additionally, response surface models simplify the process of integrating several design codes in multidisciplinary optimization (Ref 26, 27).

The approximate optimization process starts by analyzing multiple designs using CAE simulations to generate design sets. Each design set consists of objective and constraint function values corresponding to a particular design **b.** Approximations such as in Eq 12 are then fit to the available design information, and an optimization is performed using these simple approximate functions rather than expensive CAE simulations. The optimal design for the approximate problem is then evaluated with a CAE simulation, and the approximation is updated using this new response data. The iterative process continues until convergence is achieved.

The application of approximation methods varies based on the choice of optimization algorithm, the method for selecting designs for full CAE simulation, and the sequence of updating terms in Eq 12 (Ref 2, 8, 26, 28). For example, the number of design sets N_d that are required to define Eq 12 is $L = 1 + N + N(N + 1)/2$. For $N_d < L$, only a partial fit of Eq 12 is possible, whereas when $N_d > L$, a least-squares fit is commonly performed to determine the best approximate response surface for the data sets that are available. Weighting is often used to place more emphasis on designs nearest the one with the best overall performance. Designs for CAE simulation may be chosen near the nominal design $\mathbf{b}^0$ using finite difference perturbations that results in a second-order Taylor series expansion for Eq 12. This selection of designs may render an approximation that is only good near $\mathbf{b}^0$ and poorly represents the rest of the design space. Alternatively, designs may be randomly distributed throughout the design space, making Eq 12 merely a quadratic polynomial approximation to the design (Ref 2), which may be good at predicting overall trends but possibly miss local features. Furthermore, care must be taken when selecting candidate designs **b** for CAE simulation because linear independence between the design sets must be maintained.

Structural Optimization

Structural optimization enjoys a rich history of advances dating back to the 18th century and possibly further if one considers the beam designs by Galileo Galilei (Ref 29). Early optimization techniques searched for design functions that described the properties of the structure much as the analysis methods of that time solved for displacements and stresses analytically. With the advent of high-speed computers in the late 1950s and early 1960s, numerical solution methods such as the finite element method and numerical optimization algorithms emerged. The analytical solutions and analytical optimizations were replaced by numerical discrete solutions and numerical optimization methods, opening the field of what is now considered structural optimization.

The aircraft, aerospace, and automotive industries have been the primary drivers for structural optimization. Here, the principal focus has been on weight reduction because weight affects many attributes of the design including cost, performance, and fuel economy. Constraints are often imposed to maintain durability and vibration characteristics. Much of the developments in sizing and shape design, design sensitivity analysis (Ref 13), and more recently, topology design (Ref 30) have been pursued to support structural optimization.

A structural optimization example is shown in Fig. 5 (Ref 12). A turbine wheel is designed for minimum mass moment of inertia while satisfying constraints on the maximum von Mises stress. Forces acting on the wheel include centrifugal loads from the turbine blades (not shown) and thermal loads from the hot gases that drive the wheel. By adjusting the shape of the wheel structure in the optimization, the mass moment of inertia and the maximum stress are reduced by 12.5% and 35.0%, respectively.

Emerging Technologies

Computer-aided-engineering-based design optimization has evolved along the classical path of first being researched by universities and government agencies, then demonstrated with special-purpose programs and finally, to some extent, marketed by commercial software vendors. There are still, however, hurdles that must be overcome for widespread use of the technology, and numerous extensions and enhancements are still to be discovered. Below are a few emerging research areas in the optimization community.

Topology Optimization

Topology optimization, a form of structural optimization, computes the best geometric configuration or layout of a structure (Ref 30, 31). It is most beneficial early in the design cycle when least is known about the design and when design changes are easily accommodated. Results from a topology optimization help determine the placement and number of holes and/or stiffening members, and therefore provide a good starting point for further structural refinement via sizing and shape optimization.

The goal of topology optimization is to determine where to place material and where to leave the structure void of material. Two topology optimization approaches have emerged, one based on material homogenization and the other on material density. In the homogenization method (Ref 32), the dimensions and orientation of a void in the material of each element are adjusted as a function of the design variables. Effective material properties are then computed by smearing or homogenizing over each element so that its stiffness and density take on values between those of the void and the solid. The density method (Ref 33, 34) is often considered an engineering approach where the modulus and density of each element are parameterized as functions of the element's design parameter. The element's density is chosen to be a linear function of it's design parameter, and the relationship between it's elastic modulus and this parameter is typically of higher order. This implementation tends to drive the material to become either solid or void by penalizing intermediate designs.

The homogenization method enjoys a rigorous mathematical derivation and has been applied to design composite materials. Homogenization requires three design variables per element for planar structures, which carries with it an undesirable computational burden for practical applications, especially if composites are not to be considered in the final design. The density method works well for isotropic materials, is easily implemented using commercial finite element programs, and accepts multiple objectives and constraints. It also requires only one design variable per element.

Figure 6 (Ref 35) illustrates the use of the homogenization approach of topology design to optimize the material distribution in a frame structure. The first natural frequency is maximized subject to a constraint on the total mass of the structure. In this analysis, the first eigenvalue was increased by 910% with the addition of 66.6% of material distributed in an optimal manner within the frame structure.

(c) Optimal material distribution from topology optimization as computed and after filtering the topology image to simplify the structural layout. Source: Ref 35

Materials Processing Optimization

Advances in numerical methods for materials processing analysis have recently made it possible to optimize both a structural component and its manufacturing process. Optimal design has been applied to metal forging (Ref 36), casting (Ref 37), and welding (Ref 38), and to polymer injection molding and sheet extrusion (Ref 39).

Formulation of the optimization problem statement for these applications is critical because all key physical process attributes must be properly represented in the objective function and constraints. Design parameters and performance measures are often unique to the particular processing operation. Furthermore, additional complexity exists because the numerical simulations for these processes are typically nonlinear and transient and often require a coupled simulation to accurately model the interaction between different physical phenomena. Computations can be quite extensive and require accurate and efficient analytical design sensitivities so that the design problem is tractable.

Morthland et al. (Ref 37) optimized the riser design for a hammer casting using design optimization and solidification simulations. Design variables parameterized the shape of the riser shown in Fig. 7, and design sensitivities were computed using a transient direct method. The riser volume was minimized to reduce manufacturing costs. In the same analysis, constraints on the freezing times of the elements labeled in Fig. 7(a) were defined to enforce directional solidification in the section of the hammer casting leading to the riser. The riser volume was decreased by 42% in the optimization, and the liquid region near the end of the solidification process was moved from the hammer to the riser (thus avoiding porosity in the hammer itself).

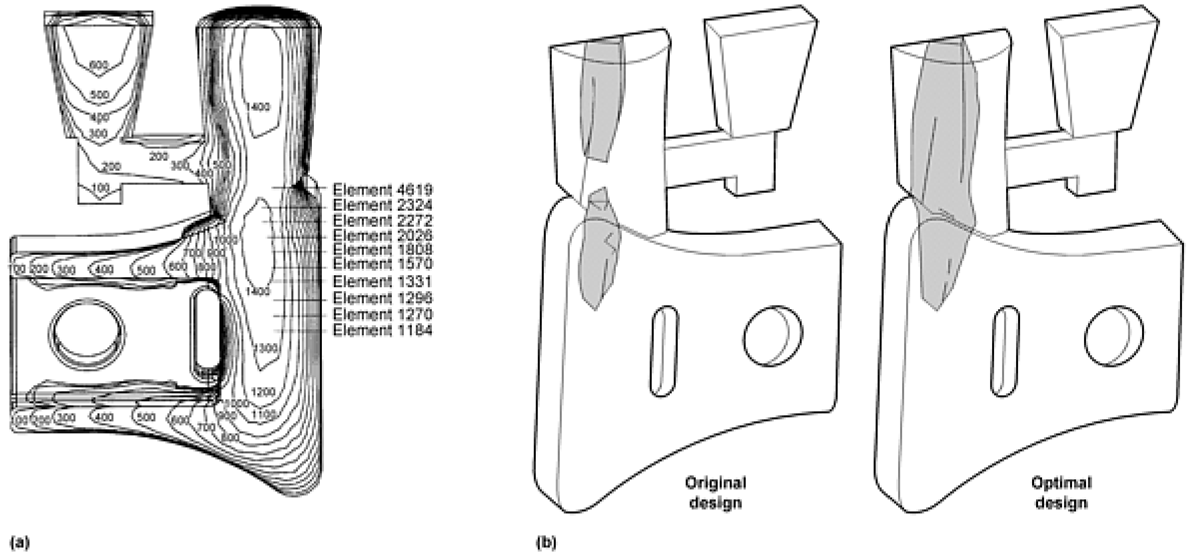

Fig. 7 Optimal riser design for metal casting. (a) Computed solidus isochrones on the symmetry plane for the initial infeasible design. Also shown are the elements specified to enforce directional solidification. (b) Casting regions with liquid after 1565 s for the original (infeasible) and optimal designs. Source: Ref 37

Multidisciplinary Optimization

Multidisciplinary optimization has recently received much attention in areas such as aerospace, aircraft, and automotive design. Various physics, each of which may require a unique analysis program and, most probably, analytical expertise, must be merged to compute the performance measures and complex couplings that are characteristic of these designs (Ref 40). Aircraft design, for example, must include the interactions between disciplines such as aerodynamics, dynamics, aerolastic stability, structures, controls, and acoustics (Ref 18).

Key issues that must be addressed when performing multidisciplinary design are computational cost, convenience of implementation, data exchange, integration across various design and analysis methods and possibly across engineering organizations, and the use of *black-box* analysis tools. Several approaches have been proposed to solve multidisciplinary optimization problems (Ref 41). *All-at-once* procedures combine two or more disciplines by addressing each design criterion in a single optimization problem statement similar to that in Eq 1. This approach may be prohibitive for large-scale applications and is difficult to integrate in moderate or large engineering organizations. Alternatively, multilevel decomposition methods have been developed that replace the large single optimization problem with several subproblems and a coordination problem that is used to maintain the couplings between the subproblems (Ref 42). These methods are designed to promote disciplinary autonomy while achieving interdisciplinary compatibility and are most useful when couplings between the various disciplines can easily be broken or neglected (Ref 41).

One implementation of multidisciplinary optimization for automotive applications employs design sensitivity analysis information to approximate changes in attribute responses (Ref 27). The method considers design attributes such as noise, vibration, and harshness (NVH), durability, safety, vehicle dynamics, and manufacturing, which must all be satisfied in the design process. The method accepts data in the form of design sensitivities and function values from independent analyses. Thus, analysis results from different engineering organizations are easily merged in order to perform the multidiscipline optimization.

Global Optimization Using Stochastic Search Methods

Stochastic search algorithms compute globally optimal designs in a manner that is quite different from the mathematical programming methods discussed previously. Two stochastic search methods, genetic algorithms and simulated annealing, mimic processes found in nature. Genetic algorithms (Ref 43) are based, in principle, on Darwin's theory of survival of the fittest and evolve generations of designs with bias given to the best members in a population. Simulated annealing techniques (Ref 44) are quantitatively based on the behavior of particles in thermal equilibrium where a gradual lowering of the temperature causes atoms to assume a lower, more orderly, energy state analogous to an optimal design.

One advantage of using stochastic search methods is that they are readily adapted to new problems because only function evaluations are required; that is, design sensitivities are not needed. These search algorithms often possess a mechanism for accepting less optimal designs during the search process, which provides a means to escape from a local optimum and find the global minimum. Furthermore, both continuous and discrete design variables can be used in the optimization. The computational requirements for stochastic searches is usually not as great as that for random (zeroth order) searches. However, they often require hundreds of function evaluations making them impractical for optimization problems that rely on computationally expensive CAE simulations. Examples of stochastic searches in structural optimization are given in Ref 45.

Conclusions

Over the past 30 years, numerical optimization and CAE have individually made significant advances and have together been developed to impact the way engineering components and systems are designed. This article has attempted to give a brief overview of current CAE-based optimal design and provide a starting point for further study and/or implementation of these methods. While issues still remain and advanced research and development continue, practical design applications indeed demonstrate that optimization is no longer a subject restricted to the researchers.

Dimensional Management and Tolerance Analysis

Mark Craig, Variation Systems Analysis, Inc.

Introduction

DIMENSIONAL MANAGEMENT is an engineering methodology combined with computer-simulation tools used to improve quality and reduce cost through controlled variation and robust design. The objective of dimensional management is to create a design and process that "absorbs" as much variation as possible without affecting the function

of the product. Dimensional management accomplishes this through optimal selection of datums, feature controls, assembly methods, and assembly sequence.

Companies that design and produce multicomponent assemblies must effectively manage the cost, timing, and quality related to manufacturing and assembly variation if they are to survive in an increasingly competitive world market. Dimensional management differs from the traditional design practice of assigning tolerances to drawings prior to release. In traditional design practice, the design engineer assigns tolerances on component parts just before drawing release. The values of the tolerances might be based on past experience, best guess, or anticipated manufacturing capability. In some cases a one-dimensional tolerance stack-up analysis is performed to determine if an assembly limit would be exceeded when adding the tolerances in any given one-dimensional direction. This approach is still commonly used in many engineering organizations today.

The potential limitations of this traditional approach include:

- The tolerances are assigned at the end of the design cycle where it is too late to make any changes in the design and/or assembly tooling to help desensitize the design and process to variation.
- One-dimensional tolerance analysis does not represent the three-dimensional geometries of the component parts and assemblies.
- The manufacturing, assembly, quality, and supplier team may not be involved during the initial design phase of the product.

The dimensional management process provides an advantage over this traditional approach by combining three-dimensional tolerance analysis and measurement systems within an integrated computer-aided engineering (CAE) system.

Dimensional Management and Tolerance Analysis

Mark Craig, Variation Systems Analysis, Inc.

Dimensional Management Process

The dimensional management process follows six basic steps as described below.

Step 1: Define Product Dimensional Requirements. The first step in the process is to clearly define the dimensional requirements of the product early in the concept-design phase. This step involves formally documenting the assembly variation targets for the entire product (i.e., assembly specifications). These targets can be identified based on product functional requirements (i.e., seal pressure, leaks, interference concerns, etc.), competitive benchmarks (i.e., fit and finish of competitive products), or quality improvement goals determined from known build problems of an existing, similar product. The product dimensional requirements must be "signed off" by all members of the product team including design, manufacturing, assembly, quality, and suppliers. This process ensures that all members of the product team have a consistent understanding of the product build requirements.

Step 2: Determine Process and Product Requirements. During the design phase of a product, there are only three ways to determine if the product and process, as designed, meets the dimensional product requirements: (1) Make an educated guess. (2) Build many assemblies using production tools and measure the results. (3) Use a computer simulation model to simulate the design and build of the product including the three-dimensional geometry, geometric dimensioning and tolerancing schemes, assembly method variation, assembly sequence, and any known part deflection or distortion.

As previously mentioned, traditional tolerance analysis relies on simple one-dimensional analysis and the "educated guess." Most variation problems are resolved during the prototype building cycle before committing to production tools. This approach lengthens development time.

Simulation of the assembly process is another way to determine if the product and process, as designed, meets the dimensional product requirements. The simulation should predict the amount of assembly variation that is expected to occur and the major contributors to the variation.

Step 3: Ensure Accurate Documentation. Dimensional management product documentation includes: geometric dimensioning and tolerancing schemes, assembly methods, locating schemes, and statistical process control (SPC) checkpoints. The objective is to make sure that the product specifications used as input to the simulation in step 2 are the same specifications documented in step 3 and are fully understood and used by those individuals performing steps 4 to 6.

Step 4: Develop a Measurement Plan that Validates Product Requirements. The simulation performed in step 2 proves that the design, manufacturing, and assembly process as specified meets all dimensional product requirements. The next step in the process is to develop a measurement plan that validates these requirements.

The measurement plan must directly reflect the documented tolerancing schemes and assembly methods represented in the simulation. The features identified as critical in the simulation need to be measured using the same datum reference and feature constraints as defined in the analysis. This approach determines if manufacturing capability achieves actual design intent.

If there is a "disconnect" between the measurement plan and the analysis, the actual measurement data cannot be used to determine if the product variation is acceptable to meet final assembly product objectives. For example, if an organization specifies tolerances as three-dimensional zones, and the assembly is analyzed using one- or two-dimensional tolerance analysis, and then the component parts are checked according to three-dimensional zones, there is no indication if the tolerance zones specified are really required to meet overall product assembly requirements.

At the completion of step 4 one should be confident that the product will build within the functional specifications identified in step 1 if:

- The simulation model was created correctly (i.e., no errors).
- The design and process as specified contains all identifiable sources of variation.
- The manufacturing capabilities achieve design intent.

In almost all cases the design and process as specified do not contain all sources of variation. Design and build process documentation typically provides a tolerance specification on component parts and a final build specification as the only sources of variation. Part deflection, weld distortion, gravity effects, fixture variation, and so forth are typically not included in the released design specifications, yet in actual production these variation contributors exist. The dimensional management process helps identify these additional sources of variation and provides a method to capture and quantify their effect on functional requirements.

Step 5: Establish Manufacturing Capabilities versus Design Intent. The measurement plan is next implemented, and capability studies are performed on component parts to ensure component variation meets design intent. Assembly tool validation and verification are also performed to determine if the assembly method variation (between-component variation) meets design intent.

Step 6: Establish Production-to-Design Feedback Loop. In those areas where manufacturing or assembly capability does not meet design intent, the actual production variation data can be input into the simulation model to:

- Determine if the "out-of-spec" conditions adversely affect the overall product function.
- Evaluate several designs or process changes to help reduce the effect that each of the "out-of-spec" conditions has on product function.
- Provide quantification of additional sources of variation that exist in the process that should be specified in the design and process intent documentation.

Since the simulation model comprehends the interactive effects of geometry, assembly methods, and measurement schemes, the model can provide a tool to help ensure that effort is put forth in those areas that will directly improve the overall product.

Mark Craig, Variation Systems Analysis, Inc.

General Requirements and Simulation

An organizational structure that supports concurrent engineering, computer-aided-engineering simulation tools, and a dimensional management process directly integrated with the existing design-and-build processes are all necessary ingredients. This activity cannot be a part-time job for the design engineer. It requires a dedicated resource to work with the entire product team from concept to production to ensure continuity.

A three-dimensional simulation model is an important consideration in a dimensional management process. Without a simulation model, there seems to be no practical way to determine if the design and process meet the build objectives. Also, just by following the steps necessary to create a simulation model, the product team identifies potential problem areas in the assembly early in the design phase of the product. The creation of a simulation model also forces cross-functional communication as described below.

A functional feature product model contains the three-dimensional surface features on the component parts in an assembly defined by the functional geometric dimensioning and tolerancing (GD&T) scheme (Fig. 1). Features are related to one another according to the GD&T datum references and feature control constraints (i.e., form, orientation, location, and size). These features are the same features that are important for assembly methods, manufacturing process, fixturing, and SPC checking. Identifying them up front in the design process is extremely valuable for the overall product team. (Additional information about GD&T, including a definition of symbols used, is provided in the article "Documenting and Communicating the Design" in this Volume.)

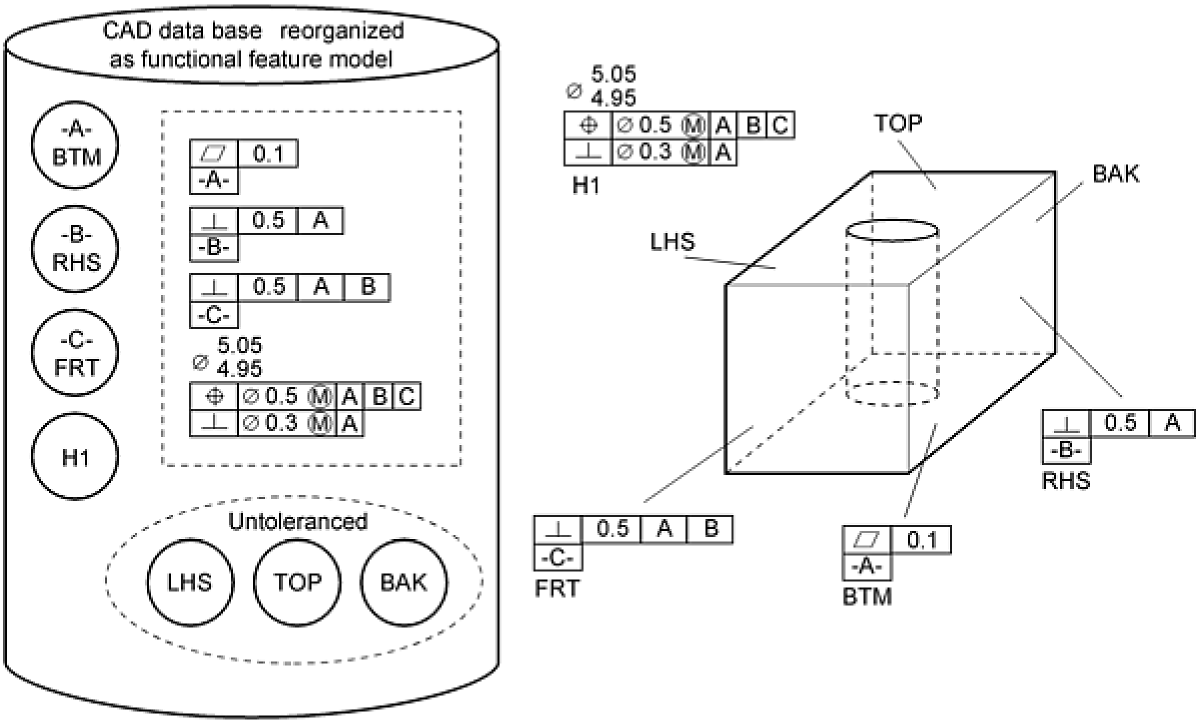

Fig. 1 Functional feature model

Component part variation is simulated based on the three-dimensional features and constraints defined in a functional feature product model (Fig. 2). Each feature is allowed to vary, within its defined zone, according to the feature

control constraints established by GD&T. Simulating the variation of the component parts using the same three-dimensional geometry and constraints defined by GD&T provides the link between the component part, downstream measurement scheme, and the assembled product dimensional requirements.

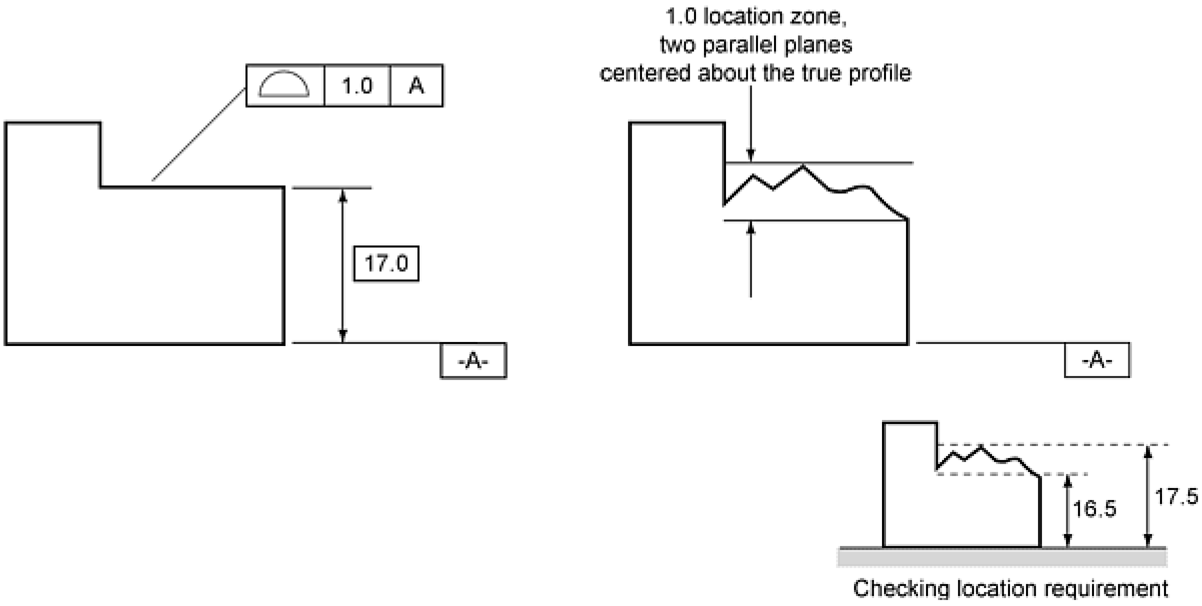

Fig. 2 Component part variation

Assembly method variation (or between-component variation) is defined according to how the component parts are assembled (Fig. 3). For example, fixtures, bolt-to-hole clearances, weld sequence, clamp sequence, and gravity effects all should be comprehended in the model and have a major influence on desensitizing the design to variation. The dimensional management process requires the manufacturing assembly engineers to work with the design team, early in the design phase, to determine optimal locating schemes for controlling variation and reducing the cost of manufacturing.

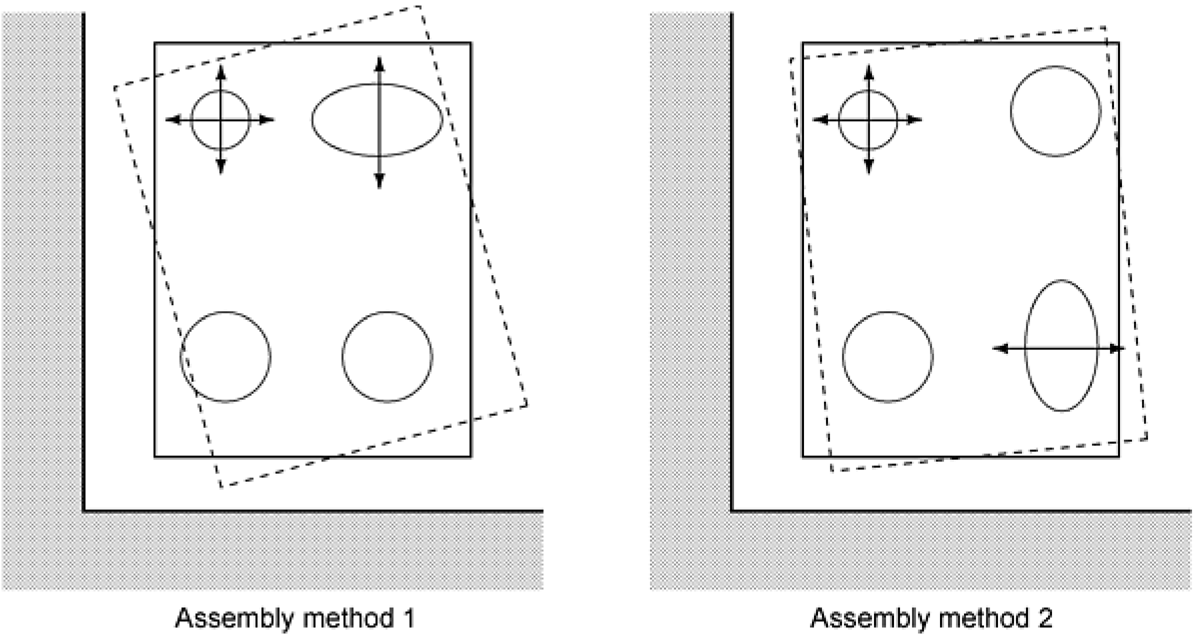

Fig. 3 Assembly method variation

Measurement Schemes. Critical assembly measurements (product dimensional requirements) are defined during concept design. This provides the product team with a well-defined variation goal and provides the quality group with an early indication of what will be required for prototype and production measurement activities.

Assembly sequences are simulated to take into account the effects of subassemblies, assembly method order, and fixtures. Defining the assembly sequence basically defines the process flow through the plant.

Conclusions

A three-dimensional simulation model is often key in dimensional management. Several tolerance analysis simulation packages are commercially available. These packages are integrated with existing CAE systems to provide a direct link between the three-dimensional product design model and the functional feature product model.

Traditional tolerance analysis focuses on determining if the tolerances assigned on a completed design meets assembly objectives. The tolerances assigned did not relate to the actual manufacturing process, and the tolerance analysis did not reflect the assembly methods.

Dimensional management focuses on creating a robust design that can absorb as much variation as possible without affecting product function. The dimensional management process ensures that the design and process, as specified, meets objectives and that there is a coordinated measurement plan to help resolve any manufacturing build problems during production. Dimensional management is required to achieve continuous improvement in product quality, cost, and design-to-production cycle time. Real concurrent engineering cannot exist without this process.

Documenting and Communicating the Design

Gary Vrsek, Ford Research Laboratory

Introduction

REDUCING THE TIME TO MARKET for new products is increasingly important. The engineering process can be very complex, involve many people, and require spending large sums of money. Producing a high-quality product initially and maintaining that quality level is more important than ever. The purpose of this article is to describe how documentation supports the process of bringing a product to market, who uses the information, and how it serves as a key form of communication. Volumes have been published on basic drafting principles and techniques, and overall, industry standards have been very effective. Clear and complete documentation is imperative. Properly creating and organizing the necessary documents can greatly facilitate the product development process.

Even the simplest part or product requires geometric definition in some form of drawing and documentation, to bring it from concept to production. However, the documentation needed goes well beyond a few drawings. A company's reputation for delivering a quality product depends on how well the design intent is communicated to the necessary people downstream in the process. It is very important to understand exactly what information is required for individual tasks such as fabrication, machining, or assembly.

An important early step is to define who is involved in the product development effort. Often, the specific configuration of the product will dictate the kinds of disciplines that will be required. For a particular product, the parties involved might include manufacturing, finance, inspection, stamping, assembly, material control, casting, and machining. Each area has its own specific information needs.

Background

The Traditional Design Process. Product design and its accompanying documentation have been approached many different ways through the years. Traditionally, the engineering process has been departmentalized and hierarchical (Fig. 1), with separate entities responsible for product-related engineering, drafting, process engineering, tool engineering, and tool design (Ref 1). A formal request process to initiate a new design or change existing drawings has been typically used to organize and track the work in larger organizations. Even though drafting standards have varied greatly among companies, standards are more important than ever and serve to pass on the experience gained from past projects (see the section "Standards" in this article and the article "Designing to Codes and Standards" in this Volume).

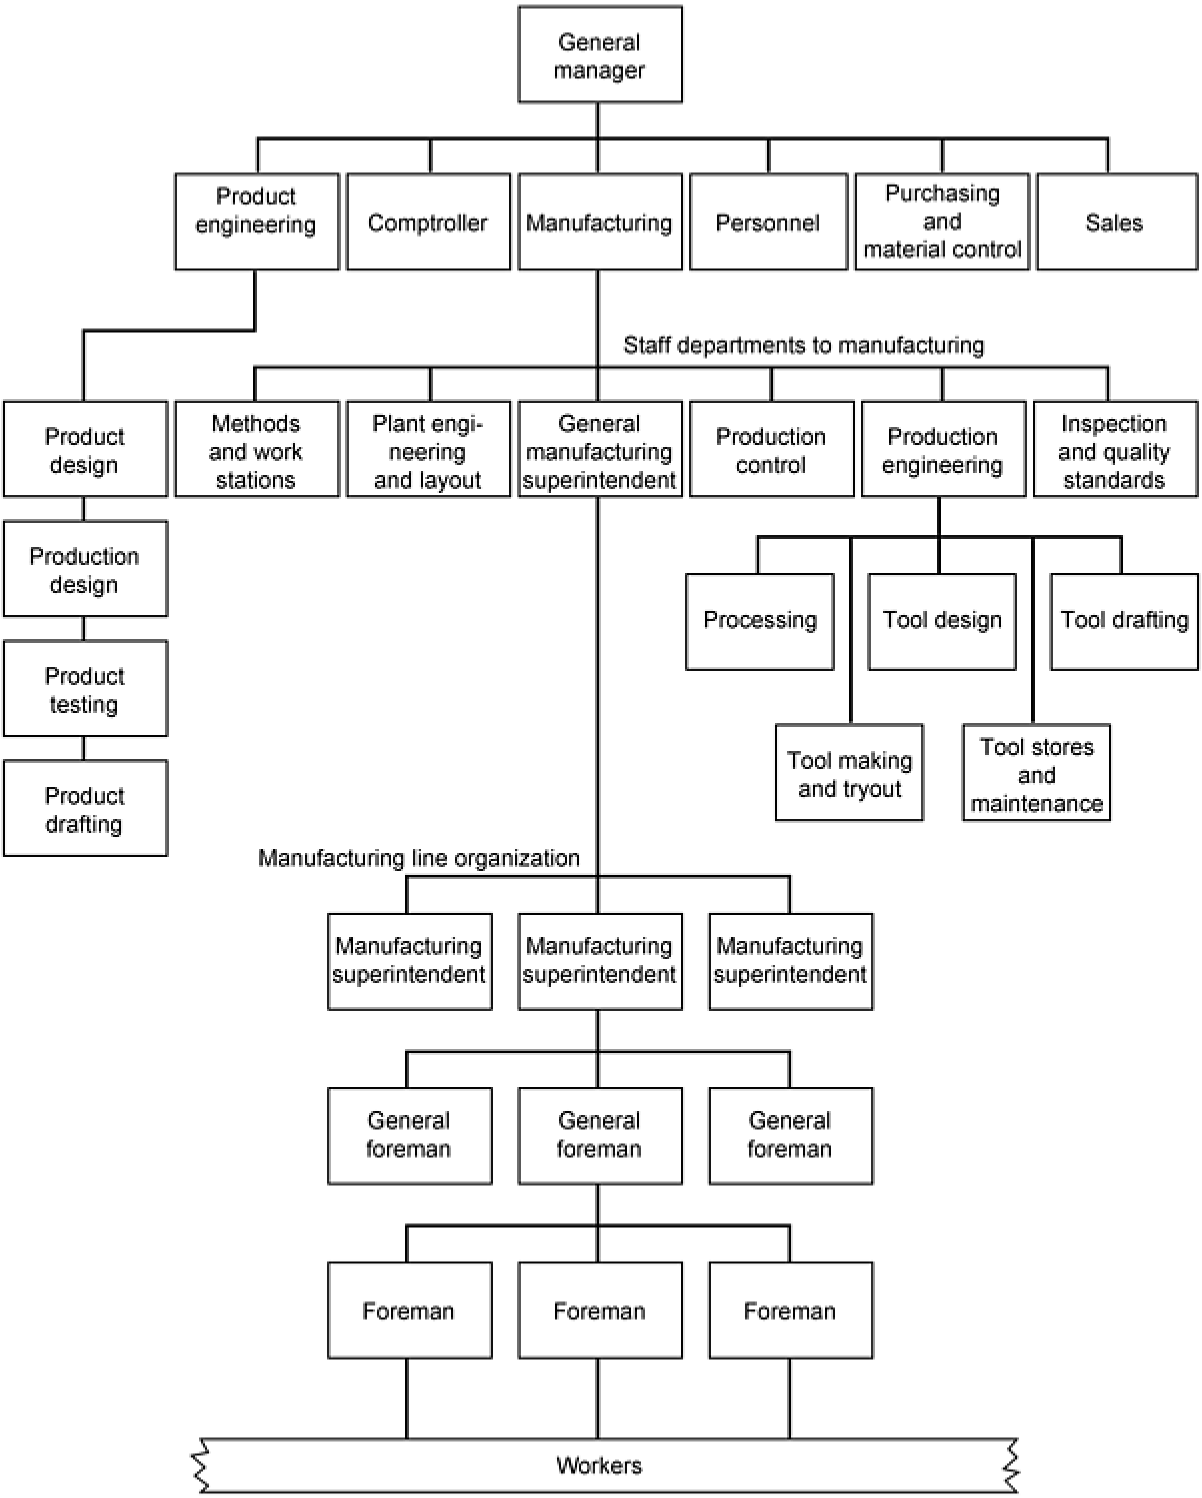

Fig. 1 Traditional organization structure for product design and manufacturing

The classic drafting room was usually quite large and full of drawing boards (Ref 2). It was the place where engineers and draftsmen congregated to develop a new product design. The drawings were created using an artistic approach, and the tools consisted of triangles, compasses, and, most important, pencils.

The traditional design process is valid and can result in successful products. However, it has been documented that up to 50% of the drawings created using this approach were flawed (Ref 3). Competitive pressures made it necessary to improve the approach, and new technologies have made this possible. Team work, concurrent engineering philosophies, and communication of the overall scope help all involved ultimately achieve their goals. In industry, all must share the

same goals if successful products are to be achieved. The benefit of complete documentation is fewer errors at the hardware stage and less variation in interpretation of the design intent.

The Computer-Aided Design Environment. There has been an evolution in the tools used by designers. The advances in the tools have generated new potential in the way information is formatted and communicated to others. Electronic forms of documentation have become the primary media in recent years. However, changes in the process to maximize the benefits of this technology have not progressed as quickly as many believe they should.

Computer-aided design (CAD) information can take a variety of forms. The key issue to address is what information is required by the various activities involved and how it can best be communicated to those requiring it. Too often, practitioners continue to adhere to the requirements of the historical design process: numerous drawings, prototypes, and physical tests. The acronym "CAD" too often stands for "computer-automated drafting" instead of "computer-aided design" (Ref 4).

A CAD database can contain detailed information about surface topology, contour, size, and location; however, this information generally is not included in a formal drawing format (Ref 5). Generating useful information is a matter of putting oneself in the position of the person who is going to use it. One good example is a machining drawing. Envisioning the information needs of the machinist may help the designer decide how the part should be dimensioned. This outlook will help determine what data should be used and what machines are required to meet the stated tolerances, surface finishes, and so on.

As we examine the documentation issue further, we will better understand the role and benefits of the CAD environment. The two-dimensional (electronic drawings) and three-dimensional (solid models) forms co-exist, with good reason. A mix of information such as wire frame geometry, surface details, solid models, numerical control tool path files, finite element models, and parametric or variational geometry is needed. Spreadsheets, database tools, and file management software also play key roles in the design process.

Documenting and Communicating the Design

Gary Vrsek, Ford Research Laboratory

The Overall Design Process and General Documentation Requirements

The key to a successful design project is to follow a process such as that identified in Fig. 2 (see the article "Overview of the Design Process" in this Volume). Many companies have followed such processes and procedures over the years. While it may seem complex, furnishing complete documentation for such a process is not bureaucratic if the appropriate participants do their part.

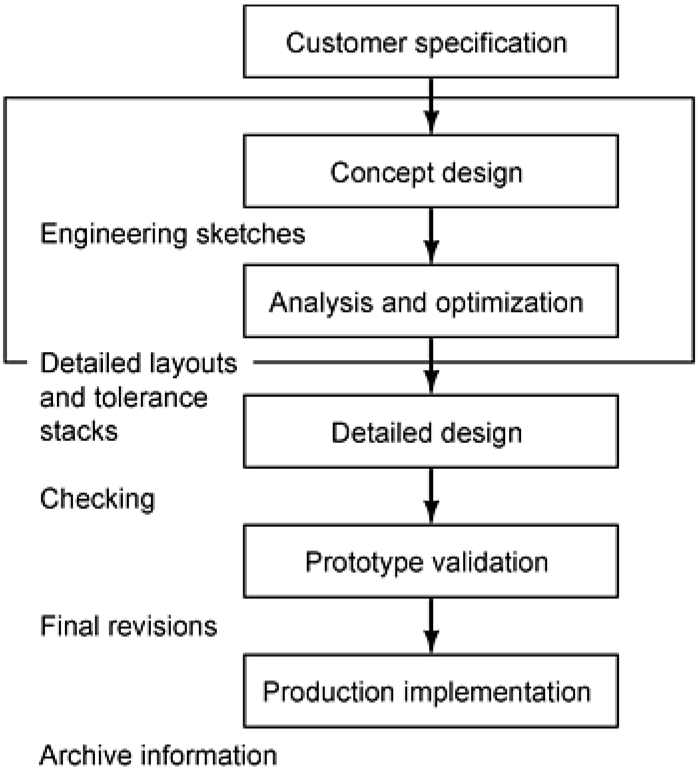

Fig. 2 Overview of the design process and related documentation requirements

Often, a product design program has several phases and involves designing, redesigning, and refining the product through the creation of several preliminary prototypes. Sound project management is important to ensure that each phase is started on time and that opportunities to overlap tasks are not missed. It can be argued that extensive documentation is not necessary and is just a sign of unneeded overhead. Also, early in a project, time and resources often are limited, and all aspects of the documentation may not be completed. However, failure to adequately capture a critical new product or technology through documentation can be devastating, and poor documentation can result in safety and liability risks. Following is a brief description of the major design phases and corresponding documentation requirements.

Concept Design. The initial phase of design should focus on the systems-level aspects of the project. The product-related goals must be clearly understood, and a general feeling for the competitive position of the product is needed. Information on the environment is necessary, as well as the definition of key guidelines and performance specifications. Identification of the appropriate level of detail is needed to ensure that ideas can be communicated without spending too much time or effort on parameters that can wait until the detail design phase, such as general tolerances, machining specifications, and so on.

The result of this initial phase is a clear idea of the design, components required, and, generally, the manufacturing process options. Drawings made at this point are the first communication tools used for the project. They must convey the design intent but also expose the design issues and challenges that need to be resolved. A first attempt at determining the cost and competitiveness of the design should also take place at this stage. Because the following phases require more time and labor, it is important to have high confidence in the success of the decisions made in order to continue. The design process tends to filter the various options and refine the chosen concept into a mature design (Ref 6).

Additional information is provided in the articles "Conceptual and Configuration Design of Products and Assemblies" and "Conceptual and Configuration Design of Parts" in this Volume.

Detail design focuses on the individual components. The goal of this phase, historically, has been to generate drawings that can be sent to manufacturing. It is at this point that manufacturing tolerances and full part definition are determined. The document generated is the primary engineering drawing or database that manufacturing will be working from.

The CAD model is becoming the master for much of the component definition, reducing the amount of information historically found on the detail drawing. This is especially appropriate when dealing with complex surfaces and features that would be difficult to describe dimensionally. Typically, the "detailer" is a novice who is guided by a senior member of the design staff.

Checking is a critical review of the information and documentation generated during the detail design phase. This step ensures the fit and function of the design. Traditionally, checking has been performed by someone not initially involved in the project, who can offer a fresh and objective review of the work done, prior to releasing the job for fabrication. This step is too often passed over to expedite the job, resulting in high cost, last-minute corrections, and modifications to the parts to complete the job. When detailing is done by a less experienced person, checking is especially critical.

Design Approvals and Release. Product design is an evolutionary process, so it is important to record the history of the project and changes along the way. The title block and revision column on a drawing can detail the history of a component. To ensure that changes are properly implemented, they must be communicated to and agreed upon by everyone involved in the processing of the part. A formalized release process is the proven approach to accomplish these goals. It is often necessary to release information early, in order to obtain cost and delivery estimates.

Tracking the document status is important. Some of the things to look for are:

- Key names and dates in steps such as release for quote, release for tooling, product engineering approvals, manufacturing approvals, and materials approval
- Identification of significant or critical characteristics
- Sourcing information (for heat treating, balancing, special tools, etc.)

Filing and Archiving. Ensuring that information is retrievable is extremely important. The issue concerns whether any undocumented changes can be reproduced, or, if the changes did not perform as expected, whether the component can be returned to the original configuration. The process of storing and retrieving information is complicated today. We are faced with many different formats based on whether the data was created manually (on paper) or electronically. If the information is stored electronically, in what format? Can information stored in different electronic formats be communicated across different CAD platforms? In many cases, paper versions or two-dimensional raster images of computer-generated data are stored for easier access. A variety of coding schemes are used in the industry that typically distinguish the various types of information and where to find it. Database technology has enhanced this segment of the business significantly.

Documenting and Communicating the Design

Gary Vrsek, Ford Research Laboratory

Types of Documentation

Documentation must be focused toward explaining a specific task. The techniques presented in this article follow a general design process; differing situations will require adjusting the process accordingly. The following sections identify the key features that most documents must define and what users should be able to determine from these documents.

Historically, the challenge in blueprint reading has been to visualize the part, having only two-dimensional views. Now, electronic tools can represent a three-dimensional image, thereby significantly improving that first step. In either case, drawings are typically done in orthographic projection, with additional views added as required to clearly define the part.

The drawing allows people from many different disciplines to understand and contribute to the ultimate goal of producing the part or product. The following sections describe the typical documents created to develop and produce a product.

Product Specifications. Concept design is the most unstructured point in the design process, and initial product specification documentation can come in a wide variety of forms. The simplest documentation can be a typed page of the envisioned product objectives and a list of general parameters, such as cost, size, performance, and/or production volume. The addition of any historical and benchmark information can be helpful. Reinventing the wheel or falling short of the competition are real concerns. Becoming too specific at this stage and requiring too many or unrealistic constraints can cause problems for the project. One must define the project with sufficient detail to enable engineering and design efforts to move forward, but accommodate the project launch as quickly as possible. At this stage, there is often great pressure to cut corners. Examples of preliminary product specifications are provided in the article "Conceptual and Configuration Design of Products and Assemblies" in this Volume.

Engineering sketches are produced by the design engineer or a senior designer/draftsperson. The design will go through several iterations, and the goal of these preliminary drawings is to narrow the options and communicate the objectives of the design (Fig. 3). Frequently, this stage of the design process is carried out in a team environment, depending on the magnitude of the project. The assembly or systems-level aspects are the primary concern of this stage. The engineering sketches serve as important tools for design and redesign.

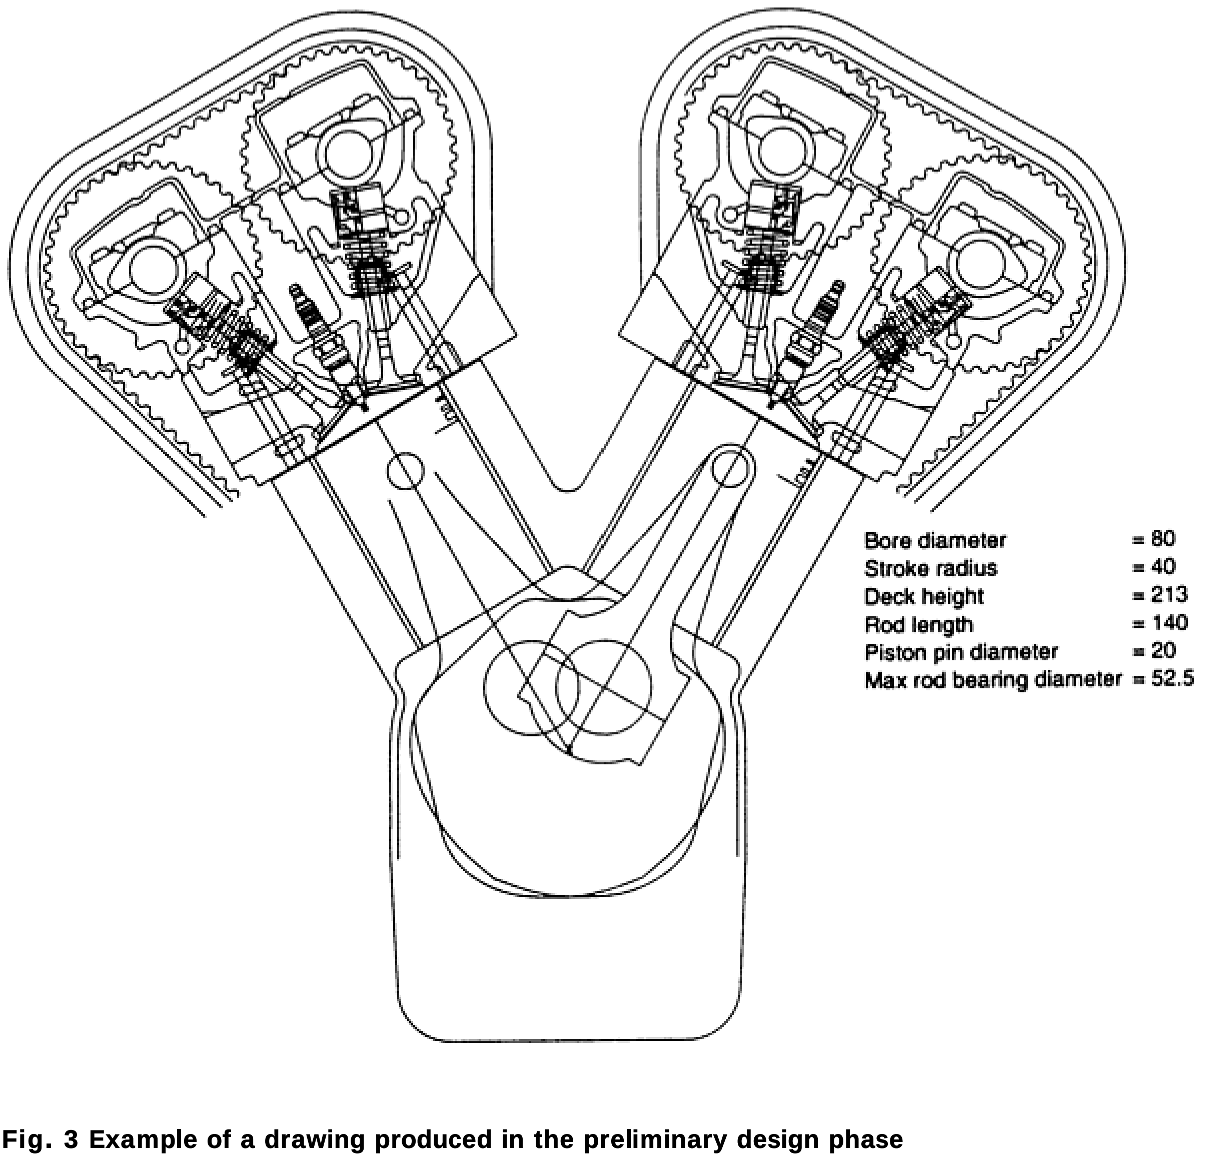

Fig. 3 Example of a drawing produced in the preliminary design phase

Product engineering assumptions documents provide a first look at the specifications for the individual components that will be required in the design. These documents should be considered a systems-level communication

tool; spreadsheets are well suited for this type of communication (Fig. 4). A preferred format is a list of the basic assumptions and constraints for each component. This document can be used to define the general bounds of the design, and also to clarify peripheral issues such as the need for standard parts, bolts, pins, and other items that will not require redefinition. An assumptions sheet is an important tool for communicating across the organization the scope of the task and objectives for the final product. This document is usually controlled by the responsible engineer and should be considered a working document that will evolve with the design. Its real value comes as a means of sharing the overall design aspects among all of the engineers and designers, keeping them current on issues that might affect their own areas of concern.

Fig. 4 Example of a project assumptions data sheet

Design layouts are produced by the designers assigned to the project; an example is shown in Fig. 5. Once the general design direction is set, the specific aspects of the design and environment need to be defined. Design layouts are very important to design personnel and to other personnel involved with the project, such as manufacturing, finance, quality, and rough forming. They are also useful for designers working on systems or components that are either similar to, or interact with, the ones being designed for the current project. The design layout serves as the main document to keep all participants on the same track.

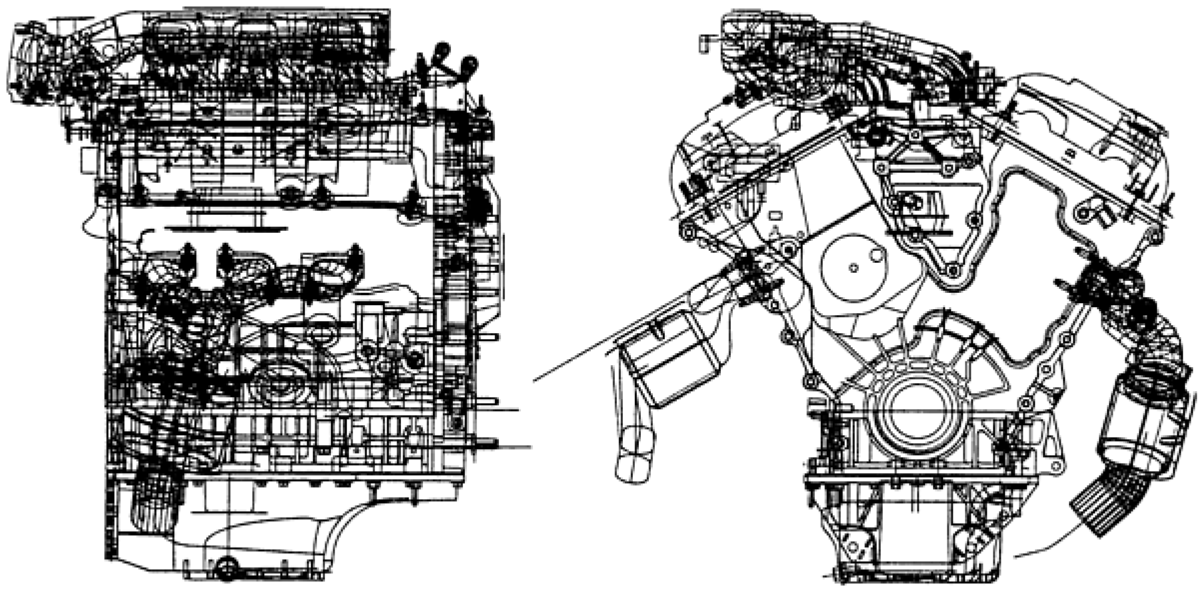

Fig. 5 Example of a design layout

In the CAD environment, design layouts are critical for ensuring that components fit together properly. These layouts can be very effective with the use of solid models, in either a two-dimensional format for presentation and discussion, or a three-dimensional isometric shaded image that can help others not as closely related with the project to grasp the design fundamentals. Many CAD systems have powerful systems-level tools that allow the user to design and investigate clearances in the same environment.

Detail drawings provide the information that is used to make the parts. All of the information required by a fabricator should be documented in a manner that leaves very little room for misinterpretation. Using CAD, a wealth of information can be extracted from the model. It is important to consider what information might be redundant or counterproductive to add. On the other hand, it is extremely important to ensure that all involved with the detail information can access that data and use it. All of the different areas must be considered; for example, if the quality office needs locations of some critical holes but nothing else, they may want those identified on the drawing even though the machinist did not (Ref 7).

A basic detail drawing includes:

- Standard views (and layers in CAD)--plan, front, side, etc.--the objective is to use conventional views to allow familiarization with the part (Fig. 6)
- Auxiliary views, sections, enlarged views, and isometric views--to aid in the understanding of specific details and clarify the design--will usually have special designations
- Dimensions--for machining information
- Tolerances--dimensional limits--to ensure the appropriate part integration

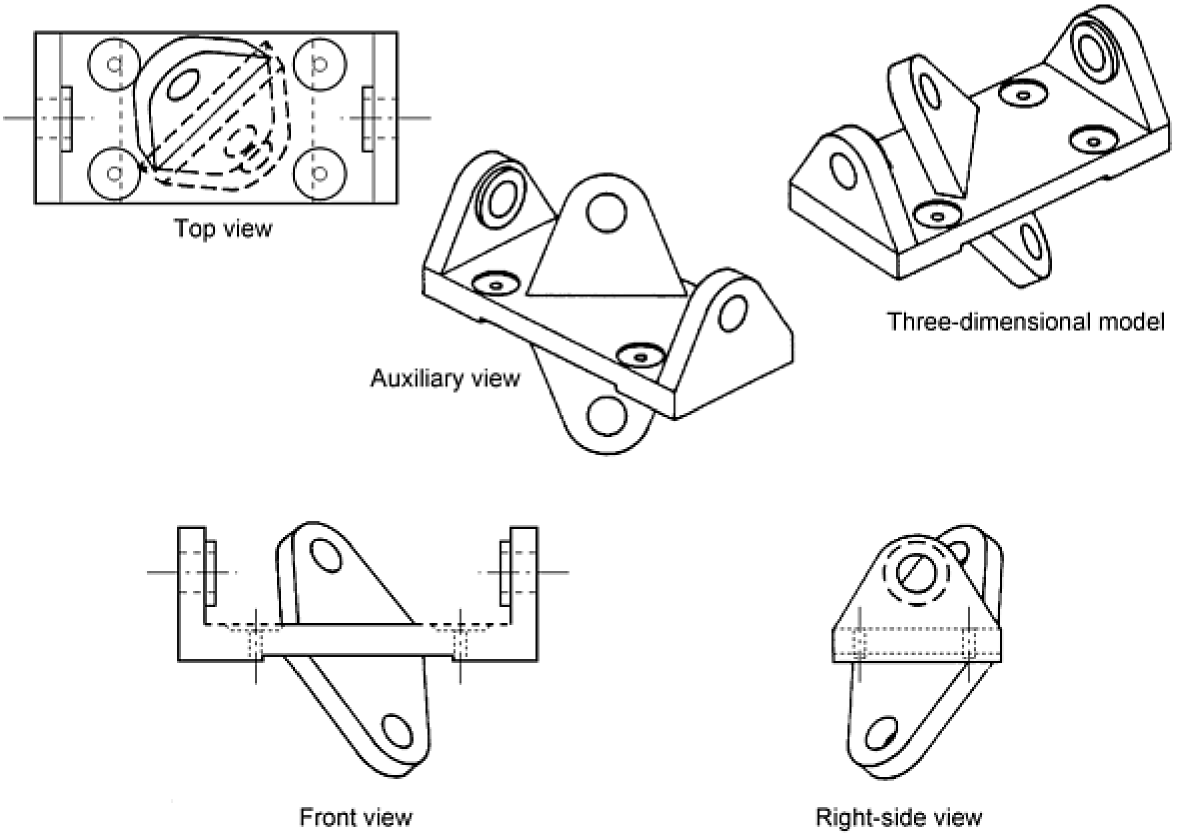

Fig. 6 Examples of standard views in detail design drawings

The approach to the detail drawing can vary (Fig. 7). Some flexibility is necessary to accommodate the unique drawing types. Formats and sizes are typically established by company standards. Other approaches, such as charting dimensions, can benefit organization and consistency (see the section "General Dimensioning Guidelines" in this article). Charting the coordinates as well as the size and tolerance information cleans up the drawing significantly. Charting will probably become increasingly common, because this is an easy step to automate.

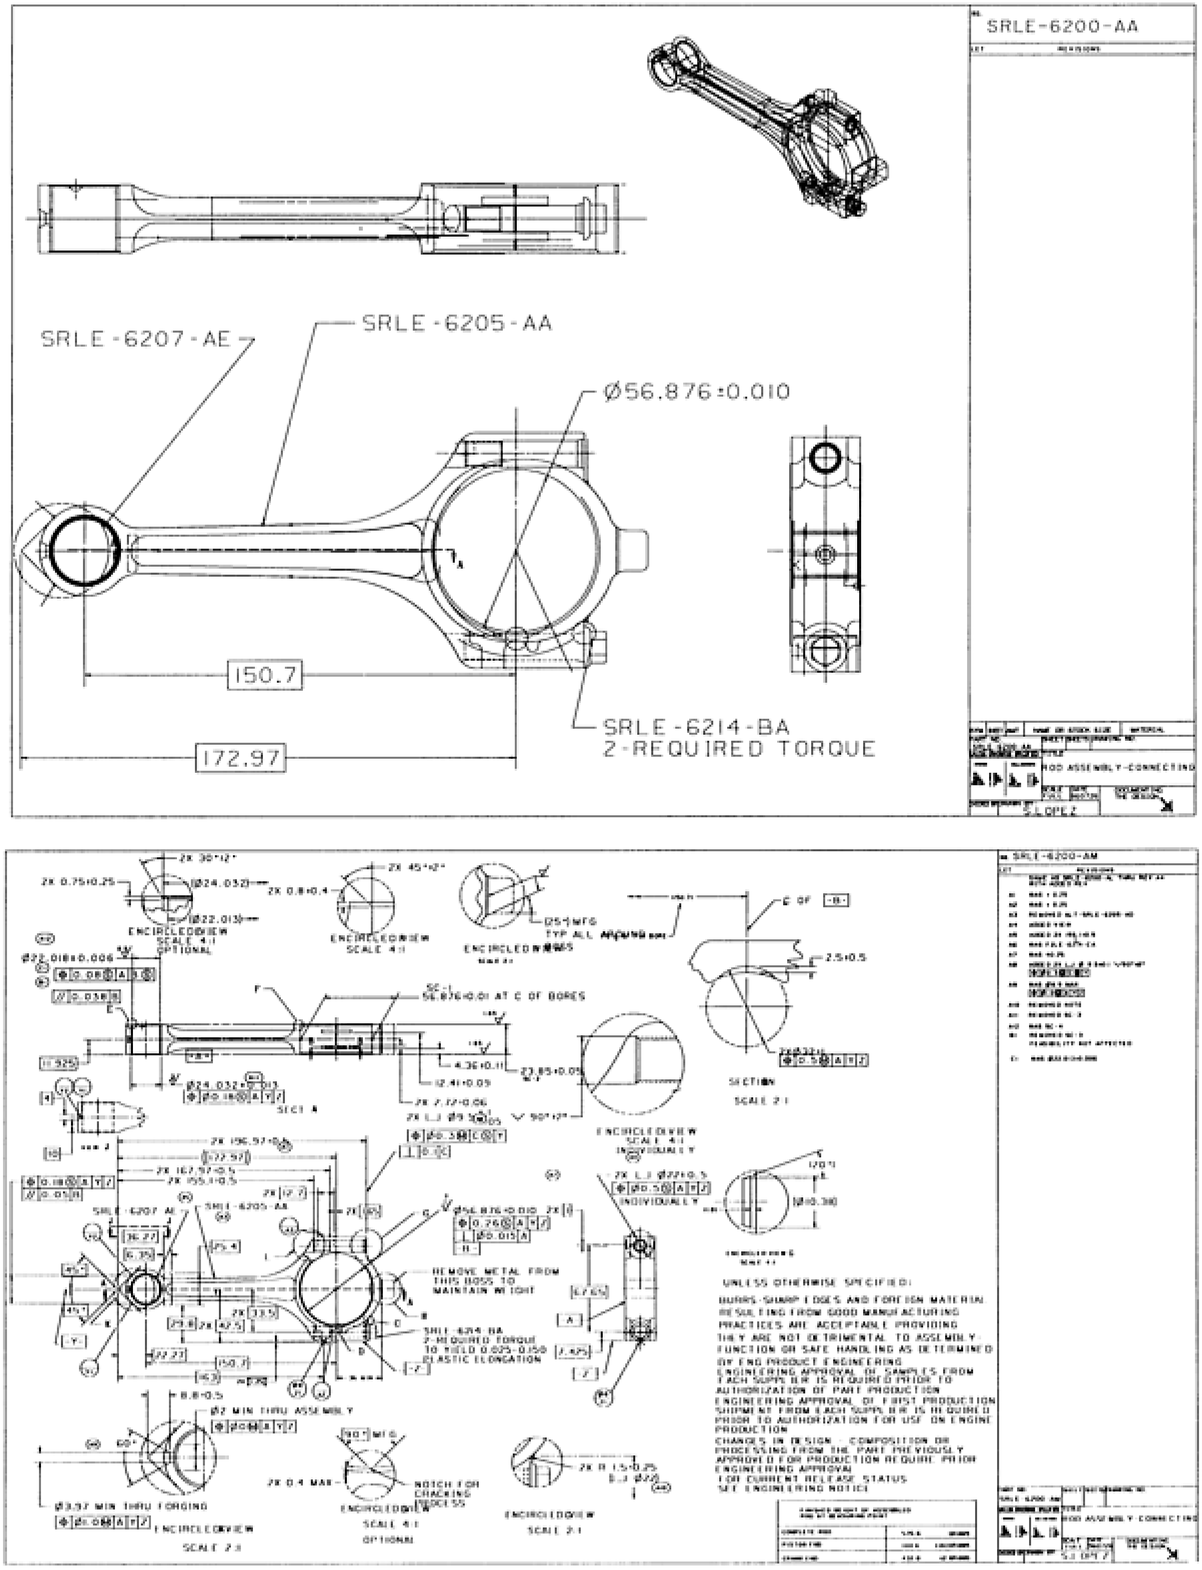

Fig. 7 Examples of detail drawings

Bill of Materials. The entire team is responsible for keeping records that are accurate and current. An important step in the organization of the project is accomplished with a document usually called the "bill of materials" or "parts list" (Fig. 8). This document is used to track the parts in an assembly or project and plays a significant role in information retrieval long after the engineering phases are completed. In its most basic form, the bill of materials lists the part number, part name, and quantity for each part in the complete assembly. Its utility is often increased by adding procurement tracking and special assembly instructions. The generation of this document is an excellent application for spreadsheets; however,

for simple assemblies, the bill of materials can be part of the assembly drawing. New aids have been embedded into some CAD packages to allow assembly of the CAD models and to track the components of these assemblies in a bill of materials.

Specialized Drawings. So far, this article has addressed the aspects of the design related to designing the product and machining the part. Other drawings or CAD models are often required to accomplish the task of fully defining the finished product. While it is important to ensure that there is no redundancy in the project, additional forms of information may be required to more clearly communicate the design intent.

A common situation occurs when a casting or forging is required. A "rough form" drawing is helpful for documenting the part prior to any final machining. While it requires additional time to create, it removes possible ambiguity on complex parts, where trying to distinguish between cast and machined features can be difficult. Ideally, a CAD solid model can more completely define the rough form, and computed-aided tools can then be used to finish machine the part.

Assembly drawings are also common tools for clarifying the design intent. These drawings are especially important in cases where the design includes several components and the assembly sequence must be described. Also, where it is difficult to control tolerances, special instructions and part specifications can be identified on the assembly drawing. Examples are select fit parts (batches of like parts with slight size variations) or shims--the use of which is determined at the time of assembly. Additional documents used to clarify the design are worthwhile but will add to the maintenance tasks as the design matures.

Revisions, Record Changes, and Engineering Change Notices. Initiating, tracking, and transmitting changes to the design accurately is very important and can be costly if not handled properly. A formal request system and related documentation is important to ensure that the project flows smoothly and that a change does not negatively affect some unexpected area of the product.

Several issues should be considered when a change to a product is required. On a drawing it is relatively easy to make changes. However, the impact on manufacturing can be significant. Design changes can be categorized as record changes, in-process changes, and replacement or new designs.

Record changes are those changes that have no manufacturing cost implications. Usually, they are required to correct a mistake on a drawing that was discovered after the drawings were released, but before any parts were made. They are also additions or changes that clarify some aspect of the documented design.

In-process changes are those changes required to solve a product- or manufacturing-related problem. These changes do not affect part interchangeability. Expenses are incurred in the change.

Replacement and new designs are major changes. They generally change product application and interchangeability of parts.

It is important to evaluate how the product will be affected by any changes required. It may be wise to consult manufacturing personnel, asking them to make an assessment and to forge an implementation plan.

Understanding and Using Design Documentation

Layout and assembly drawings promote understanding of the product function and its environment. The detail drawing focuses on construction and manufacturing. It must convey the needs of product engineering, materials engineering, and manufacturing (manufacturing encompasses rough forming, machining, and inspection). This section describes the detailed requirements of engineering and manufacturing and how drawings are used as a communication medium.

Product-Related Information. Product design and systems-level engineers typically focus on the issues that affect the performance and function of the parts. The performance of the final product and aspects related to the assembly will be dictated by the design layouts and detail drawings. Design layouts are extremely important in tracking the environment for the subsystem or assembly. Particularly when dealing with subassemblies and other parts in the environment, issues of interaction are critical. Functional tolerances for fit, durability, cleanliness, and assembly sequence must be clearly conveyed. From the drawings and specifications generated, product engineers must be able to understand the following:

- Size
- Fit (relationships between mating components)
- Function and performance (acceptance test criteria)
- Cost and complexity
- Weight
- Product safety issues
- Inspection requirements

Material specifications affect product function, manufacturing feasibility, and planning. Key issues include basic material properties and factors such as required heat treatment or surface finish. This information is usually contained in the title block or note column. It is important to examine the heat treatment specification, to determine if a specification such as case hardening results in the need for a special machining sequence.

Manufacturing Attributes. It is important for the designer to understand the manufacturing process and include related information in the product definition. The specific information needed varies, depending on the operations used. Especially critical are rough forming operations such as casting, forging, or stamping--operations where the process requirements affect the shape of the part. The most common manufacturing-related features that appear on a drawing are draft and parting line definitions. The information required for all the operations specified will have a significant effect on the product definition. Minimum corners, fillets, and finish machine stock requirements are also specified on the detail drawing.

General Dimensioning Guidelines. Reading a detail drawing can be overwhelming. Among the features found on a drawing are references to milled faces, drilled holes, and threading operations. Viewing the part drawing from the perspective of someone who must perform finishing operations on the rough workpiece can be helpful. Several manufacturing handbooks give direction in terms of the tolerances to be shown on a drawing and possible manufacturing approaches. Additional features that are typically found on part drawings include special manufacturing locators to set up the part for clamping, manufacturing, and inspection.

There are three primary approaches to dimensioning a component. The traditional approach (Fig. 9a) is to use linear dimensions, with arrowheads and leader lines (Ref 8). This is the preferred approach if manual manufacturing methods are being used, as in prototyping, where features are being addressed one at a time. The approaches shown in Fig. 9(b) and 9(c) are more appropriate for numerical programming processes. Zero line dimensioning (Fig. 9b), sometimes referred to as datum line dimensioning, has become very popular. This method has occasionally been the source of confusion in the interpretation of the tolerances. The common mistake is to assume that the part tolerances are related to these datum lines, but it is important to remember that zero lines are dimensioning aids only and that datum lines for feature tolerances could be different. The third approach (Fig. 9c) also can utilize the traditional linear dimensions, or zero lines, but it uses tables for the coordinate data and hole specifications (hole charts). Hole charts can be a good way to visually clean up a complex drawing. Reference dimensions, though considered redundant information, are often appropriate in clarifying particular features.

6	150	250		

(c)

Fig. 9 Approaches to dimensioning on engineering drawings. (a) Linear dimensioning. (b) Zero line dimensioning. (c) Zero line dimensioning with coordinate data and hole specifications

Tolerances and Tolerance Stacks. Tolerances are initially developed to ensure that the part will fit and function as intended. Most often the initial tolerances are selected by referring to past projects of a similar nature, applying the best-known information about that project to the job at hand. Manufacturing engineers use this tolerance information to decide how best to process the job. This includes what machines to use, how to set up and locate the workpiece in the machines, and what sequence of manufacturing operations to use. Tolerances for the part can be found in a variety of locations on the part drawing, including in a general note in the title block, in the notes column, and in the dimensions as a limit or using the ANSI geometric dimensioning and tolerancing (GD&T) notation (Fig. 10).

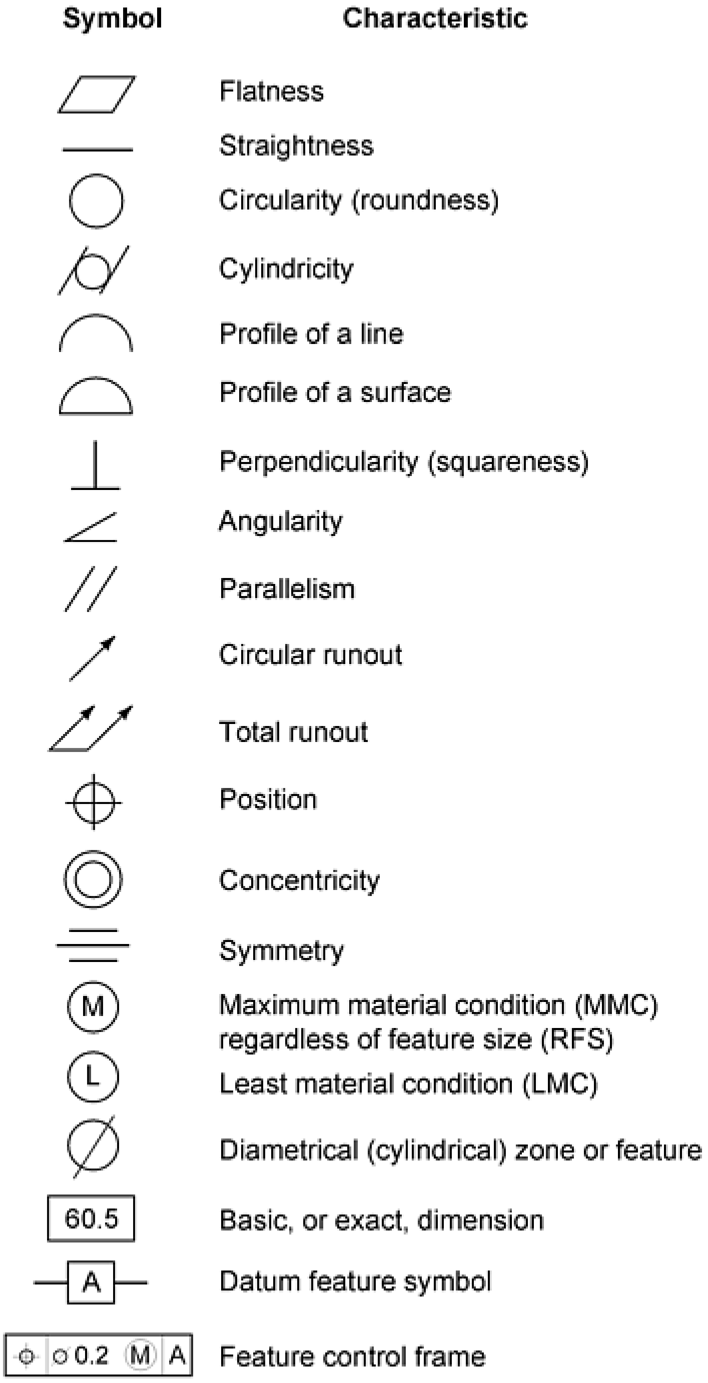

Fig. 10 Geometric dimensioning and tolerancing symbols and characteristics. Source: Ref 9

The variety of approaches to tolerance analysis are beyond the scope of this article (see the article "Dimensional Management and Tolerance Analysis" in this Volume). However, it is important to remember that the aim is to ensure functionality and manufacturability. The tolerance stacks (the cumulative effects of tolerances in an assembly) can

provide insight into the product performance and process capability, and all possible sources of variation (dimensional, tooling, heat treatment, surface quality, etc.) must be taken into account.

Standards

Geometric dimensioning and tolerancing has evolved to become the most significant tool for designers to communicate uniformly with the manufacturing world. Throughout this article, the importance of uniformity has been stressed, but it is in the area of dimensioning and tolerancing that it is most difficult to achieve. The completeness of the ASME/ANSI standard has allowed many major companies to abandon the maintenance of separate internal standards, which has proven beneficial to external suppliers as well. Caution must be used to avoid building a specification too complex for the machinist or inspector to understand, too difficult to measure without expensive gaging, or, worse yet, not really applicable to the situation. A company's specific manufacturing practices must dictate the standards that are used by the design group (Ref 10). The GD&T standards define the following:

- *Datum references:* A primary surface or feature, used as a location reference for other features
- *Basic dimensions:* The exact theoretical location for a feature (the tolerance for such a feature is usually in the feature description)
- *Positional tolerances:* Feature tolerances pertaining to location
- *Form tolerances:* Feature tolerances related to the shape, runout, or size variation

The most widely used GD&T standard is ANSI Y14.5M.

ISO 9000. With suppliers playing a key role in the product development and manufacturing processes, standards for passing complete and consistent data is another step toward ensuring the highest possible levels of quality. ISO 9000 is a series of standards that define the criteria for a functional quality assurance system. Maintenance and control of documents is a key component of the ISO 9000 standards and other similar standards.

Local or Corporate Standards. An important goal in design should be to have consistent processes across the company. The ability to attain a level of familiarity with the documentation within the engineering community improves quality and efficiency. Local standards ensure a common language across the various departments in a company that work in related areas, such as powertrains or body structures in an automotive company. Furthermore, the ANSI GD&T specification sometimes allows two or three options in handling certain situations. Local standards can define which option is best suited for the company's manufacturing process.

Typically, key process engineering specifications are required for tests, heat treatment, and screw threads. Local standards for these items help reduce variation within a family of parts, and they also can reduce the amount of written information needed on the part drawing (Ref 1).

Conclusions

The complexity of the various types of engineering documentation can be overwhelming. However, each of the many pieces of information is necessary and reveals its usefulness at some stage of the design process. By the time the detail drawings are prepared, the design has matured and parts are ready to be machined. Below is a step-by-step approach that should be helpful in understanding a design based on its detailed documentation:

1. Visualize the physical part, using the views provided on the detail drawing.
2. Review and understand the correlation between the detail drawings and the parts list.
3. Refer to assembly drawings to understand the intended function of the component and how parts are integrated into the system.
4. Observe the drawing scale used and take time to read the general and/or special notes, instructions, and specifications.
5. Review the material specification and determine the process route for the initial form (e.g., bar stock, casting, forging).
6. Look for the key locating features.
7. Examine dimensions and tolerances to understand the functional requirements and manufacturing strategy.
8. Look for the approvals and revision history.

The key to a successful product development project is communication. All of the parties involved in a project must understand how designs are evolving, and all must be able to make their contributions in a way that brings the product to market quickly. The new electronic environment is helping to generate information more efficiently and more completely. New tools will continue to help designers perform many of these functions concurrently and across greater geographic distances.

Rapid Prototyping

Charles L. Thomas, University of Utah

Introduction

RAPID PROTOTYPING is a relatively new field in manufacturing that involves techniques/devices that produce prototype parts directly from computer-aided design (CAD) models in a fraction of the time required using traditional techniques. The prototypes are used as form models, to check the touch and feel of the part; as fit models, to verify geometry and alignment of the part in its intended application; and in some cases as function models assembled onto a working mechanism to test the ability of the part under design to perform its intended duty. The prototyped object can also be a mold or a pattern for secondary techniques that produce preproduction or production tooling.

Rapid prototyping techniques generally produce prototypes by decomposing a three-dimensional CAD model into parallel cross sections. Typically, each cross section is constructed atop the previous cross section, building the part layer by layer from layers that are 0.1 to 0.2 mm (0.004 to 0.008 in.) thick. The layers are bonded together either before or after cutting or as a natural consequence of layer formation. The construction materials available for these techniques include photopolymerizable or thermoplastic resin, paper, wax, and metal or ceramic powder. Secondary operations expand the list of available materials to include castable metals and certain forms of composites.

Rapid Prototyping

Charles L. Thomas, University of Utah

General Description

The traditional product realization process requires iteration to create a successful design for a manufactured product. Engineers use design and analysis skills to produce an initial design that is then prototyped and tested. If problems are identified during testing, the engineers return to the design and analysis stage. This iterative loop is at the core of successful engineering design.

Using traditional techniques, prototyping and testing are usually expensive and time consuming. As a result, engineers have developed improved modeling and analysis techniques in an effort to catch errors before the physical testing begins. An extreme example of this is seen in the aerospace industry where designs are developed very carefully, using extensive simulation and analysis. The resulting design is often allowed one or no iterations before the design is frozen. When iteration is performed, the engineers often are not allowed to change anything that would require replacing the prototype tooling.

While the value of iteration in the design process is recognized, the cost of iteration (in both time and money) often restricts the number of iterations allowed. This is the impetus for the concept of rapid prototyping (RP). In concept, an RP device is a three-dimensional version of a printer. The designer sends an electronic representation of a three-dimensional object to the device, and an accurate physical representation of the object is created without requiring operator skill or interaction. Actual commercial RP devices typically produce parts with dimensional variations of at least ±0.13 mm (±0.005 in.) and generally require significant skill from the operator to produce prototypes with this accuracy. Rapid prototyping devices allow the designer to complete a design iteration loop significantly faster than was traditionally possible by reducing the time and cost required to produce a prototype.

Paradigms for Part Creation. Rapid prototyping goes by a variety of names, each preferred by different people with different goals for the process. The term *rapid prototyping* seems to include any method as long as it is fast. Some use the term *solid freeform fabrication* (SFF), which implies that the part is not necessarily a prototype and focuses on the ability of the device to build any desired shape. Numerical control (NC) machining techniques would not be considered SFF, because there are some restrictions on the shapes that can be produced using NC. The term *auto fab* seems to include any automated process, but would not include processes with significant manual components. *Desktop manufacturing* is usually used when referencing small, desktop numerically controlled devices that automate standard machining techniques. *Layered manufacturing* refers to the fact that most techniques discussed here build parts from thin parallel layers.

The search for and discussion of an appropriate term for these techniques is an effort to define a new paradigm for part creation. Although there are many ways to categorize manufacturing techniques, one way they can be discussed is in terms of the mechanics of the part formation process. In these terms, the manufacturing processes fall into four categories (Fig. 1):

- Subtractive processes
- Forming processes
- Additive processes
- Hybrid processes

Most traditional manufacturing processes fall into one of the first two categories. Parts are produced by either removing excess material from a blank (milling, sawing, drilling, etc.), or by forcing raw material to take the shape of a mold (forging, injection molding, casting, etc.).

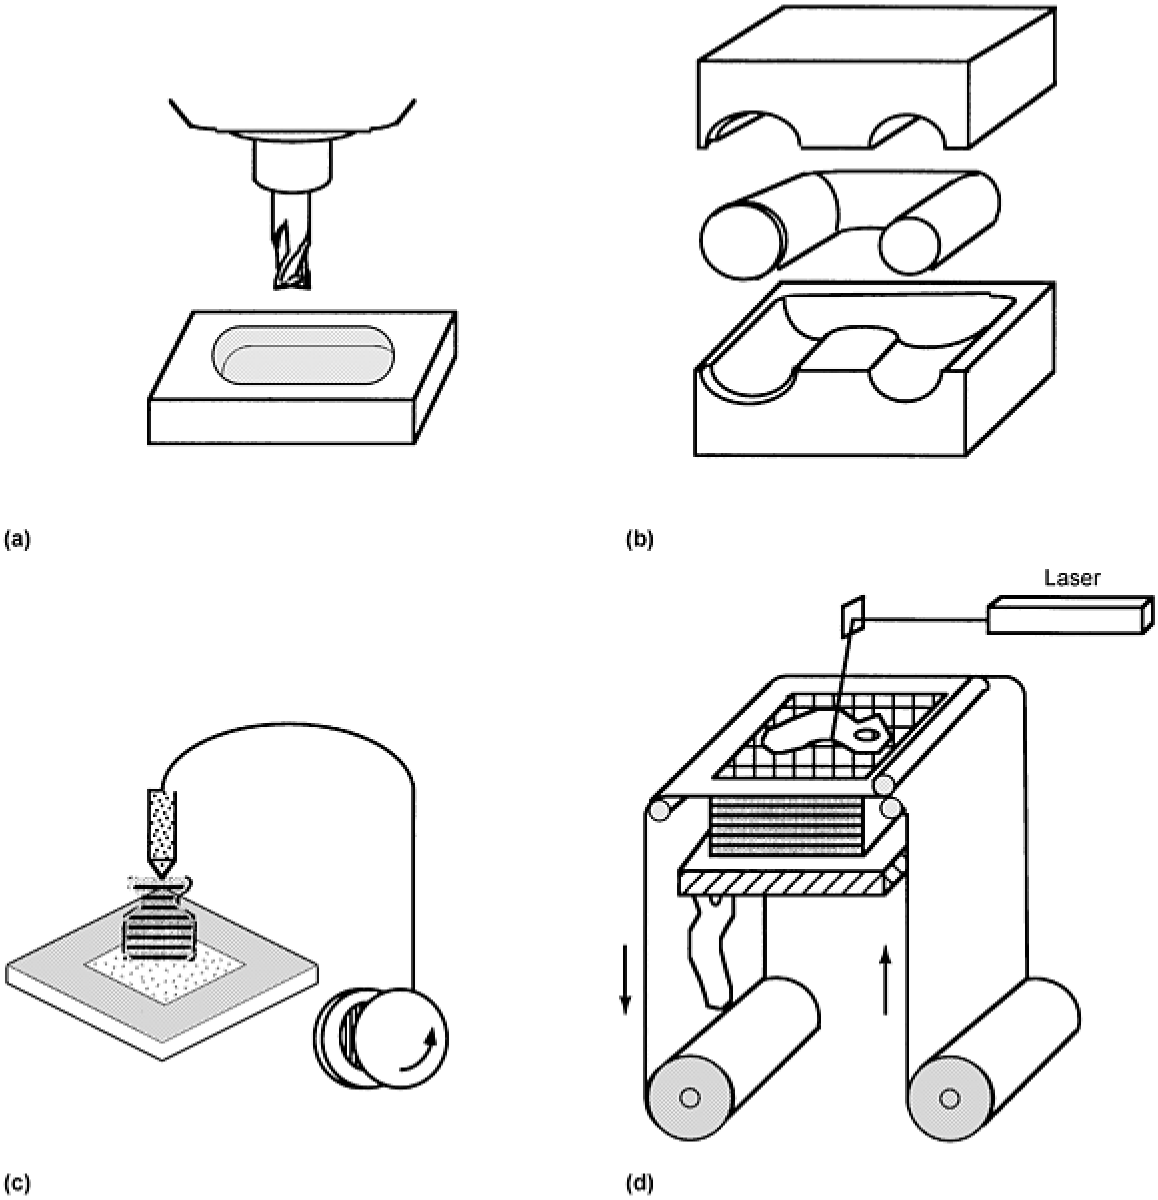

Fig. 1 Four manufacturing paradigms. (a) Subtractive process. (b) Forming process. (c) Additive process. (d) Hybrid process

Most RP techniques fall into one of the last two categories. For additive processes, parts are produced by adding material to create a part. Some of the RP techniques are considered hybrid processes because they require an initial subtractive process to cut each layer from a sheet, but then additively bond the layers together to create the part.

Rapid prototyping devices are generally relatively expensive (often in the range of $60,000 to $500,000). Typically only larger companies can justify the expense of purchasing an RP device. For this reason many prototypes are produced by service bureaus that receive part files by modem and send out the RP prototypes in a day or two. In either case, the time required to produce a prototype is reduced to less than a week. The example later in this section demonstrates the utility and savings that can be achieved through the use of RP.

Typical Rapid Prototyping Process (Stereolithography). The first commercial RP device was introduced in 1987 based on a patent by Charles Hull (Ref 1). The process, termed stereolithography, is described here to outline the general principles of RP. The process can be broken into three subphases:

- Preprocessing
- Building the part
- Postprocessing

Preprocessing includes mathematical manipulation of the electronic model in preparation for the physical construction. Postprocessing covers operations required to produce the finished prototype after the basic shape has been created.

Preprocessing. A designer first develops a three-dimensional solid model of an engineering part. This model may be created in a variety of different CAD softwares (Fig. 2a). The solid model is converted to an industry standard file format called the stereolithography format (or a file extension, *.stl). This conversion is necessary so that the RP device can communicate with the various CAD packages. To convert to the *.stl format, the solid model is tessellated with triangular tiles as shown in Fig. 2(b). Conversion to *.stl format is performed by a module in the CAD software and is a standard function of nearly every CAD software capable of producing solid models. The *.stl file is created and delivered to the RP device. This delivery can be done physically on a disk, over a modem, or through the Internet. The computer controlling the RP device reads the *.stl file and slices the model into a series of parallel cross sections as shown in Fig. 2(c). The cross sections are spaced at a thickness equal to the dimension of the layers that will be created.

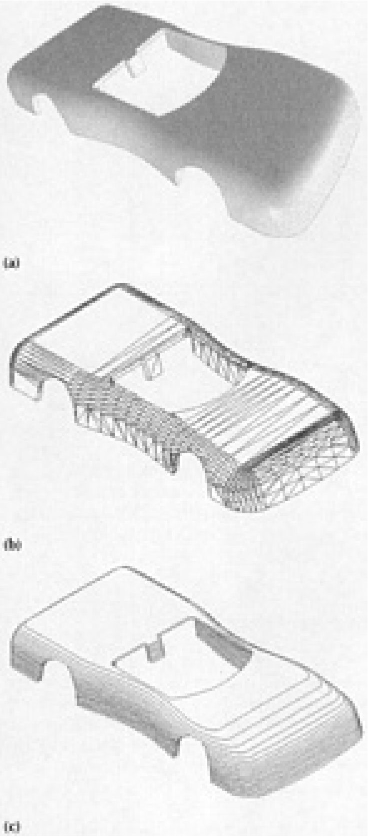

Fig. 2 Preprocessing for RP begins with the creation of a solid model, which is converted to stereolithography format and then sliced into parallel cross sections. Source: Ref 2

Building the Part. At this point the electronic cross-section data must be physically created. While the preprocessing is similar for all RP techniques, the part construction processes are quite varied (Fig. 3). A schematic of the stereolithography process is shown in Fig. 4. Using stereolithography, the part is constructed by curing liquid photopolymer resin in a vat. The photopolymer resin consists of plastic monomer and oligomer combined with a photoinitiator. When light of the appropriate wavelength exposes the liquid, it rapidly polymerizes into a solid. A movable platform immersed in the photopolymer vat is initially positioned just at the liquid surface and then indexed down into the polymer, incrementing after each layer is created. At each increment of depth a liquid layer of resin forms above the part under construction, and the laser scans the liquid surface tracing out the appropriate cross section of the

part to be built. Where the light exposes the photopolymer, it rapidly solidifies. In order to create the complete cross section, the laser must scan the periphery of the part and crosshatch the interior solid sections. Once a layer is formed, the build platform drops down and a wiper levels the surface of the liquid. This cycle is repeated for each cross section until the top layer of the part is formed. Finally the platform is raised, and the finished part is removed from the device.

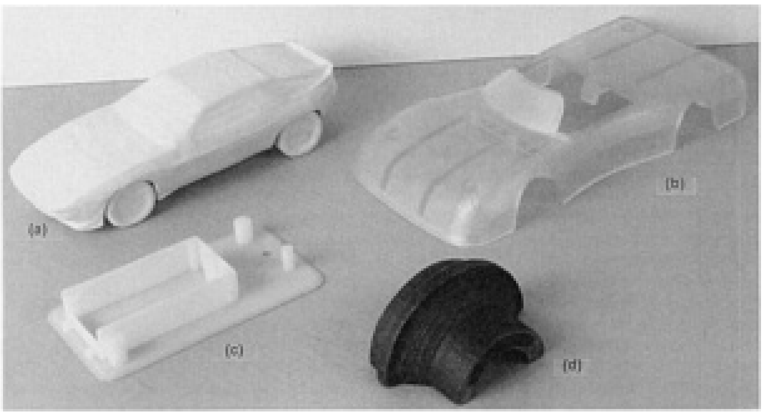

Fig. 3 Parts made by various RP techniques. (a) Car made from layers of paper using a cut-then-stack process. (b) Car cured from liquid photopolymer using stereolithography. (c) Housing base made from thermoplastic polyolefin using FDM. (d) Part investment cast from carbon steel using a foam plastic model made using a cut-then-stack process

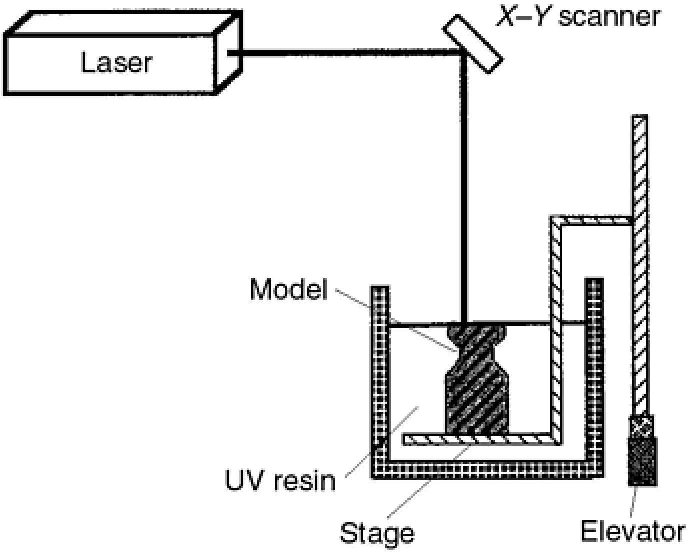

Fig. 4 Schematic of the stereolithography process

Prototypes do not generally sit directly on the build platform during construction, but are supported by a structure that is built along with the prototype. This support is generated automatically by the preprocessing software that creates the support structure as a hollow rectangular grid. This grid provides an interface between the part and the build platform, it provides support for cantilever sections where there is a significant increase in cross section compared with the previous layer, and it prevents the layers from curling or warping during the building process. While other RP processes do not use these rectangular grids for supports, nearly all processes provide support structures that are automatically generated as the part is constructed.

Figure 3(b) is an example of a part built using stereolithography. This model car body is a thin-shelled structure with stiffening ribs on the interior. The car was built upside down supported by a rectangular grid structure (see Fig. 5a).

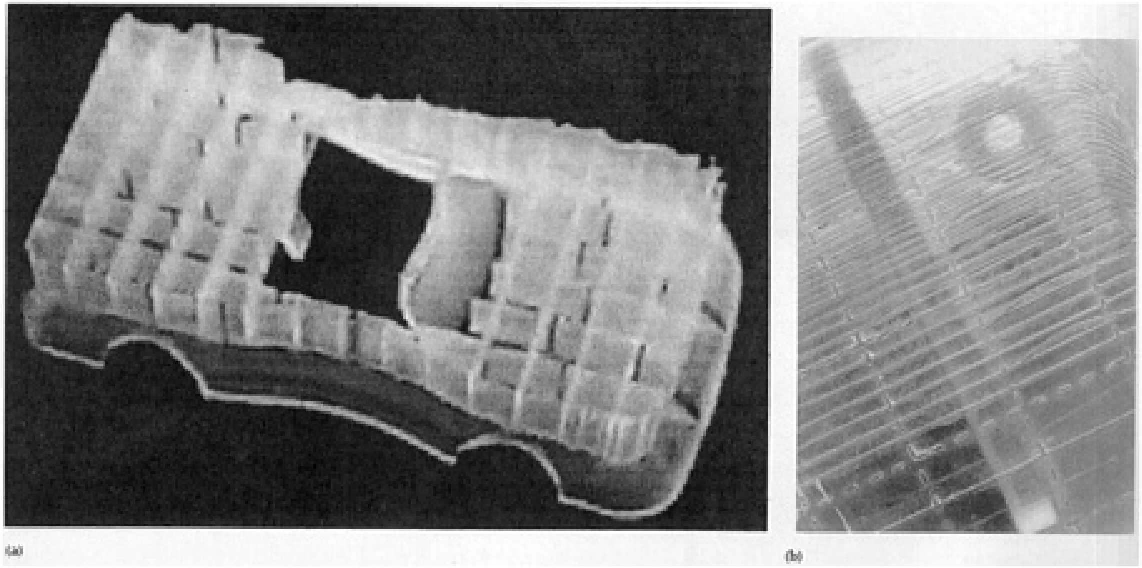

Fig. 5 Model car created using stereolithography. (a) Support structures before removal. (b) Surface finish resulting after removal of the supports

Postprocessing. Once the part is removed, it is washed with a solvent to remove excess photopolymer from the surface. The part is placed in a chamber and exposed to ultraviolet (UV) light to ensure that the cure is complete. Any support structures that may have been required are then removed. These operations are specific to stereolithography. Each different RP process has a series of postprocessing operations that are specific to that process.

At this point the part has a stepped surface finish (Fig. 5b). This is not unique to stereolithography, but is a result of the layered construction technique, which makes the surface finish depend on the layer thickness. The part may also have surface imperfections caused by removal of the support structures. Parts are often sanded and/or painted to improve the surface appearance, depending on the wishes of the customer.

Example: Electric Current Sensor Design.

This case study, based on the experience of a company that designs and manufactures electric current sensors is given as an example to describe the utility and savings that can be achieved by RP technology. The company (F.W. Bell, a division of Bell Technologies Inc.) is involved in the development of a split core current sensor--a hybrid design using two existing products. The large investment required by such a project could not be justified based only on the two-dimensional drawings supplied by the design team.

Designers at F.W. Bell (with the help of a product engineering and prototyping services bureau) developed a three-dimensional CAD model, taking the ambiguity and miscommunication of part detail typical of two-dimensional drafting out of the design process. In addition, physical models--using a Stratasys Fused Deposition Modeling process (Stratasys Inc., Eden Prairie, MN)--were produced for form, fit, and function evaluation. The models were fabricated using acrylonitrile-butadiene-styrene (ABS) plastic, a material that has properties similar to the polycarbonate considered for production. The design team used the models to identify high-stress areas, to get a concept of the real part, to debug the design, and to perform preliminary electrical tests. A prototype made using fused-deposition modeling (FDM) is shown in Fig. 6.

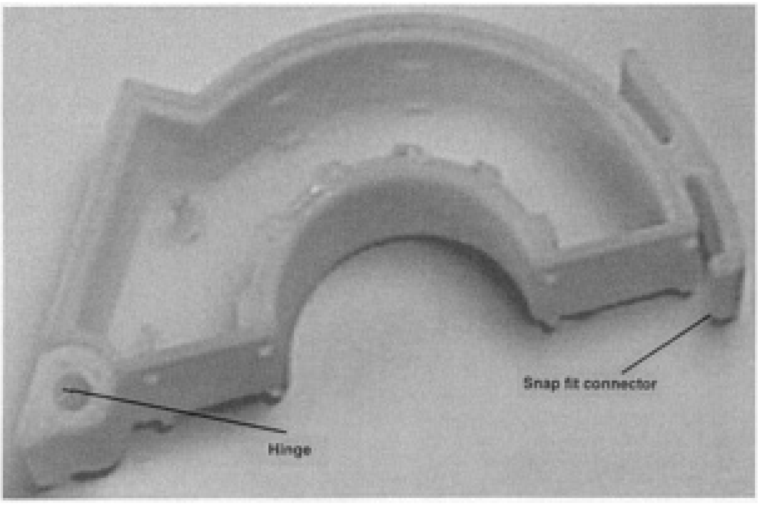

Fig. 6 Housing for a split core electric current sensor was prototyped using FDM. Part is hinged to a mating piece, and the snap fit connector holds the fitting closed.

The snap fits between the components of the split core sensor were an area of high "stress" for the designers. The highly accurate (±0.005 in. tolerances are typical for the FDM process) ABS parts were snapped in place hundreds of times by F.W. Bell's designers, engineers, sales persons, and potential customers. This allowed them to assess not only the design but also the manufacturing processes required to make the parts.

Because the CAD models can be easily modified and the RP service bureau was able to produce the ABS parts literally overnight, several design iterations were produced in a short period of time. This allowed F.W. Bell to try out a multitude of "what-if" scenarios before freezing the design for the development of production tooling. By using ABS models to test design iterations, the company realized cost savings of 60% over the iterative modifications of a production mold, and the time needed to produce the final tooling design was reduced by 70%.

Rapid Prototyping

Charles L. Thomas, University of Utah

Major Commercial Processes

There are a range of processes currently available commercially, either by purchasing a machine, or through service bureaus. Each process uses a distinctly different method for constructing the part layers and, as a result, each process has a unique set of advantages and disadvantages for producing parts. For discussion here, the various processes have been separated into three categories based on their layer creation method:

- *Selective Cure Layered Processes:* These processes create layers by selectively solidifying portions of a layer of precursor material.
- *Extrusion/Droplet Deposition Processes:* These processes build each cross section by selectively depositing material to create the layer.

- *Sheet Form Fabricators:* Layers are cut from sheet form construction material and laminated together.

Speed and Accuracy

Rapid prototyping techniques in general build parts with an accuracy of approximately ±0.005 in. with closer tolerances possible on small local features. While specific machines may do better or worse than this, it is difficult to tag a machine with a specific number because the tolerance capability generally varies with part geometry, construction material, and operator skill. The build speed for a given machine is also difficult to specify as it is dependent on the part geometry and level of accuracy desired. In general terms, small parts 1 to 3 $in.^3$ solid volume, can be built in 1 to 5 h. Larger parts, 60 $in.^3$ or more may take several days to complete. In the discussion of the specific commercial machines below, speed and accuracy are not quantified; instead general classes of part geometry and material are discussed that represent the market niche for each device.

Selective Cure Layered Systems

Stereolithography (SLA) was the first commercial system introduced. A basic description of the process is provided in the section "General Description" in this article. This process has the largest installed user base and the longest development history. Stereolithography builds a part by sequentially solidifying small bits of volume and, as a result, it is most efficient for producing thin-walled structures. Although any part can be built that fits within the 20 by 20 by 23 in. build volume (SLA-500), a large part that requires curing most of the polymer in the build volume would require several days to produce. Parts are produced from a rigid, epoxy-base resin that can be sanded and polished to produce a glossy, optically clear part.

The range of materials available for prototype parts can be increased by prototyping molds instead of parts or by producing patterns for subsequent molding operations. The epoxy-base construction material used in SLA is not directly amenable to investment casting because of thermal expansion of the polymer during the baking of the ceramic shell. To solve this problem, the pattern can be built as a thin-shelled honeycomb structure that will burn out without breaking the ceramic mold. This allows parts to be produced from any metal that can be investment cast.

It is also possible to directly manufacture prototype cavity inserts for injection molding that can be used to produce multiple parts from a select group of injection-moldable polymers and wax (Ref 3). The injection-molded wax patterns can be used to produce multiple metal parts through investment casting. There are restrictions on the geometries that are available using this technique. The prototype part as mold or as pattern can also be used as the starting point for traditional prototyping techniques such as RTV molding.

Solid Ground Curing (SGC). This process involves the curing of each liquid photopolymer layer in a single step using a two-dimensional photomask. The build process results in a polymer part embedded in a solid wax support structure. The surface of each layer is machined to a known thickness, increasing the accuracy of the process. The process steps can be described by the steps shown in Fig. 7.

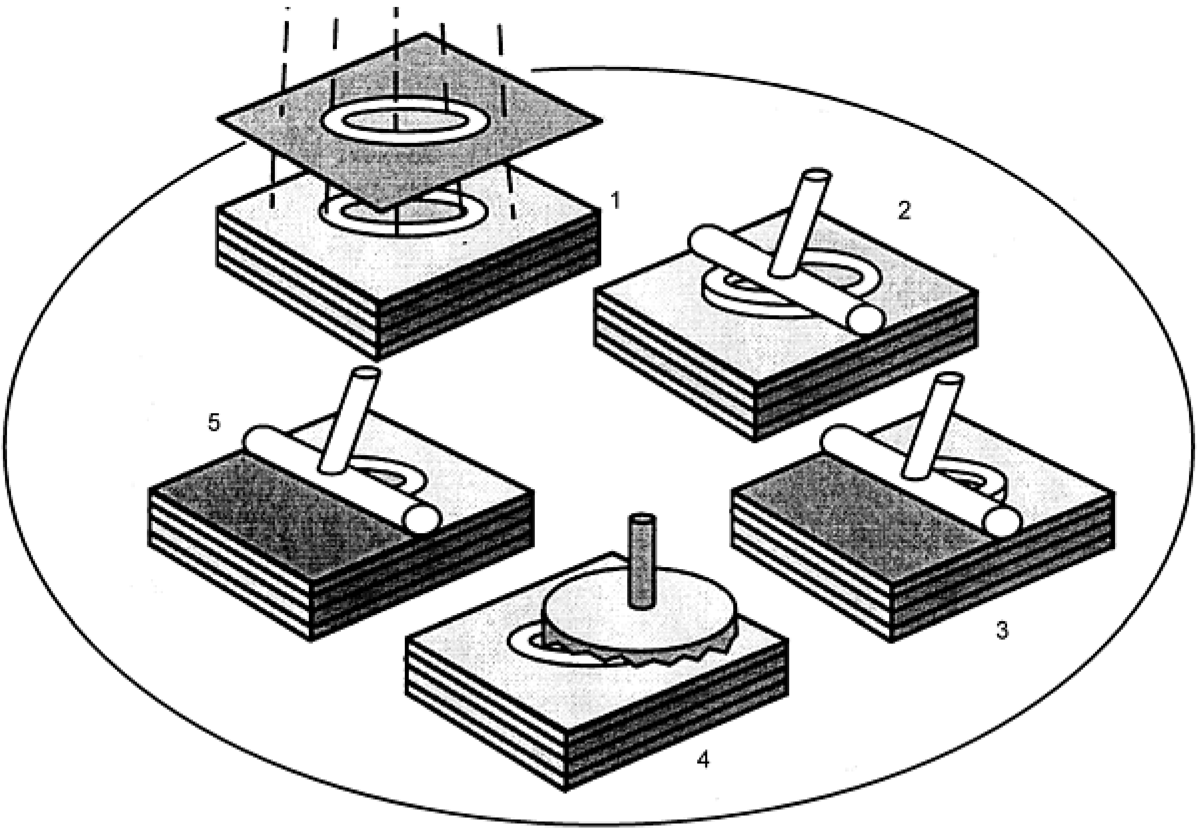

Fig. 7 SGC process: (1) photomask exposure, (2) removal of uncured polymer, (3) coating with wax, (4) milling a flat surface, (5) coating the next polymer layer

First, a thin layer of liquid photopolymer is deposited on a flat substrate. A photomask is generated that matches the cross section of the bottom layer of the part, and the photopolymer is exposed through the mask. Uncured polymer is removed, and a layer of wax is deposited, filling in around the cured cross section. The wax is cooled to a solid, and the surface of the layer is machined flat. This process repeats until the complete prototype has been built. Because of the complexity of the process, SGC is one of the more expensive RP processes.

Postprocessing for SGC involves dissolving away the wax supports and any sanding or polishing that might be desired. A postcuring step is not generally needed using SGC. Each layer is cured against a background of solid polymer and wax. Thus, there is no problem with overexposure curing deeper and increasing the layer thickness.

Solid ground curing has several unique advantages. Because the part is completely supported in solid wax, it is not necessary for the software to design support structures. This also implies that there will be no blemishes to remove from the part surface during postfinishing. The solid wax support allows parts to be nested within the build volume, building parts within the hollow regions of other parts, parts on top of parts, and mechanisms consisting of multiple parts to be built as assembled units. While a single part is typically built more rapidly by SLA, SGC can often exceed SLA in total throughput by building many parts simultaneously. This feature is a distinct advantage to service bureaus that typically build multiple parts in a single run. The wax support and machined layers tend to result in accurate parts with little tendency to warp or deform. The wax can be identified as "part" instead of support structure and can be used for investment casting.

Selective laser sintering (SLS) is similar in principle to SLA in that a laser is used to solidify sequential cross sections from thin layers to create a prototype. In SLS the liquid photopolymer resin from SLA is replaced with a fine thermoplastic powder. Following the schematic shown in Fig. 8, the construction platform consists of three cylindrical tanks with pistons mounted to a planar surface. The two outside cylinders supply powder to the surface, and the central cylinder contains the build volume. The build volume piston translates downward a distance equal to one layer thickness, and pistons in the outside cylinders translate upward supplying powder to the construction plane. A roller spreads the powder into a flat layer covering the construction volume. A laser traces the periphery and crosshatches the solid area of a

part cross section on the powder layer sintering the powder into a solid layer. The process repeats until all layers have been created, then the build piston translates upward and the part is removed. To minimize warpage, the entire process is placed in a heated chamber and heated near the melting temperature of the powder. In order to keep the powder chemically stable at these temperatures, the chamber is purged with an inert gas.

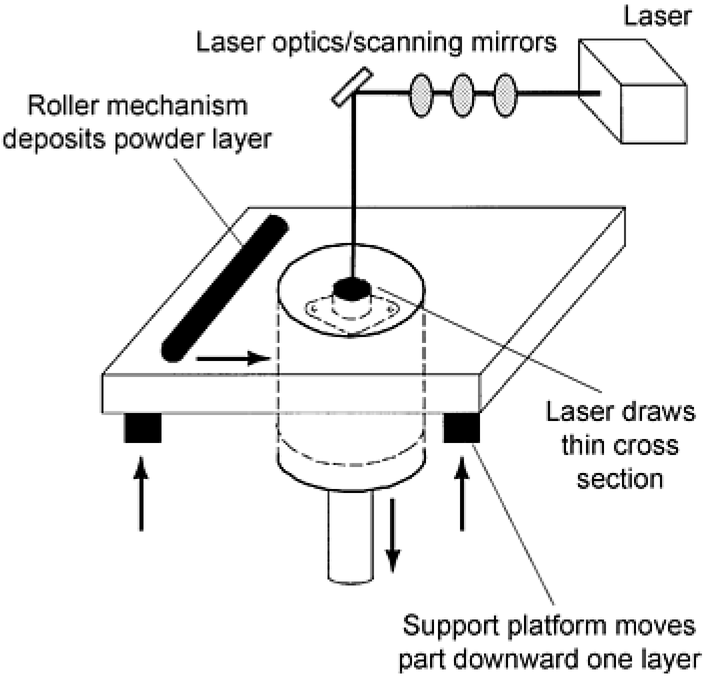

Fig. 8 SLS process. A laser sinters powdered materials, creating the part from thin layers.

Selective laser sintering parts have a surface texture that is somewhat coarse with the surface finish dependent on the particle size of the powder as well as the layer thickness. The parts tend to be somewhat porous. The most common construction materials are nylon and ABS powders; however, the process can theoretically be used with any powder material that can be sintered, which gives SLS a distinct advantage in the range of construction materials.

A process has been recently developed that uses SLS as an initial process in the production of metal injection-molding inserts. This process begins with a steel powder that is coated with a layer of polymer. Using SLS, a "green" part is fabricated by melting the polymer coating on the powder. The green part is placed in an oven with a copper blank. When the temperature is elevated, the polymer burns out of the powder, and the copper melts and infiltrates the powder through capillary action. The result is a composite, steel/copper insert that can be used for low to medium production runs of injection-molded plastic parts. A similar process is under investigation that produces electrical discharge machining (EDM) dies from a composite of ceramic powder and copper (Ref 4).

Extrusion/Droplet Deposition Processes

Fused Deposition Modeling (FDM). This process uses an extruder head attached to a three-axis motion device to generate the part from sequential two-dimensional cross sections (see Fig. 9). Polymer leaves the tip of the extruder at just above the melting temperature of the polymer and rapidly solidifies when it strikes the support substrate or the previous layer. The extruder head acts essentially as a plotter pen, drawing the outline of each cross section and then filling the solid interior. The temperature, plotting speed, and extrusion rate are controlled so that the extruded line bonds to the layer below and to some extent to adjacent lines. The direction of the hatching that fills the interior solid area of each layer is varied from layer to layer, which increases the rigidity of the part. The line of extruded polymer is approximately 0.002 to 0.030 in. thick and 0.010 to 0.125 in. wide allowing wall thickness as small as 0.01 in.

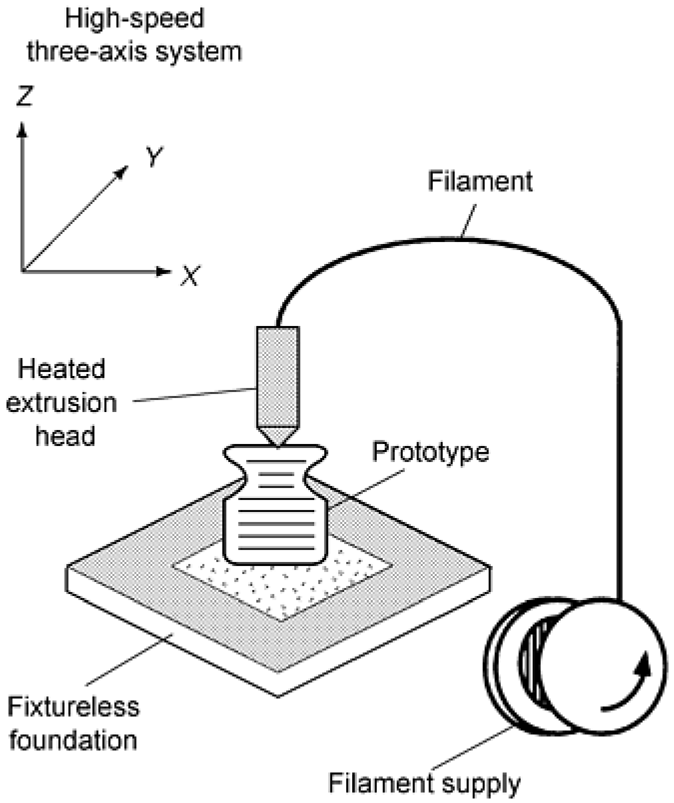

Fig. 9 The FDM process. An extruder head positioned by a three-axis motion controller creates a part from lines of melted polymer.

The line of extruded polymer requires a base on which to rest, and thus support structures are necessary when cantilever features are created. The supports are created from the polymer construction material and separated from the part with a thin layer of a material with low mechanical properties. This allows the supports to be removed easily. A typical part produced using FDM is shown in Fig. 3(c). Figure 10 shows the surface texture produced using this process. The part is somewhat porous because the lines do not completely fuse to adjacent lines. This effect can be varied somewhat by varying the line spacing.

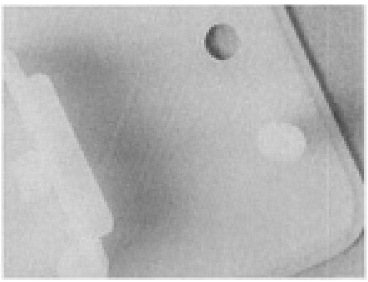

Fig. 10 Porous texture of parts made using FDM caused by adjacent lines of polymer that do not fuse together perfectly

The FDM process requires very little postprocessing. It is clean, with no chemical fumes or solvents required. The device is relatively small and would be acceptable in an office environment. It is most efficient for thin-walled parts due to the voxel sequential construction process. It is relatively difficult to produce a smooth glossy surface finish even with postprocessing.

Droplet Deposition Processes. Several processes are available that create parts through the deposition of droplets. Two of these processes utilize an inkjet printing head to generate part geometry: one by depositing a liquid binder to solidify a powder and a second that deposits polymer droplets that solidify to form the part. A third process uses a droplet deposition device attached to a five-axis motion controller that allows droplets to be deposited at angles other than vertical.

The three-dimensional printing process developed at the Massachusetts Institute of Technology deposits droplets of a liquid binder material onto thin layers of ceramic powder producing a green ceramic part that is later fired to full strength in a kiln (Fig. 11). The ceramic part is typically used as a casting mold to produce metal parts. Machines using this technique are not commercially available, but investment-cast parts in a variety of castable metals made by this process are available from a single-service bureau.

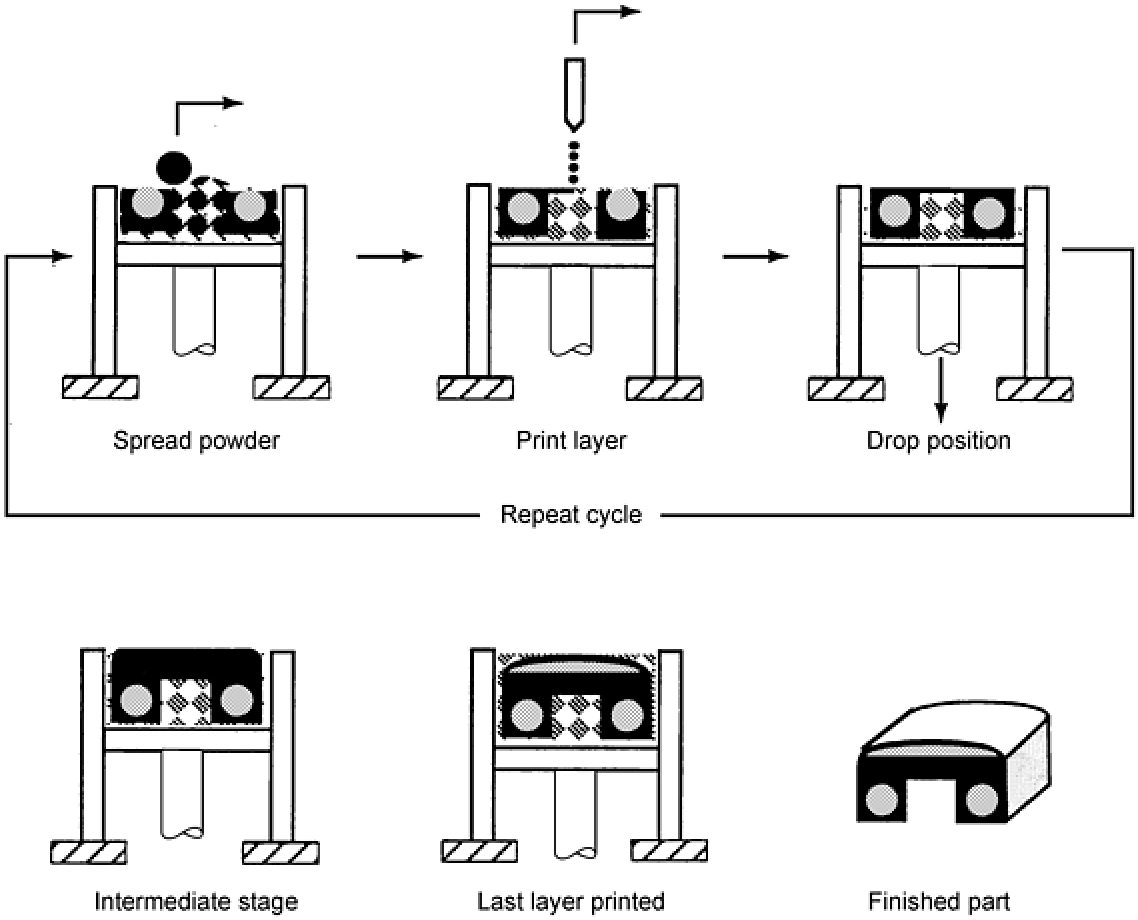

Fig. 11 Three-dimensional printing process solidifying cross sections in layers of powder by depositing a liquid binder

When the RP processes discussed in this article are used to produce models or molds that are traditionally produced by machining, the models produced must often be considered form prototypes because the material properties and tolerances achieved do not match the requirements for the manufactured parts. However, when using the three-dimensional printing process as a replacement for traditional investment casting, parts can be produced that meet or exceed the material properties and tolerances of the traditional process. Thus, this process is often used for functional prototypes or short-run manufacturing.

Inkjet Droplet Deposition (Polymer). Another class of droplet deposition devices deposit droplets of molten polymer and/or wax. The liquid droplets solidify when they strike the substrate or the previous layer. Two commercial machines are available using this process. The first device uses a relatively large deposition head and creates parts as much as three to five times faster than many competing processes. The accuracy of these models is somewhat reduced.

The second device uses two inkjet heads to deposit droplets of polymer and wax to create a part (Fig. 12). Although it is usually used as support structure, the wax can be used for investment-casting patterns. The commercial device based on this process mills the surface of each layer after the layer is deposited, producing layers as thin as 0.0004 in. thick. Because of the extremely thin layers, parts can be produced with a surface finish that is an order of magnitude smoother than the competing processes. An undesirable result of the thin layers is that the machine is also quite slow. The most appropriate use for the machine is for small models that require excellent surface finish such as jewelry.

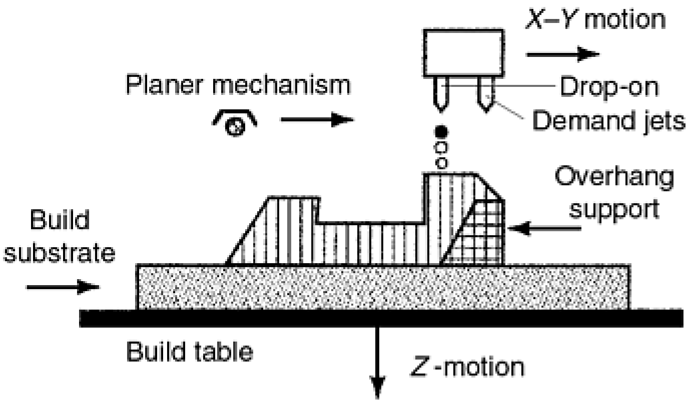

Fig. 12 The inkjet droplet deposition process.

Ballistic Particle Manufacturing (BPM). This process is quite similar to polymer droplet deposition.The difference is that BPM allows five-axis control of the droplet deposition head, which allows certain cantilever features to be grown horizontally from the part (eliminating the need for support structures). The commercial BPM device is one of the lowest cost RP devices and uses inexpensive construction materials. It is considered an "office modeler" because the machine is relatively small, quiet, and odor free.

Sheet Form Fabricators

These processes produce parts from thin layers of sheets of construction material. The cross sections are cut from the sheet, stacked, and bonded together to produce the prototypes. There is some variation in the methods used to cut the cross sections from the sheets and in the sequence of operations that gives each process unique advantages and disadvantages.

Stack-Then-Cut (Laminated Object Manufacturing). The laminated object manufacturing (LOM) process follows the schematic shown in Fig. 13. The construction sheet is a roll of paper that has a polyethylene coating on one surface. The paper is unrolled across a flat support, and a heated roller rolls across the build volume, melting the polyethylene and bonding the sheet to the support or to the previous sheet. Next, a laser scans the periphery of the part. The power and speed are adjusted so that the laser burns through only the surface sheet. The laser also cuts a square that defines the edges of the build volume and cuts parting lines and crosshatches the waste material to form small removable cubes. This process is repeated until all layers have been completed, resulting in a rectangular block of construction material with the part hidden inside. Postprocessing consists of manually breaking away the waste material to reveal the part inside and sanding or coating if desired. The finished parts have a texture and consistency similar to wood.

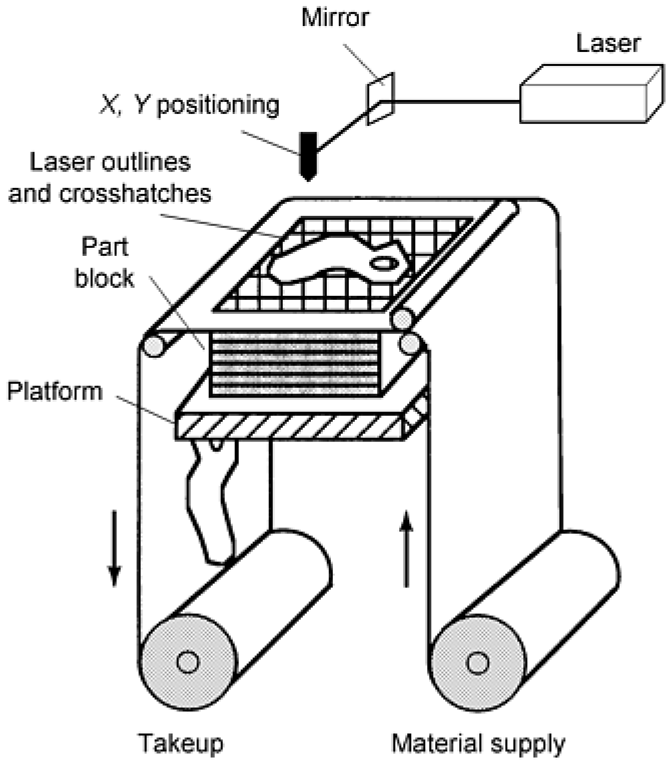

Fig. 13 The laminated object manufacturing process. Parts are built from layers of sheet material (usually paper).

When using LOM, it is necessary to scan only the periphery instead of the entire solid area of each cross section. As a result, this process is most competitive for larger parts with large solid volumes. The build volume of the largest commercial LOM machine available in the United States is 32 by 22 by 20 in. Small features and thin-walled structures must be handled carefully during decubing to avoid breakage. Hollow structures are often built in two pieces so that the interior volume can be decubed and then manually joined during postprocessing. These parts have been used successfully as sand-casting patterns, vacuum-forming patterns, and investment-casting patterns (the paper burns out of the ceramic shell during firing).

Cut-Then-Stack Process. An alternative to the "stack-then-cut" process has been introduced in an inexpensive, partially manual sheet-form prototyping process. The construction sheets consist of an adhesive-backed material attached to a backing sheet. Part cross sections are cut through the adhesive-backed materials--but not through the backing--using a plotter with a knife instead of a pen. Registration and bonding process proceeds manually with an operator registering the sheets on a build platform using registration holes cut through both layers of the construction sheets.

The process uses a parallel decomposition technique that automatically slices small parts into subparts and positions the subparts to cover the entire construction sheet. This is shown in Fig. 14. Using this decomposition a 100-layer part can often be decomposed into ten subparts requiring ten sheets of construction material. The operator performs ten operations registering and bonding the ten sheets resulting in a backing sheet that contains ten, ten-layer thick subparts. The subparts are then stacked, requiring ten more operations.

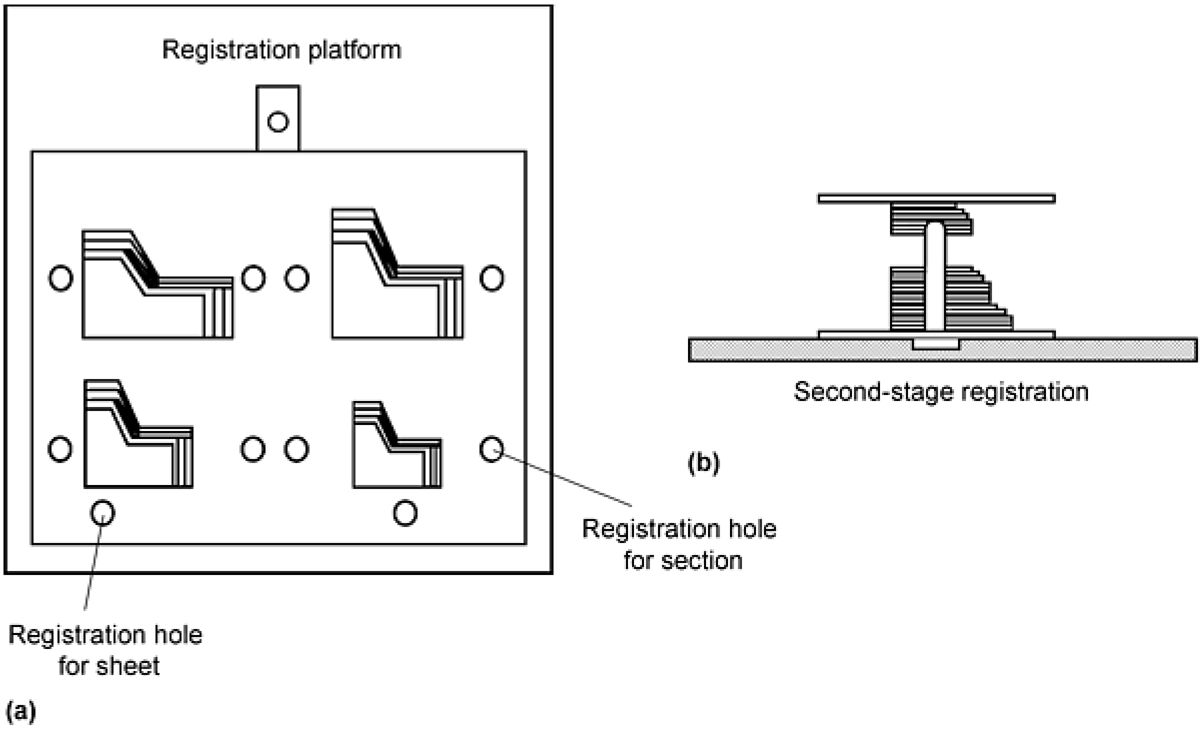

Fig. 14 The two stages of the "cut-then-stack" process. (a) Four subparts are built in parallel. (b) Subparts are stacked to complete the part.

Common construction materials are 0.1 mm (0.004 in.) thick paper and 1 mm (0.04 in.) thick polystyrene foam. An example paper part is shown in Fig. 3(a). This car, requiring more than 300 layers, was built in two pieces using 155 sheets of construction material. Parts constructed from the foam material can be used as patterns for investment casting. A typical cast part is shown in Fig. 3(d).

The combination of manual registration and bonding, parallel decomposition, and "cut-then-stack" processing results in a unique combination of advantages and disadvantages:

- The machine is an order of magnitude less expensive than most commercial processes.
- The tolerance capability is operator dependent and generally an order of magnitude lower than competing processes.
- Parts that take advantage of the parallel decomposition can often be built four to five times faster than competing processes.

Numerical Control Machining for Prototyping

As techniques for numerical control (NC) machining have improved, it has become possible to create complex parts quite rapidly by machining. Modern CAD tools can interpret the geometric features of a solid model and generate the tool paths necessary to machine the part on an NC machining center. The tool path generation process requires some assistance from a skilled machinist. The machinist must develop a manufacturing plan that may require manual repositioning of the part one or more times during the machining process and may require the use of more than one machine. The machinist is also required for the actual machining.

Numerical control as a prototyping technique has its own advantages and disadvantages. A broad range of construction materials can be used. Once the manufacturing plan is completed and the first part is produced, multiple copies of the part can often be produced very rapidly. For example, the part shown in Fig. 15 was created on a five-axis machining center. The manufacturing plan and initial part required 16 h to develop. Production of subsequent parts required approximately 20 min per part. An added advantage of NC as a prototyping technique is that once the prototype is completed, the designer already has a manufacturing option in place. Numerical control machining techniques are capable of producing very tight tolerances.

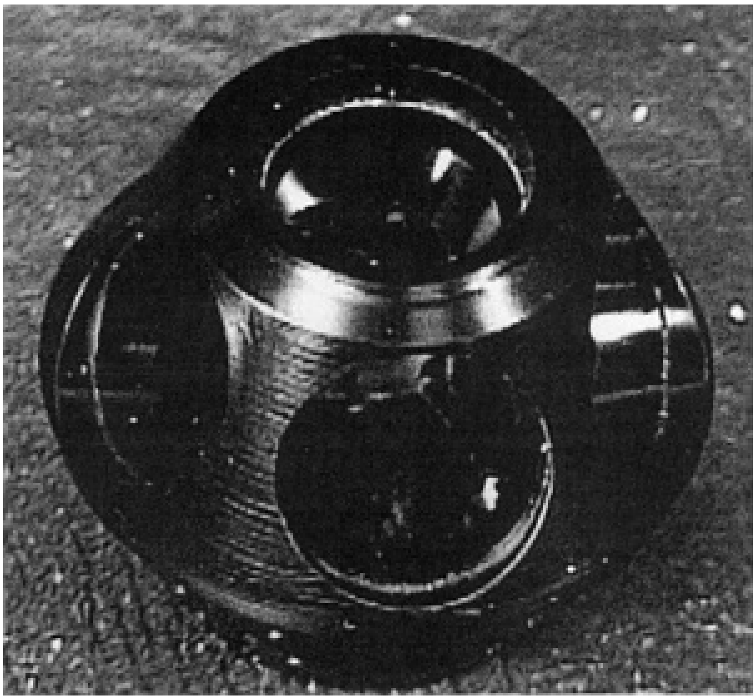

Fig. 15 Sensor casing for a head position tracking sensor machined from aluminum using an NC machining center. The first copy required 12 h to produce. Duplicates would require 15 min each to produce. Courtesy of S. Drake, University of Utah

Along with these advantages come disadvantages: The level of operator skill required is much higher than for the other techniques discussed here. The range of geometries that can be created using NC is more limited. The ability to create a wide variety of geometries requires a broad range of tools and several machines. Many parts require one or more fixtures to hold the part during machining. This fixture must be designed and built along with the part, requiring added costs and time delay.

Designing with Manufacturable Features. It is interesting to note that the increased flexibility of RP processes over NC machining can be considered both an advantage and a disadvantage. Rapid prototyping techniques put very few limits on the imagination of the part designer. Almost any geometry that can be modeled can be prototyped. However, the designer is generally developing a product that must be manufactured using traditional manufacturing techniques. Using NC as a prototyping tool forces the designer to produce prototypes made up of manufacturable features. Designing with prototypes built using RP techniques can cause the designer to produce a design that is impossible to manufacture with any technique except RP.

Rapid Prototyping

Charles L. Thomas, University of Utah

Analyzing Speed and Accuracy

For each of the processes discussed in this article, the technique used for layer creation produces a definable relationship between part geometry and build speed. Three general classes that appear are voxel sequential volume addition, periphery cutting, and area sequential volume addition.

Voxel Sequential Volume Addition (VSVA). Where a pixel represents the smallest area unit in a two-dimensional picture, the term voxel is used here to represent the smallest volume unit that can be created by an RP device. A voxel is a single droplet for a droplet deposition device or the volume extruded by an FDM device as the extruder head moves a single step of the motion controller. The build time for voxel sequential devices is directly proportional to the solid volume of the part. As a result, these processes create thin-walled structures relatively quickly and thick-bodied structures more slowly. Because they deposit (or cure) only the material needed for the part and required supports, there is little waste.

Periphery Cutting (PC). The sheet-form processes discussed previously in this article create cross sections by cutting the periphery of the part and cutting parting lines to turn the waste material into cubes. In this case, the time required to cut a cross section is proportional to the periphery length. A solid object is constructed faster than if it were hollow because it is not necessary to cut the interior surface. Periphery cutting processes are therefore, optimal for larger, heavy-bodied parts with large volume-to-surface-area ratios. Because the material cut away from each cross section is waste, these processes are relatively wasteful and more so for thin-walled structures.

Area Sequential Volume Addition (ASVA). This class includes processes that create each cross section as a two-dimensional area in a single step. The two-dimensional photomask curing used in the SGC process is an example. For these processes, the build time for the part is only a function of the number of layers in the part. The build times for thin-walled structures and heavy-bodied structures are identical if the vertical height is the same.

These concepts are demonstrated in Fig. 16, in which a generic part is represented by a cube whose wall thickness varies from very thin to a solid cube. The build times for each of the three classes are represented by the equation below:

$$T_B = \sum_{i=1}^{n} (T_R + T_{LCi}) \quad \textbf{(Eq 1)}$$

where T_B is the time required to build the part, T_R is the time required to produce a new layer of liquid or powder or to apply a new sheet, and T_{LCi} is the time required to create a specific cross section for a part consisting of *n* layers. For each process *T* is assumed constant. *T* for each process is shown below:

For VSVA: $T_{LC} \propto L_o^2 - L_i^2$
For PC: $T_{LC} \propto 4L_o + 4L_i$
For ASVA: T_{LC} = Constant

where L_i and L_o are the inside and outside dimension, respectively, of the cube as shown in Fig. 16.

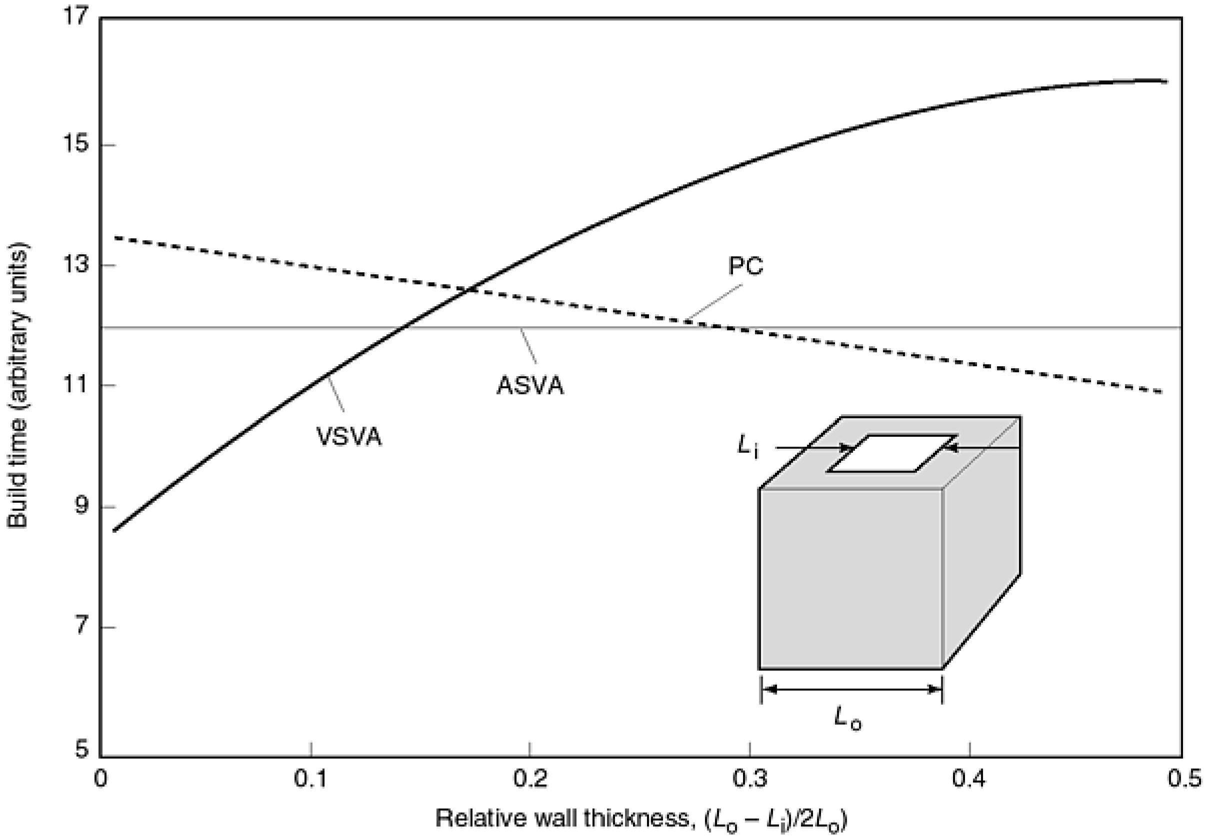

Fig. 16 Variation of build time with wall thickness for three classes of RP processes: voxel sequential volume addition (VSVA), area sequential volume addition (ASVA), and periphery cutting (PC)

As the wall thickness increases, the build time for a VSVA process increases while the time actually decreases for the PC process. The build time for the ASVA is unchanged because in this example, the vertical height of the part is unchanged. The exact shape of the curves in Fig. 16 result from the coefficients selected for the equations, the part shape, and the method chosen for varying the geometry. While different assumptions and conditions will change these shapes, the general trends should be preserved.

Rapid Prototyping

Current Research Efforts

The discussion so far has been limited to techniques that are available commercially. There are numerous other techniques that are current topics for research. These topics fall into three general classes:

- Improving construction accuracy
- Developing new construction techniques
- Prototyping new materials and complex structures (composites, functionally gradient materials, creating microstructure, embedding components, etc.)

Improving Construction Accuracy. Research in this area proceeds for each of the commercial devices. The work generally revolves around characterizing the behavior of the construction materials during processing (Ref 5, 6), improving the operating characteristics of the machine (Ref 7), or reducing material shrinkage and warp during processing (Ref 8).

Developing New Construction Techniques. The research here is not on processes that would compete with existing processes, but processes that will fill in areas that are not currently represented. A research tool developed for prototyping large objects builds parts from thick sheets of polystyrene foam. This sheet-form process cuts custom-ruled surfaces on the edges of the cross sections, allowing a reasonable representation of the object geometry to be produced from very thick layers. The technique has been used to create models up to 20 ft in length and to produce foam molds for the production of large composite structures (Ref 9). A new technique termed *selective area laser deposition* (SALD) uses laser energy to selectively induce chemical vapor deposition. This process is capable of creating three-dimensional geometric features on the micron scale (Ref 10, 11). An automated version of "cut-then-stack" sheet-form prototyping is under development that will allow layers of a part to be created simultaneously by many machines in parallel, then collated, stacked, and bonded. This has the potential to dramatically increase the speed of prototype production (Ref 12).

Prototyping with New Materials and Complex Structures. Researchers are investigating techniques for directly prototyping fiber-reinforced composites (Ref 13). The three-dimensional printing technique is being used to directly prototype materials with custom microstructures (Ref 14). This allows the potential for creating functionally gradient materials, with properties that vary with position in the prototype. Shape deposition manufacturing allows the construction of prototypes using multiple materials and embedded components (Ref 15). The manual "cut-then-stack" technique is being used to create prototypes that are operational devices by embedding functional components such as motors, switches, and wiring during the stacking process (Ref 12).

Overview of the Materials Selection Process

George E. Dieter, University of Maryland

Introduction

THE SELECTION OF THE CORRECT MATERIAL for a design is a key step in the process because it is the crucial decision that links computer calculations and lines on an engineering drawing with a working design. Materials and the manufacturing processes that convert the material into a useful part underpin all of engineering design. The enormity of the decision task in materials selection is given by the fact that there are well over 100,000 engineering materials from which to choose. On a more practical level, the typical design engineer should have ready access to information on 50 to 80 materials, depending on the range of applications.

The importance of materials selection in design has increased in recent years. The adoption of concurrent engineering methods (see the article "Concurrent Engineering" in this Volume) has brought materials engineers into the design process at an earlier stage, and the importance given to manufacturing in present day product design has reinforced the fact that materials and manufacturing are closely linked in determining final properties. Moreover, world pressures of competitiveness have increased the general level of automation in manufacturing to the point where materials costs comprise 50% or more of the cost for most products. Finally, the great activity in materials science worldwide has created a variety of new materials and focused attention on the competition between six broad classes of materials: metals, polymers, elastomers, ceramics, glasses, and composites. Thus the range of materials available to the engineer is much larger than ever before. This presents the opportunity for innovation in design by utilizing these materials in products that provide greater performance at lower cost. To achieve this requires a more rational process for materials selection.

George E. Dieter, University of Maryland

Relation of Materials Selection to Design

An incorrectly chosen material can lead not only to failure of the part but also to unnecessary cost. Selecting the best material for a part involves more than selecting a material that has the properties to provide the necessary performance in service; it is also intimately connected with the processing of the material into the finished part (Fig. 1). A poorly chosen material can add to manufacturing cost and unnecessarily increase the cost of the part. Also, the properties of the material can be changed by processing (beneficially or detrimentally), and that may affect the service performance of the part.

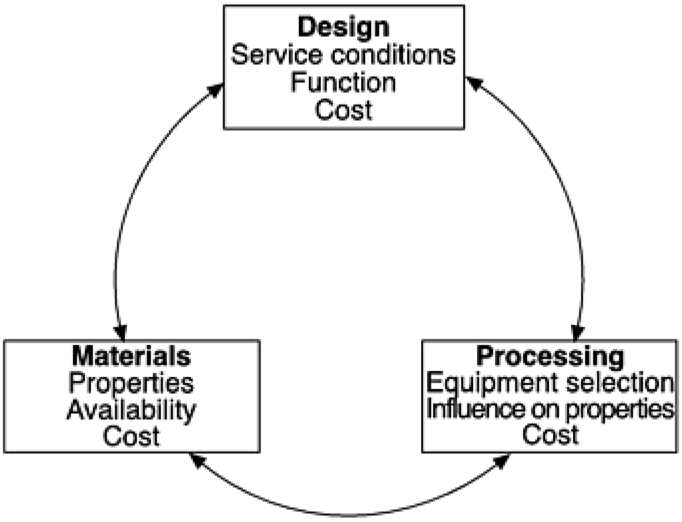

Fig. 1 Interrelationship among design, materials, and processing

With the enormous combination of materials and processes to choose from, the task can be done only by introducing simplification and systemization. Design proceeds from concept design, to embodiment (configuration) design, to detail (parametric) design, and the material and process selection then becomes more detailed as the design progresses through this sequence. The steps in the design process are discussed in the Section "The Design Process" in this Volume. Figure 2 contrasts the design methods and tools used at each stage with the materials and processes selection.

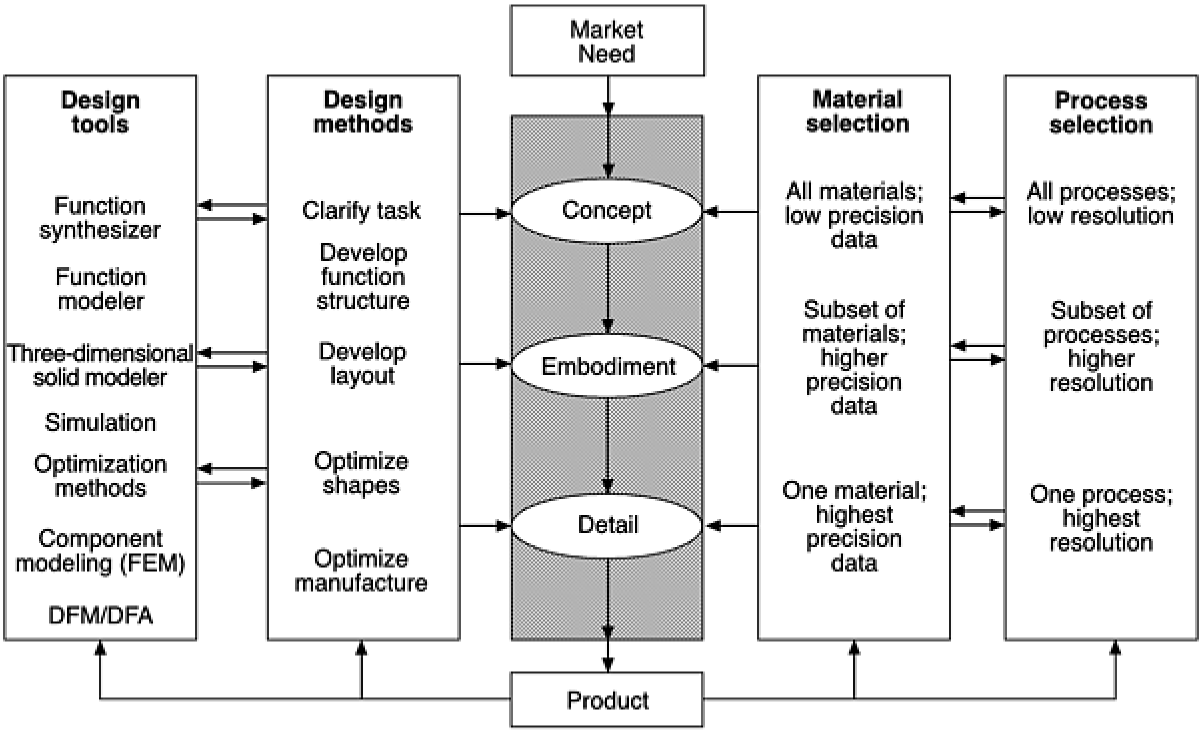

Fig. 2 Schematic of the design process with design tools on the left and materials and process selection on the right. At the concept stage of design, the emphasis is on breadth; in the later stages, it is on precision. FEM, finite element modeling; DFM, design for manufacturing; DFA, design for assembly. Source: Ref 1

At the concept level of design, essentially all materials and processes are considered rather broadly. The materials selection methodology and charts developed by Ashby (Ref 2) are highly appropriate at this stage (see the articles

"Material Property Charts" and "Performance Indices" in this Volume). The decision is to determine whether each design concept will be made from metal, plastics, ceramic, composite, or wood, and to narrow it to a group of materials. The precision of property data needed is rather low. If an innovative choice of material is to be made, it must be done at the conceptual design step because later in the design process too many decisions have been made to allow for a radical change.

At the embodiment or configuration level of design, the emphasis is on determining the shape and approximate size of a part using engineering methods of analysis. Now the designer will have decided on a class of materials and processes, for example a range of aluminum alloys, wrought and cast. The material properties must be known to a greater level of precision.

At the detail or parametric design level, the decision will have narrowed to a single material and only a few manufacturing processes. Here the emphasis will be on deciding on critical tolerances, optimizing for robust design (see the article "Robust Design" in this Volume), and selecting the best manufacturing process using quality engineering and cost modeling methodologies. Depending on the criticality of the part, materials properties may need to be known to a high level of precision. At the extreme, this requires the development of a detailed data base from an extensive materials testing program.

In a more detailed approach to engineering design, Dixon and Poli (Ref 3) suggest a four-level approach to materials selection:

- *Level I.* Based on critical properties, determine whether the part will be made from metal, plastic, ceramic, or composite.
- *Level II.* Determine whether metal parts will be produced by a deformation process (wrought) or a casting process; for plastics, determine whether they will be thermoplastic or thermosetting polymers.
- *Level III.* Narrow options to a broad category of material. Metals can be subdivided into categories such as carbon steel, stainless steel, and copper alloys. Plastics can be subdivided into specific classes of thermoplastics and thermosets such as polycarbonates and polyesters.
- *Level IV.* Select a specific material according to a specific grade or specification.

Thus material and process selection is a progressive process of narrowing from a large universe of possibilities to a specific material and process selection; see the next section "The Process of Materials Selection" in this article. Levels I and II often may suffice for conceptual design. Level III is needed for embodiment (configuration) design and sometimes for conceptual design. Level IV usually can be postponed until detail (parametric) design.

Overview of the Materials Selection Process

George E. Dieter, University of Maryland

The Process of Materials Selection

A materials selection problem usually involves one of two situations:

- Selection of the materials and the processes for a new product or design
- The evaluation of alternative materials or manufacturing routes for an existing product or design. Such a redesign effort usually is taken to reduce cost, increase reliability, or improve performance. It generally is not possible to realize the full potential of substituting one material for another without fully considering its manufacturing characteristics. In other words, simple substitution of a new material without changing the design rarely provides optimum utilization of the material.

Materials Selection for a New Design. In this situation, these steps must be followed:

1. Define the functions that the design must perform, and translate these into required materials properties such as stiffness, strength, and corrosion resistance, and such business factors as the cost and availability of the material.
2. Define the manufacturing requirements in terms of such parameters as the number of parts required, the size and complexity of the part, its required tolerance and surface finish, general quality level, and overall fabricability of the material.
3. Compare the needed properties and parameters with a large materials property data base (most likely computerized) to select a few materials that look promising for the application. In this initial screening process, it is helpful to establish several screening properties. A screening property is any material property for which an absolute lower (or upper) limit can be established. No trade-off beyond this limit is allowable. It is a go-no go situation. The idea of the screening phase in materials selection is to ask the question: "Should this material be evaluated further for this application?"
4. Investigate the candidate materials in more detail, particularly in terms of trade-offs in product performance, cost, fabricability, and availability in the grades and sizes needed for the application. Material property tests and other testing often is done at this stage. Methods for making this detailed evaluation are discussed in the articles "Performance Indices" and "Decision Matrices in Materials Selection" in this Volume.
5. Develop design data and/or a design specification. Step 4 results in the selection of a single material for the design and a suggested process for manufacturing the part. In most cases, this results in establishing the minimum properties through defining the material with a generic material standard such as those issued by the American Society for Testing and Materials (ASTM), the Society of Automotive Engineers (SAE), the American National Standards Institute (ANSI), and the United States military (MIL specs). For critical parts in sensitive applications, for example in aerospace and nuclear areas, it may be necessary to conduct an extensive testing program to develop design data that are statistically reliable (see the article "Statistical Aspects of Design" in this Volume).

Materials Substitution for an Existing Design. In this situation, the following steps pertain:

1. Characterize the currently used material in terms of performance, manufacturing requirements, and cost.
2. Determine which characteristics must be improved for enhanced product function. Often failure analysis reports play a critical role in this step (see the article "Use of Failure Analysis in Materials Selection" in this Volume).
3. Search for alternative materials and/or manufacturing routes. Use the idea of screening properties to good advantage.
4. Compile a short list of materials and processing routes, and use these to estimate the costs of manufactured parts. A method of engineering analysis called *value engineering* has proven useful for this purpose (see the article "Value Analysis in Materials Selection and Design" in this Volume). Value engineering is a problem-solving methodology that focuses on identifying the key function(s) of a design so that unnecessary costs can be removed without compromising the quality of the design.
5. Evaluate the results in step 4, and make a recommendation for a replacement material. Define the critical properties with specifications or testing as in step 5 of the previous section.

There are two approaches (Ref 3) to determining the material-process combination for a part. In the *material first approach*, the designer begins by selecting a material class and narrowing it down as described above. Then manufacturing processes consistent with the selected material are considered and evaluated. Chief among the factors to consider are production volume and information about the size, shape, and complexity of the part. With the *process first approach*, the designer begins by selecting the manufacturing process, guided by the same factors. Then materials consistent with the selected process are considered and evaluated, guided by the performance requirements of the part. Both approaches end up at the same decision point. Most design engineers and materials engineers instinctively use the materials first approach since it is the method taught in strength of materials and machine design courses. Manufacturing engineers and those heavily involved with process engineering gravitate toward the other approach. No studies have been done to determine which leads to the best results.

Overview of the Materials Selection Process

George E. Dieter, University of Maryland

Performance Characteristics of Materials

The performance or functional characteristics of a material are expressed chiefly by physical, mechanical, thermal, electrical, magnetic, and optical properties. Material properties are the link between the basic structure and composition of the material and the service performance of the part (Fig. 3). The goal of materials science is to learn how to control the various levels of structure of a material (electronic structure, defect structure, microstructure, macrostructure) so as to predict and improve the properties of a material. Not too long ago metals dominated most of engineering design. Today the range of materials and properties available to the engineer is much larger and growing rapidly. This requires familiarity with a broader range of materials and properties, but it also introduces new opportunities for innovation in product development. Table 1 provides a general comparison of the properties of metals, ceramics, and polymers. A detailed review of fundamental structure-property relationships in engineering materials, and a consideration of the effects of composition, processing, and structure on the properties of steels, nonferrous metallic alloys, ceramics and glasses, engineering plastics, and composites is provided in the Section "Effects of Composition, Processing, and Structure on Materials Properties" in this Volume. Table 2 provides a listing of the broad spectrum of material properties that may be needed.

Table 1 General comparison of properties of metals, ceramics, and polymers

Property (approximate values)	Metals	Ceramics	Polymers
Density, g/cm^3	2 to 22 (average ~8)	2 to 19 (average ~4)	1 to 2
Melting points	Low (Ga = 29.78 °C, or 85.6 °F) to high (W = 3410 °C, or 6170 °F)	High (up to 4000 °C, or 7230 °F)	Low
Hardness	Medium	High	Low
Machinability	Good	Poor	Good

Tensile strength, MPa (ksi)	Up to 2500 (360)	Up to 400 (58)	Up to 140 (20)
Compressive strength, MPa (ksi)	Up to 2500 (360)	Up to 5000 (725)	Up to 350 (50)
Young's modulus, GPa (10^6 psi)	15 to 400 (2 to 58)	150 to 450 (22 to 65)	0.001 to 10 (0.00015 to 1.45)
High-temperature creep resistance	Poor to medium	Excellent	. . .
Thermal expansion	Medium to high	Low to medium	Very high
Thermal conductivity	Medium to high	Medium, but often decreases rapidly with temperature	Very low
Thermal shock resistance	Good	Generally poor	. . .
Electrical characteristics	Conductors	Insulators	Insulators
Chemical resistance	Low to medium	Excellent	Good
Oxidation resistance	Generally poor	Oxides excellent; SiC and Si_3N_4 good	. . .

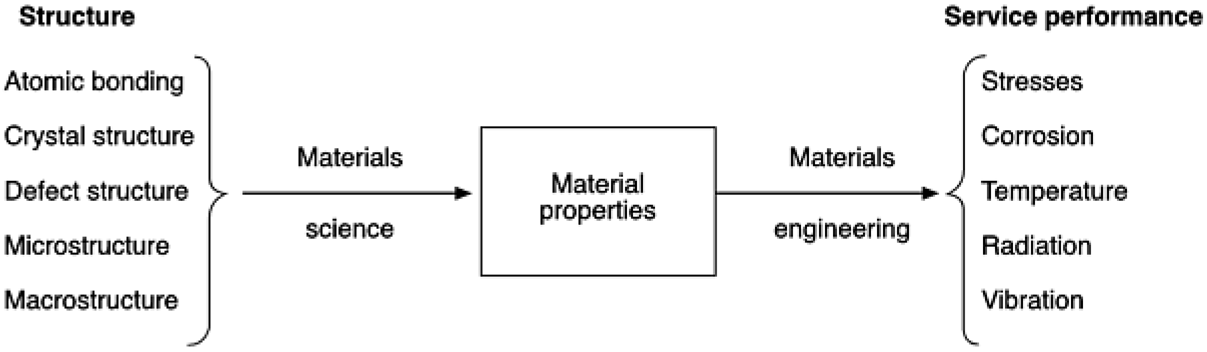

Fig. 3 The role played by material properties in the selection of materials

An important role of the materials engineer is to assist the designer in making meaningful connections between materials properties and the performance of the part or system being designed. For most mechanical systems, performance is limited, not by a single property, but by a combination of them. For example, the materials with the best thermal shock resistance are those with the largest values of $\sigma_f/E\alpha$, where σ_f is the failure stress, E is Young's modulus, and α is the

thermal coefficient of expansion. Ashby (Ref 2) showed how to derive these *performance indices* (groupings of material properties that, when maximized, maximize some aspect of performance) and how to use them in conjunction with his materials selection charts (see the article "Performance Indices" in this Volume). Table 3 shows the relationships between standard mechanical properties and the failure modes for materials (Ref 5). For most modes of failure, two or more material properties act to control the material behavior. Also, it must be kept in mind that the service conditions met by materials are in general more complex than the test conditions used to measure material properties. Usually simulated service tests must be devised to screen materials for critical complex service conditions. Finally, the chosen material, or a small group of candidate materials, must be evaluated in prototype tests or field tests to determine their performance under actual service conditions.

Table 3 Relationships between failure modes and material properties

Failure mode	Material property														
	Ultimate tensile strength	**Yield strength**	**Compressive yield strength**	**Shear yield strength**	**Fatigue properties**	**Ductility**	**Impact energy**	**Transition temperature**	**Modulus of elasticity**	**Creep rate**	K_{Ic} [(a)]	K_{Iscc} [(b)]	**Electrochemical potential**	**Hardness**	**Coefficient of expansion**
Gross yielding		X		X											
Buckling			X						X

Example 1: Materials Selection for an Automotive Exhaust System (Ref 6).

The product design specification for the exhaust system must provide for the following functions:

- Conducting engine exhaust gases away from the engine
- Preventing noxious fumes from entering the automobile
- Cooling the exhaust gases
- Reducing the engine noise
- Reducing the exposure of automobile body parts to exhaust gases
- Affecting engine performance as little as possible
- Helping control undesirable exhaust emissions
- Having a service life that is acceptably long
- Having a reasonable cost, both as original equipment and as a replacement part

In its basic form, the exhaust system consists of a series of tubes that collect the gases at the engine and convey them to the rear of the automobile. The size of the tube is determined by the volume of the exhaust gases to be carried away and the extent to which the exhaust system can be permitted to impede the flow of gases from the engine. An additional device, the muffler, is required for noise reduction, and a catalytic converter is required to convert polluting gases to less-harmful emissions. The basic lifetime requirement is that the system must resist the attack of hot, moist exhaust gases for some specified period. In addition, the system must resist attack by the atmosphere, water, mud, and road salt. The location of the exhaust system under the car requires that it be designed as a complex shape that will not interfere with the running gear of the car, road clearance, or the passenger compartment. The large number of automobiles produced each year requires that the material used in exhaust systems be readily available at minimum cost.

This system requires numerous material property requirements. The mechanical property requirements are not overly severe: suitable rigidity to prevent excessive vibration and fatigue plus enough creep resistance to provide adequate service life. Corrosion is the limiting factor on life, especially in the cold end, which includes the resonator, muffler, and tail pipe. Several properties of unique interest, that is, where one or two properties dominate the selection of the material, are found in this system. These pertain to the platinum-base catalyst and the ceramic carrier that supports the catalyst. The majority of the tubes and containers that comprise the exhaust system were for years made of readily formed and welded low-carbon steel, with suitable coatings for corrosion resistance. With the advent of greater emphasis on automotive quality and longer life, the material selection has moved to specially developed stainless steels with improved corrosion and creep properties. Ferritic 11% Cr alloys are used in the cold end components, with 17 to 20% Cr ferritic alloys and austenitic Cr-Ni alloys in the hot end of the system.

Standards and Specifications. Materials properties usually are formalized through standards and specifications. The distinction between these entities is that a standard is intended for use by as large a body as possible, for example ASTM or ANSI standards, whereas a specification, though dealing with similar technical content, is intended for use by a more limited group, for example a company specification. There are two types of standards or specifications: performance standards and product standards. Performance standards delineate the basic functional requirements of a product and set out the basic parameters from which the design can be developed. Product standards define the conditions under which the components of a design are purchased and manufactured. Materials standards are invariably product standards. They stipulate performance characteristics, quality factors, methods of measurement, tolerances, and dimensions.

Relation of Materials Selection to Manufacturing

The selection of a material must be closely coupled with the selection of a manufacturing process. This is not an easy task for there are many processes that can produce the same part. The goal is to select the material and process that maximizes quality and minimizes the cost of the part. Figure 4 gives a breakdown of manufacturing processes into nine broad classes.

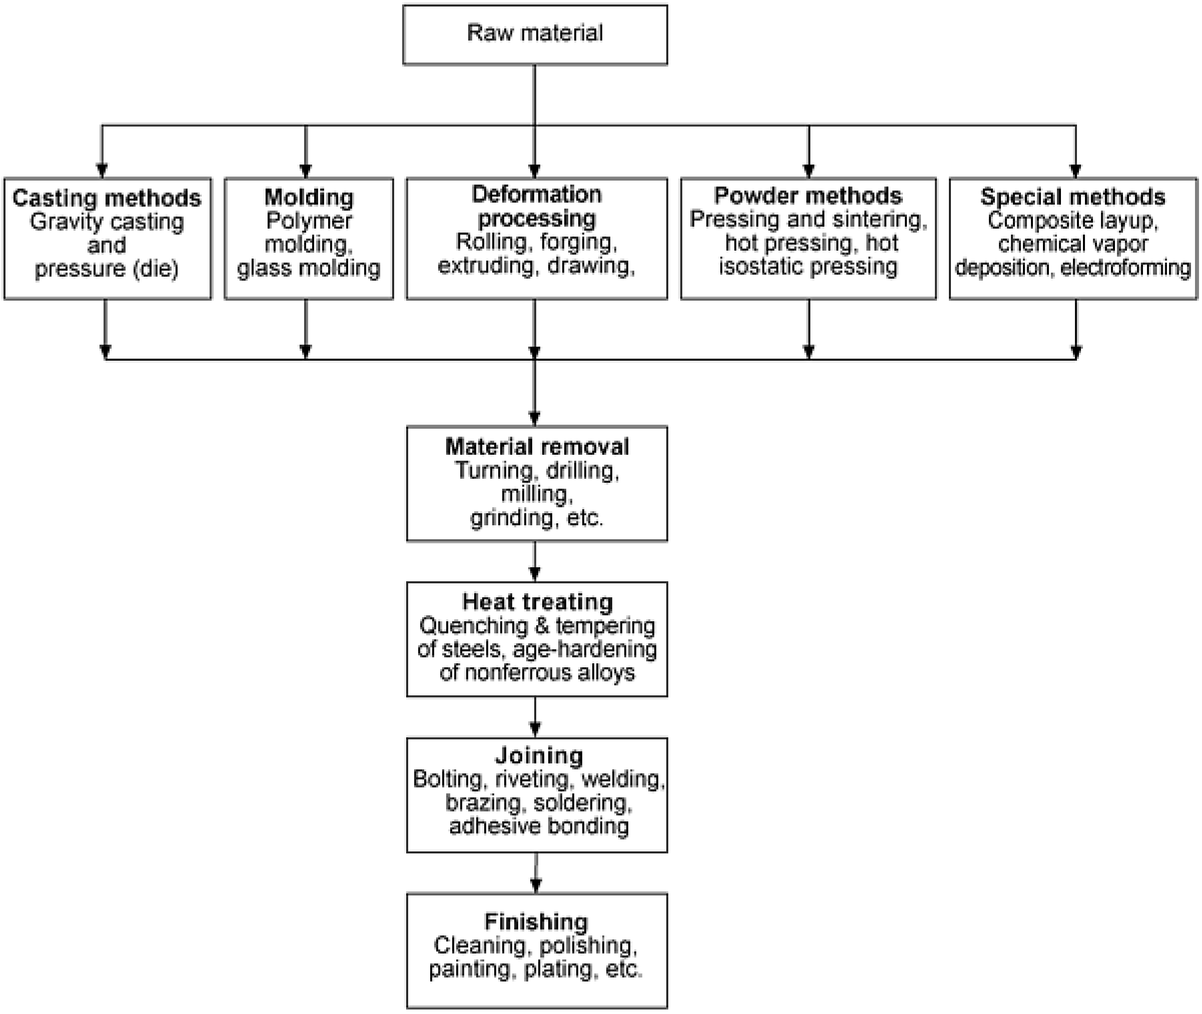

Fig. 4 The nine classes of manufacturing processes. The first row contains the primary forming (shaping) processes. The processes in the vertical column below are the secondary forming and finishing processes. Source: Ref 2

In a very general sense, the selection of the material determines a range of processes that can be used to process parts from the material. Table 4 shows the manufacturing methods used most frequently with different metals and plastics (Ref 7). The material melting point and general level of deformation resistance (hardness) and ductility determine these relationships. The next aspect to consider is the minimum and maximum overall size of the part, often expressed by volume, projected area, or weight. Maximum size often is controlled by equipment considerations. Shape is the next factor to consider. The overall guide should be to select a primary process that makes the part as near to final shape as possible (near-net shape forming) without requiring expensive secondary machining or grinding processes. Sometimes the

form of the starting material is important. For example, a hollow shaft can be made best by starting with a tube rather than a solid bar. Shape is often characterized by aspect ratio, the surface-to-volume ratio, or the web thickness-to-depth ratio. Closely related to shape is complexity. Complexity is correlated with lack of symmetry. It also can be measured by the information content of the part, that is, the number of independent dimensions that must be specified to describe the shape. Tolerance is the degree of deviation from ideal that is permitted in the dimensions of a part. Closely related to tolerance is surface finish. Surface finish is measured by the root-mean-square amplitude of the irregularities of the surface. Each manufacturing process has the capability of producing a part with a certain range of tolerance and surface finish (Fig. 5). Polymers are different from metals and ceramics in that they can be processed to a very high surface smoothness, but tight tolerances are seldom possible because of internal stresses left by molding and creep at service temperatures. Manufacturing cost increases exponentially with decreasing dimensional tolerance. Yet another process parameter is surface detail, the smallest radius of curvature at a corner that can be produced. An important practical consideration is the quantity of parts required. For each process, there is a minimum batch size below which it is not economical to go because of costs of tooling, fixtures, and equipment. Also related to part cost is the production rate or the cycle time, the time required to produce one part. The most commonly used manufacturing processes are evaluated with respect to these characteristics in Table 5 (Ref 9).

Ashby (Ref 2) extended his concepts for materials selection for properties at the conceptual design stage to the development of a set of process selection charts that encompass most of the process attributes described above. The approach, as with material selection based on properties, is to search the entire gamut of potential processes to arrive at the small set that should be considered in detail. Figure 6 illustrates the approach. Figure 6(a) shows the relationship between part size and the complexity of the shape. Complexity is expressed in bits of information, and is given by Eq 1:

$$C = n \log_2 \left(\frac{\bar{l}}{\overline{\Delta l}} \right) \quad \text{(Eq 1)}$$

where C is the part complexity, n is the number of dimensions, $\overline{\Delta l}$ is the geometric mean tolerance, and $\bar{l}$ is the geometric mean dimension.

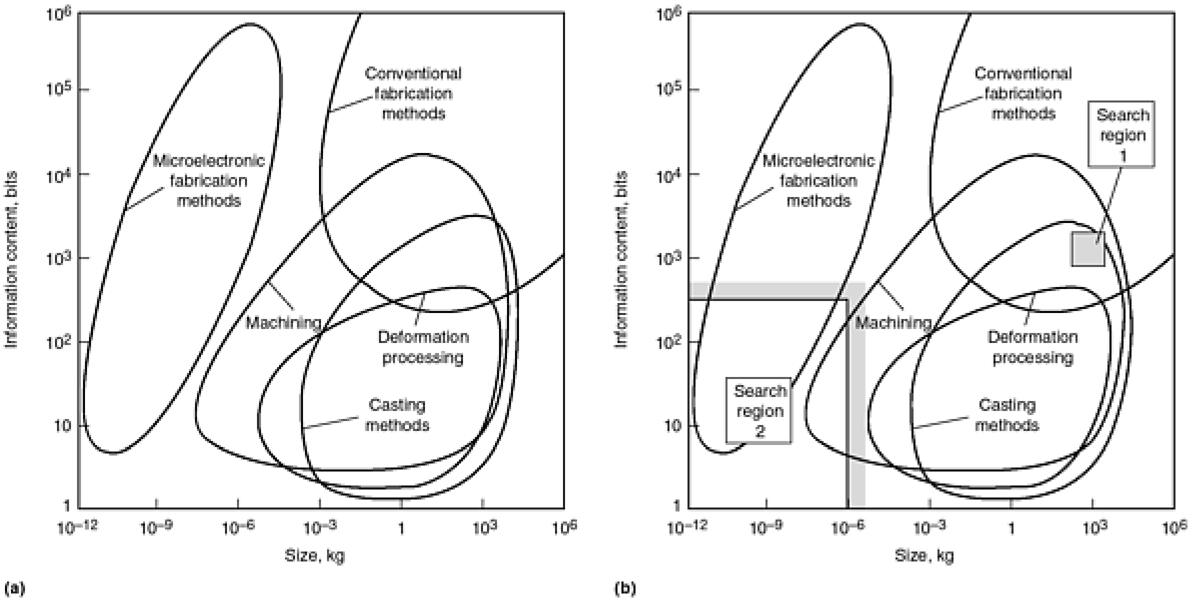

Fig. 6 Ashby process selection charts. Process attributes are given on the axes. A given process maps out a characteristic field. (a) Chart for the relationship between part size and complexity of the shape. (b) Same chart with superimposed regions for attributes of a particular design. The design requirements determine the necessary processing attributes, thus establishing a search area. Processes that overlap the search area become candidates for selection. Source: Ref 2

Simple shapes require only a few bits of information; complex shapes, like integrated circuits, require very many. The casting for an engine block might have 10^3 bits of information, but after machining the complexity increases both by adding new dimensions (n) and improving the precision (reducing $\overline{\Delta l}$). Casting processes can make parts that vary in size from about 1 gram to several hundred tons. Machining adds precision by providing parts with a greater range of complexity. Process selection is done by superimposing the envelope of design attributes (Fig. 6b). Sometimes the design sets upper and lower limits on the process attribute, region 1, while other times it imposes only upper limits, region 2. Process selection must be linked with material behavior (Table 4) and constraints imposed by material hardness, melting temperature, and flow and fracture properties.

Much attention has been directed in recent years to developing design rules and computer methods for enhancing manufacturability through proper design. The intent is to reduce product cost and increase product quality by integrating the product and process concepts so that the best match is made between product and process requirements so as to ensure ease of manufacture. This approach is called design for manufacturing (DFM). Detailed information about DFM is provided in the Section "Manufacturing Aspects of Design" in this Volume; additional information on DFM can be found in Ref 7, 10, and 11.

Overview of the Materials Selection Process

George E. Dieter, University of Maryland

Costs and Related Aspects of Materials Selection

The decision on materials selection ultimately will come down to a trade-off between performance and cost. There is a spectrum of applications varying from those where performance is paramount (defense-related aerospace) to those where cost clearly predominates (household appliances). The total cost of a part includes the cost of the material, the cost of tooling (dies, fixtures), and the processing cost. The unit cost of a part, *C*, can be expressed by:

$$C = C_{\mathrm{m}} + \frac{C_{\mathrm{c}}}{n} + \frac{C_{\mathrm{L}}}{\dot{n}} \qquad \textbf{(Eq 2)}$$

where C_m is the material cost; C_c is the capital cost of plant, machinery, and tooling required to make the part; C_L is the labor cost per unit time; *n* is the batch size; and $\dot{n}$ is the production rate (parts produced per unit time). This cost equation leads to the familiar plot of a break-even point, a batch size (*n*) beyond which it is more economical to use a manufacturing process that has higher tooling or capital costs (Fig. 7). Below an economical lot size of about 60 pieces, the cost of tooling for making the investment castings cannot be offset by savings in material and machining cost.

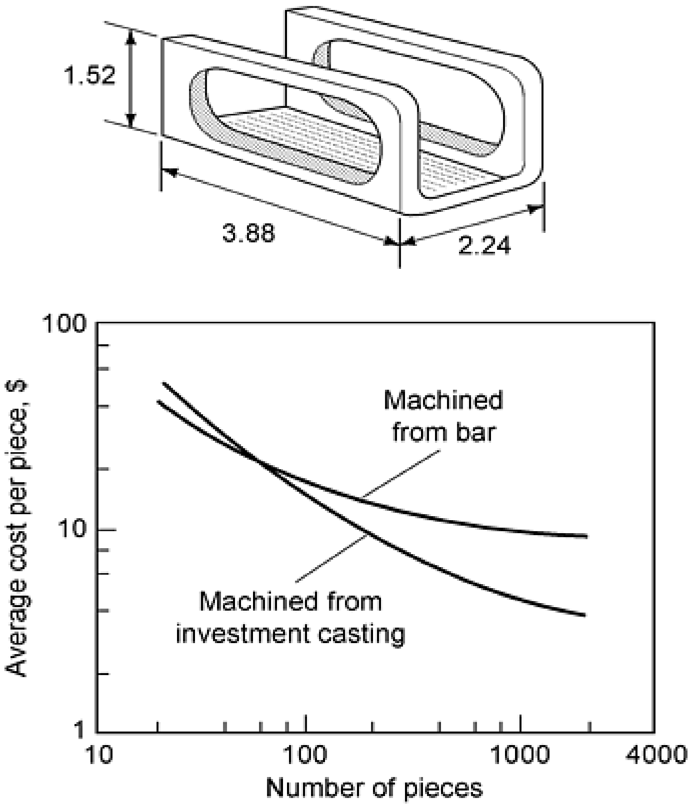

Fig. 7 Unit cost (1961 prices) of roller support made by machining from bar stock compared with machining a

blank made by investment casting. Material, AISI 8630 steel. Weight of finished part, 0.5 lb. Part dimensions in inches. Source: Ref 12

Prices of plastics are relatively easy to obtain from a trade journal such as *Plastics Technology.* However, prices for metals are more complex. The prices listed in sources such as *American Metal Market/Metalworking News* are nominal, baseline prices to which must be added many extras. For steel products, the following extras may apply (Ref 13):

Metallurgical requirements

- *Grade extra.* Each AISI grade has an extra over the cost of the generic type of steel, that is, hot-rolled bar, hot-rolled plate.
- *Chemistry extra.* Nonstandard chemical composition for the grade of steel
- *Quality extra,* for example, vacuum melting or degassing
- *Inspection and testing.* A charge is made for anything other than routine tensile tests and chemical analysis.
- *Special specifications*

Dimensions

- *Size and form.* Charge for special shapes and sizes
- *Length.* Precise requirements on length are costly.
- *Cutting.* Different charges apply to sheared edge, machined edge, flame cut edge, etc.
- *Tolerances.* Tighter than normal tolerances on outside diameter or thickness cost extra.
- *Metric dimensions.* There may be an extra cost for metric dimensions since United States steel producers produce chiefly to English dimensions.

Processing

- *Special thermal treatments,* for example, normalizing or spheroidizing cost extra.
- *Surface treatment,* for example, pickling or oil dip

Quantity

- *Purchases* in less than heat lots (50 to 300 tons) are an extra cost.

Pack, Mark, and Load

- *Packing.* Special wrapping or boxing
- *Marking.* Charge for other than stamped numbers
- *Loading.* If special blocking is needed in freight cars or trucks

This detailed list shows how inadvertent decisions of the designer can significantly influence cost. Standard chemical composition should be used whenever possible, and the number of alloy grades should be standardized to reduce the cost of stocking many grades of steel. Manufacturers whose production rates do not justify purchasing in heat lots should try to limit their material use to grades that are stocked by local materials service centers. Special section sizes and tolerances should be avoided unless a detailed analysis shows that the extra costs are justified.

To ensure minimum cost in design, every part, every material, and every manufacturing operation should pass the following tests with a negative response (Ref 5).

- Can it be done without it?

- Does it do more than required?
- Does it cost more than it is worth?
- Is there something that does the job better?
- Can it be made by a less-costly method?
- Can a standard item be used?
- Considering the quantities used, could a less costly tooling method be used?
- Can someone else provide it at less cost without affecting dependability; that is, can it be outsourced?
- Should the item not be purchased because it costs too much?

These are the basic viewpoints of value analysis, which is described in the article "Use of Value Analysis in Materials Selection" in this Volume.

The chief reason for selecting one material and process combination over another that would satisfy the same functional design requirements is the total cost of the part. It is highly desirable to be able to do this in the conceptual or embodiment phase of design, rather than after most of the design details have been frozen. The development of early cost estimating methods has been actively pursued (Ref 3 and 7), and computer programs are available for this use.

Other factors that affect cost and are key issues in materials selection are:

- *Criticality.* Is this a new material with limited documentation or specifications? Is there more than one supplier, and is it a domestic supplier? Is the lead time for material or tooling acquisition acceptable?
- *Availability.* Is it available in required shapes and sizes?
- *Storage and handling.* Are there any special requirements for the material?
- *Readiness for use.* Can the material be used as is, or does it require a conditioning treatment?
- *Hazardous features.* Are there toxic, allergic, radiological, fire, or explosive factors that must be considered?

More detailed discussion of the selection of materials and processes from the standpoint of cost is provided in the articles "Techno-Economic Issues in Materials Selection" and "Manufacturing Cost Estimating" in this Volume.

Information about Materials Properties

A new material cannot be employed in a design unless the engineer has access to reliable material properties and, hopefully, costs. This illustrates one reason why the tried and true materials are used repeatedly for designs even though

better designs could be achieved with newer materials. This article has emphasized how the needs for materials data evolve as the design proceeds from conceptual to detail design. At the start of the design process, low-precision but all inclusive data are needed. At the end of the design process, data are needed for only a single material, but they must be accurate and very detailed. Listed below are readily available sources of materials information useful at various stages of the design process. Much more information can be found in the article "Sources of Materials Properties Data and Information" in this Volume.

Conceptual Design. Useful information sources at this stage in the design process include:

- *Materials Selector,* Penton Publishing Company. A special issue of *Machine Design* magazine giving tabular data for a broad range of metals, ceramics, plastics, and composites
- *The Materials Selector,* 2nd ed., N.A. Waterman and M.F. Ashby, Ed., Chapman & Hall, 1996. A three-volume compilation of data on all materials, with selection and design guide
- *ASM Metals Reference Book,* 3rd ed., M. Bauccio, Ed., ASM International, 1993. A compilation of tabular properties and processing data for ferrous and nonferrous metals
- *ASM Engineered Materials Reference Book,* 2nd ed., M. Bauccio, Ed., ASM International, 1994. A compilation of data for ceramics, polymers, and composites
- *Cambridge Materials Selector, V2.0 for Windows,* Granta Design Limited, Cambridge, UK. Implements the Ashby materials selection scheme for personal computers

Embodiment Design (Configuration Design). At this level, the designer is deciding on the layout and size of the parts and components. The calculations needed for this step require material properties for a narrower class of materials but specific to a particular heat treatment or manufacturing process. These data are typically found in handbooks, computer data bases, and data books published by associations of material producers:

- *Metals Handbook Desk Edition,* ASM International, 1985. Considers all metallic alloys and processing methods
- *Engineered Materials Handbook Desk Edition,* ASM International, 1995. Considers polymers, ceramics, composites, and glasses
- *MAPP,* ESM Software, Hamilton, OH. Materials data bases from ASM International Mat.DB collection, in personal computer format, of properties and processing for metals and some polymers
- *Rover Electronic DataBooks,* William Andrew Inc., Norwich, NY. Materials data bases including ASM International Mat.DB data collection, in personal computer format, of properties and processing for metals and polymers
- *MSC/MVISION,* MacNeal-Schwendler Corp., Los Angeles. A materials data base that is integrated with the Pro/ENGINEER analysis system
- *PERITUS,* Matsel Systems Ltd., Liverpool. A data base for metals, polymers, and ceramics aimed at materials and process selection
- STN International, Chemical Abstracts Services, Columbus, OH. On-line service for metals, ceramics, and polymers data bases developed by the Materials Property Data (MPD) Network

Detail Design. At the detail design stage, very precise data are required. These data are best found in data sheets issued by materials producers. This is particularly true of polymers, whose properties vary considerably depending upon how they are manufactured. For critical parts, tests on the actual material from which the part will be made will be required. There is a very wide range of properties that may be needed at the detail design stage. These go beyond just material properties to include information on manufacturability, cost, experience base in use in other applications, and issues of quality assurance; see Table 6.

Table 6 Examples of materials information required during detail design

Material identification

- Material class (metal, plastic, ceramic composite)
- Material subclass
- Material industry designation
- Material product form
- Material condition designation (temper, heat treatment, etc.)
- Material specification
- Material alternative names
- Material component designations (composite/assembly)

Material production history

- Manufacturability strengths and limitations
- Material composition(s)
- Material condition (fabrication)
- Material assembly technology
- Constitutive equations relating to properties

Material properties and test procedures

- Density
- Specific heat
- Coefficient of thermal expansion
- Thermal conductivity
- Tensile strength
- Yield strength
- Elongation
- Reduction of area
- Moduli of elasticity
- Stress-strain curve or equation
- Hardness
- Fatigue strength (define test methods, load, and environment)

Temperature (cryogenic-elevated)

- Tensile strength, yield strength
- Creep rates, rupture life at elevated temperatures
- Relaxation at elevated temperatures
- Toughness

Damage tolerance (if applicable)

- Fracture toughness (define test)
- Fatigue crack growth rates (define environment, and load)
- Temperature effects

Environmental stability

- Compatibility data
- General corrosion resistance
- Stress-corrosion cracking resistance

Environmental stability

- Toxicity (at all stages of production and operation)
- Recyclability/disposal

Material design properties

- Tension
- Compression
- Shear
- Bearing
- Controlled strain fatigue life

Processability information

- Finishing characteristics
- Weldability/joining technologies
- Suitability for forging, extrusion, and rolling
- Formability (finished product)
- Castability
- Repairability
- Flammability

Joining technology applicable

- Fusion
- Adhesive bonding
- Fasteners
- Welding parameters

Finishing technology applicable

- Impregnation
- Painting
- Stability of color

Application history/experience

- Successful uses
- Unsuccessful uses
- Applications to be avoided
- Failure analysis reports
- Maximum life service

Availability

- Multisource? Vendors?
- Sizes
- Forms

Cost/cost factors

- Raw material
- Finished product or require added processing
- Special finishing/protection

Special tooling/tooling costs

Quality control/assurance issues

Inspectability
Repair
Repeatability

Computer Data Bases. The use of computer-aided tools allows the engineer to minimize the materials selection information overload. A computerized materials search can accomplish in minutes what may take hours or days by a manual search. Over 100 materials data bases are available worldwide. However, the data contained in most of them are limited to numerical values and text. Image information (micrographs, fractographs, etc.) can be provided through CD-ROM. All materials property data bases allow the user to search for a material match by comparing four or more property parameters, each of which can be specified as below, above, or within a stated range of values. Some data bases have the ability to weight the significance of the various properties. The most advanced data bases allow the materials property data to be transmitted directly to a design software package, such as finite element analysis, so that the effect of changing material properties on the geometry and dimensions of a part design can be directly observed on the computer monitor. However, this capability is generally limited to a narrow homogeneous group of materials. To compare widely divergent materials, that is, polymers versus aluminum die castings, the *Cambridge Materials Selector* is the only software available.

No materials information data base contains the broad spectrum of information called for in Table 6. Most existing data bases provide numerical material properties. Usually mechanical and corrosion properties are well covered, with less extensive coverage of magnetic, electrical, and thermal properties. Since it is unlikely that any data base will be sufficiently comprehensive for a specific user, it is vital that the system be designed so that users may easily add their own data and subsequently search, manipulate, and compare these values along with the entire collection of data.

The validity of the data in a data base is an important issue. In order to increase the reliability and accuracy of data in a computerized data base, ASTM recommends that the following descriptors be used:

- Source (name of handbook, government agency, producer, etc.)
- Statistical basis of the data
- Status of material (production, experimental, obsolete)
- Evaluation status (if so, by whom and how)
- Validation status (if so, by whom and how)
- Certification status (if so, by whom and how)

Expert systems are computer-based systems with the potential to solve problems that require reasoning. A computerized data base search is only as good as the data in the data base, but a materials selection with an expert system combines qualitative and quantitative information using decision rules in much the same way that someone with experience would do. In other words, it provides context dependent selection of a material or a process. A full materials selection expert system is decades away, but successful examples of the method have been developed in narrow areas like the selection of adhesives from a limited set or in designing against corrosion. For more information on expert systems in materials selection and computer-aided materials selection in general, see the article "Computer-Aided Materials Selection" in this Volume.

George E. Dieter, University of Maryland

Methods of Materials Selection

The act of selecting a material is a form of engineering decision making. It has been shown how in the conceptual stage of design it is important to consider a wide spectrum of materials. This list is narrowed considerably to enable embodiment or configuration design to be carried out, and it is narrowed still further to a single material for detail design. Clearly design involves decision making. Many analytical methods have been introduced into engineering design to aid in the evaluation process, which results in a rational decision. These methods are discussed in greater detail in the article "Decision Matrices in Materials Selection" in this Volume and in Ref 15, 16, 17, and 18.

Cost per Unit Property Method

In many materials selection problems, one property stands out as the most dominant service requirement. In this case, a reasonable screening method is to determine how much a material will cost to provide that requirement, that is, the cost of a function. Cost per unit property is a special type of performance index and is discussed in the article "Performance Indices" in this Volume.

Following the development due to Ashby (Ref 2), it is desired that the material for a solid cylindrical tie-rod of length *L* to carry a tensile force *P* with a safety factor *S* be of a minimum mass. The mass is given by:

$$m = A\,L\,\rho \qquad \textbf{(Eq 3)}$$

where *A* is the cross-sectional area and ρ is the density of the material from which it is made. The design requires that *L* and *P* are specified and cannot be changed; that is, they are constraints. However, the radius of the bar is a free variable so long as the bar supports the load *P:*

$$P/A = \sigma_f/S \qquad \textbf{(Eq 4)}$$

where σ_f is the failure strength (yield strength).Eliminating *A* between these two equations results in:

$$m = (S\,P)\,(L)\,(\rho/\sigma_f) \qquad \textbf{(Eq 5)}$$

Equation 5 shows that the performance of the tie-rod is described by three separate factors. The first term in brackets is the functional requirement. The second term is the geometric parameter. The last bracket is the material performance index. For this case of a bar in tension, the performance index *M* is given by:

$$M = \sigma_f/\rho \qquad \textbf{(Eq 6)}$$

The lightest tie-rod that will safely carry the load *P* without failing is that made from a material with the largest value of the performance index *M.* A similar calculation for a light, stiff tie-rod leads to the performance index $M = E/\rho$ where *E* is Young's modulus. If the design criteria is to minimize cost rather than minimize weight, then the density in Eq 5 is replaced by $C\rho$, where *C* is the cost per unit mass. Now *M* is given by:

$$M = \sigma_f / C\rho \qquad \textbf{(Eq 7)}$$

Other part geometries and types of loading would result in different performance indices. Some of these are given in Table 7.

Table 7 Performance indices

Part shape and loading for minimum weight	To maximize strength	To maximize stiffness
Tensile tie-rod: load, stiffness, and length are fixed; section area is variable	σ_f / ρ	E/ρ
Torsion bar: torque, stiffness, and length are fixed; section area is variable	$\sigma_f^{2/3}/\rho$	$G^{1/2}/\rho$
Beam: loaded externally or by self weight in bending; stiffness and length fixed; section area free	$\sigma_f^{2/3}/\rho$	$E^{1/2}/\rho$
Plate: loaded externally or by self weight in bending; stiffness, length, and width fixed; thickness free	$\sigma_f^{1/2}/\rho$	$E^{1/3}/\rho$
Cylinder with internal pressure: elastic distortion, pressure, and radius fixed; wall thickness free	σ_f/ρ	E/ρ

Design goal	Maximize
Thermal insulation: thickness given; minimum heat flux at steady state	$1/\lambda$
Thermal insulation: thickness given; minimum temperature rise after specified time	$C_p\rho/\lambda$
Thermal storage: maximize energy storage for given temperature and time	$(C_p\rho\lambda)^{1/2}$
Minimum thermal distortion	λ/α
Maximum thermal shock resistance	$\sigma_f/E\alpha$
Pressure vessel: yield before break	K/σ_f

σ_f is failure strength; K is fracture toughness; E is Young;s modulus; G is shear modulus; ρ is density; C_p is specific heat capacity; α is thermal expansion coefficient; λ is thermal conductivity. Source: Ref 2

Weighted Property Index Method

Frequently a design requires that more than one material property or requirement be optimized. The usual approach is to assign a weighting factor to each material requirement or property, depending on its importance. Since this is mostly a subjective process, the weighting must be done with care to prevent bias or getting the answer you intended. The individual weighted property values are then summed to give a comparative weighted property index.

The importance of a screening property for which go-no go limits can be set must be kept in mind. Such parameters like weldability and corrosion resistance must be delineated at the outset, and all materials that do not meet the go-no go criteria are screened out. Other nondiscriminating parameters like availability or fabricability should be used to screen out materials from the weighted property matrix or at least flag them for further deliberation.

The weighted properties index has the drawback of having to combine properties with different units. The best procedure is to normalize these differences by using a scaling factor. Scaling is a simple technique to bring all the different properties within one numerical range. Each property is scaled so that its highest numerical value does not exceed 100. The scaled value of a property, β, is given by:

$$\beta = \text{scaled property} = \frac{\text{numerical value of property}(100)}{\text{largest value in the listd}} \qquad \textbf{(Eq 8)}$$

For properties like cost, corrosion loss, and wear rate, for which a low value is best, the scale factor is formulated as:

$$\beta = \text{scaled property} = \frac{\text{lowest value in the list }(100)}{\text{numerical value of property}} \qquad \textbf{(Eq 9)}$$

For properties that are not readily expressed in numerical values, for example weldability, some kind of subjective rating is required; see Table 8. Once each material property and requirement is given a scaled value, the weighted property index for the material is simply the sum of the product of the scaled value, β, times the weighting factor, *w*, for each property:

$$\gamma = \text{weighted property index} = \Sigma \beta_i w_i \qquad \textbf{(Eq 10)}$$

Cost obviously is an important factor in selecting materials. It can be used as one of the properties, but because it is such an important factor, it may over dominate in the selection of weighting factors. One way to prevent this is to use cost as a modifier to the weighted property index instead as one of the properties:

$$\gamma' = \gamma / C\rho \qquad \textbf{(Eq 11)}$$

where C is the material cost per unit mass, and ρ is density.

Table 8 Using a subjective value to get a scaled property

Property	Alternative materials			
	A	**B**	**C**	**D**
Weldability	Excellent	Poor	Good	Fair
Relative rating	5	0	3	1

Example 2: Use of the Weighted Property Index in Materials Selection for a Cryogenic Storage Tank.

The use of this index method can be illustrated with the case of materials selection for a large cryogenic storage tank for transporting liquid nitrogen gas (Ref 18). The gas will be stored at -196 °C (-321 °F) so that concern for ductile-to-brittle transition in ferritic steels rules out their use. Also, this rules out most plastics. Since most tanks are fabricated by welding, good weldability is a go-no go requirement. Likewise availability of plate material in the required thickness and size is a nondiscriminating screening factor. With respect to mechanical properties, adequate toughness, high yield

strength, and stiffness are important. Stronger material means thinner tank walls, resulting in a lighter tank and lower cool-down losses. Also, a lower density material results in a lighter tank. Lower specific heat reduces cool-down losses while a lower thermal conductivity reduces heat losses. Finally, a lower thermal expansion coefficient reduces thermal stresses. This quick analysis results in seven material properties that must be considered in the material selection. In addition, the go-no go requirements discussed above must be followed.

The first task is to assign weighting factors to each property. The usual procedure is to adjust the weighting factors so that their sum equals unity. This is an area of the analysis wherein bias can easily creep. So that this is avoided, it is good to adopt a formal procedure for assigning weights. Pairwise comparison, sometimes called the digital logic method, works well especially if the decisions are the collective decision of a small group, not just an individual. In pairwise comparison, each property is compared in turn with each of the other properties. Thus with four properties A, B, C, and D, start with A, and ask whether property A or B was the more important. If it is A, then give this a 1, and give B a 0. Then compare A and C. If C is the more important, it gets a 1, and A receives a 0. Finally compare A and D, and find that A gets a 1 and D gets a 0. Now turn to B versus C and B versus D, etc. When all comparisons are made add the ones for each property, and total the results. The weighting factor for A is the sum of the ones it received divided by the total; in this case, 2/6 = 0.33. The total number of decisions to make is given by $N(N-1)/2$.

Table 9 shows the pairwise comparisons made for the cryogenic tank (Ref 18). The resulting weighting factors are given in Table 10. Table 11 shows that seven metallic materials were selected as candidates for constructing the cryogenic tank. Appropriate material properties are given in this table.

Table 9 Use of pairwise comparison in the cryogenic tank example

Property	Decision number																				
	1	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**	**11**	**12**	**13**	**14**	**15**	**16**	**17**	**18**	**19**	**20**	**21**

Table 11 Properties of candidate materials for the cryogenic tank example

Material	1 Toughness index[(a)]	2 Yield strength, MPa	3 Young's modulus, GPa	4 Specific gravity	5 Thermal expansion[(b)]	6 Thermal conductivity[(c)]	7 Specific heat[(d)]
Aluminum 2014-T6	75.5	420	74.2	2.8	21.4	0.37	0.16
Aluminum 5052-O	95	91	70	2.68	22.1	0.33	0.16
Stainless steel 301, fully hard	770	1365	189	7.9	16.9	0.04	0.08
Stainless steel 310, $\frac{3}{4}$ hard	187	1120	210	7.9	14.4	0.03	0.08
Ti-6Al-4V	179	875	112	4.43	9.4	0.016	0.09
Inconel 718	239	1190	217	8.51	11.5	0.31	0.07
70Cu-30Zn	273	200	112	8.53	19.9	0.29	0.06

Source: Ref 18

(a) Toughness index, TI, is based on ultimate tensile strength (UTS), yield strength *Y*, and ductility *e*, at -196 °C (-321 °F). TI = (UTS + *Y*)*e*/2.

(b) Thermal expansion coefficient is given in 10^{-6}/°C. The values are average between room temperature and -196 °C.

(c) Thermal conductivity is given in $cal/cm^2/cm/°C/s$.

(d) Specific heat is given in cal/g/°C. The values are average between room temperature and -196 °C.

These properties have been scaled using Eq 8 and 9 and placed in Table 12. Each scaled property value is then multiplied by the weighting factors in Table 10 and summed according to Eq 10 to arrive at the weighted property index for each material in Table 11.

Table 12 Scaled values of properties and calculated weighted property index

Material	Scaled properties							Weighted property index
	1	**2**	**3**	**4**	**5**	**6**	**7**	
Aluminum 2014-T6	10	30	34	96	44	4.3	38	42.2
Aluminum 5052-O	12	6	32	100	43	4.8	38	40.1
Stainless steel 301, fully hard	100	100	87	34	56	40	75	70.9
Stainless steel 310, $\frac{3}{4}$ hard	24	82	97	34	65	53	75	50.0
Ti-6Al-4V	23	64	52	60	100	100	67	59.8
Inconel 718	31	87	100	30	82	5.2	86	53.3
70Cu-30Zn	35	15	52	30	47	5.5	100	35.9

Source: Ref 18

So far, cost has not been considered in the material selection analysis. Costs are expressed in Table 13 as relative to the cost of aluminum alloy 2014. The cost of a unit of yield strength is calculated from the reciprocal of Eq 7. This is divided into the weighted property index to give the figure of merit, a cost adjusted weighted property index. It is shown that type 301 stainless steel ranks first but that aluminum alloy 2014 gains several places in rank when adjusted for cost.

Table 13 Relative cost, figure of merit, and ranking of materials

Material	Relative cost[(a)]	Cost of unit strength × 100	Weighted property index	Figure of merit	Rank
Aluminum 2014-T6	1	0.67	42.2	62.99	2
Aluminum 5052-O	1.05	3.09	40.1	12.98	6

Stainless steel 301, fully hard	1.4	0.81	70.9	87.53	1
Stainless steel 301, $\frac{3}{4}$ hard	1.5	1.06	50.0	47.17	3
Ti-6Al-4V	6.3	3.20	59.8	18.69	4
Inconel 718	5.0	3.58	53.3	14.89	5
70Cu-30Zn	2.1	8.96	35.9	4.01	7

Source: Ref 18

(a) The costs include stock material and processing cost. The relative cost is obtained by considering the cost of aluminum 2014 as unity and relating the cost of other materials to it.

While this method of material selection requires considerable calculation and may appear tedious at first reading, the growing use of computerized data bases can greatly facilitate its use. However, a word of warning is in order. It is very easy for engineers to become quickly enamored with a numerical calculation scheme and lose sight of reality. Care must be taken that all nonquantifiable factors have been properly considered in the final decision and that the numerical outcome is not unduly influenced by a hasty choice of weighting factors.

Limits on Properties Method

In this method of materials selection, the performance requirements are divided into three categories:

- Lower limit properties
- Upper limit properties
- Target value properties

For example, if it is required to have a stiff, light material, then a lower limit is put on Young's modulus and an upper limit is put on density. It has already been shown that this is the approach used when screening a large number of materials with a computer data base. After screening, the remaining materials are those whose properties are above the lower limits, below the upper limits, and within the target values of the specified requirements.

To arrive at a merit parameter for each material, the properties are first assigned weighting factors using pairwise comparison. A merit parameter *p* is then calculated for each material using the relationship:

$$p=\left[\sum_{i=1}^{n_l} w_i \frac{Y_i}{X_i}\right]_l + \left[\sum_{j=1}^{n_u} w_j \frac{X_j}{Y_j}\right]_u + \left[\sum_{k=1}^{n_t} w_k \frac{X_k}{Y_k} - 1\right]_t \qquad \textbf{(Eq 12)}$$

where l, u, and t stand for lower limit, upper limit, and target properties, respectively (Ref 18). Thus n_l, n_u, and n_t are the number of lower limit, upper limit, and target value properties; w_i, w_j, and w_k are the weighting factors on lower limit, upper limit, and target value properties; X_i, X_j, and X_k are the candidate material lower limit, upper limit, and target value properties; and Y_i, Y_j, and Y_k are the specified lower limits, upper limits, and target values. Based on Eq 12, the lower the value of the merit parameter *p*, the more suitable the material. Cost can be treated as an upper limit property and given the appropriate weight.

Conclusions

The general pattern for material selection has been described in this overview. Many references to more detailed discussions of these topics in this Volume have been given.

A competent job of material selection should include consideration and documentation of the following:

- The problem, design, or redesign objective
- The underlying design criteria (primary, secondary, or supporting criteria; manufacturing method considerations; codes and standards)
- Analysis (preliminary concepts, modeling or simulation, optimization and trade-offs, design reliability, economics and cost)
- Alternatives considered, selection criterion, and decision methodology
- Reasons for the selection of the final material and manufacturing process

Overview of the Materials Selection Process

Techno-Economic Issues in Materials Selection

Joel P. Clark, Richard Roth, and Frank R. Field III, Massachusetts Institute of Technology

Introduction

THE SELECTION OF MATERIALS in industrial applications has always been important to product designers. This is a consequence of the fact that the selection of material determines not only the basic physical characteristics of the product, but also the processing technologies that can be employed in its manufacture, the specialized properties that can be developed as a function of that processing, and, ultimately, the cost of the product.

Because of the interplay between material choice, product performance, and manufacturing economics, an effective designer must carefully balance the properties and cost that result from a specific material choice against the willingness of the market to pay the price that such a choice will require. Traditional product design tools employ detailed theoretical and empirical relationships to estimate the engineering performance of a product as a function of its geometry and materials. Through such analyses, the designer attempts to fine tune the design in order to achieve the precise

combination of desired characteristics. The economic consequences of this careful design work is rarely treated in such detail. This is a consequence of separation between the design and engineering functions of a firm and the cost accounting part of the firm. While designers rely upon these cost analysts to estimate the costs of their designs, the designer rarely receives the kind of information that would be most helpful in refining the product design; that is, the relationship between specific design elements and cost estimates.

In this article, methods for evaluating materials alternatives on the basis of costs, both direct economic costs and indirect social costs, are presented. The importance of the first of these is obvious. Social costs are presently less crucial because designers rarely consider environmental characteristics in materials selection decisions. Given the interest of government regulators and consumers in the environment, it is expected that environmental performance will increasingly become important as a strategic consideration.

Techno-Economic Issues in Materials Selection

Joel P. Clark, Richard Roth, and Frank R. Field III, Massachusetts Institute of Technology

Cost Analysis

On the face of it, cost appears to be a relatively simple concept--the financial consequences of product design decisions. However, cost in practice is a difficult metric to determine when material choices are being evaluated. This difficulty arises from the fact that the cost of material choices requires a careful consideration of the material, the process technology to be employed to form the product, and the design of the product itself (Ref 1).

Alternatives for cost analysis can be divided into several categories: rules of thumb, accounting methods, and analytical methods.

Rules of Thumb

One commonly used method of cost estimation is to employ industry rules of thumb (Ref 2). The most typical methods rely upon simple conversions of material cost into total part cost, usually a fixed multiple. For example, a good estimate of the cost of injection molded parts made from commodity plastics is twice the cost of the raw material required. Another example are X-Y plots depicting the combinations of an engineering metric (such as density or stiffness) and an indicative part cost (usually normalized by part weight) that can be achieved with individual materials or material classes (Ref 3). Both the multiplicative factor and the cost-performance plots are not based on detailed technological considerations, but on the past experience of the industry with the material in question. The predictive capabilities of this method can be extremely limited, often inaccurate and overly sensitive to changes in materials costs or to substitution of a more expensive material for a less expensive one. Although the cost-performance plot can be used to make broad conclusions about the suitability (and unsuitability) of particular material classes, the necessary degree of generalization employed to develop the figure necessitates an eventual consideration of cost in more detail.

Rules of thumb are, almost by definition, "back of the envelope" analyses that rely heavily upon the expertise of the person employing them. For example, the injection molding rule of thumb above would not be used by an expert when considering the production of a liquid crystal polymer product, but a novice might easily apply it without recognizing its limitations. In the hands of an expert, rules of thumb combined with years of experience can yield extremely good estimates of the cost of parts that are produced with materials and processes that are within that expert's experience. Unfortunately, that experience is also the greatest limitation of rules of thumb. It is expensive and time consuming to develop, and it can be a hindrance when processes and materials outside that realm of experience are under consideration.

Accounting Methods

Another approach is to examine current accounting data from the manufacturing facility and to try to allocate these costs across all of the products; that is, essentially summing up all the costs and dividing by the number of parts produced (or their mass, etc.) (Ref 4). While this approach is useful from the perspective of the manager interested in the total

production cost of a manufacturing facility, it is difficult to allocate cost among the parts. Furthermore, it offers no predictive capabilities. Because this approach relies upon current operating conditions and practice, there is no way to look at the differences in cost, which arise from switching to new materials or technologies.

A variant of this approach is to disaggregate costs between the material content of the product and the time and equipment required to convert the purchased materials into the final part (Ref 4, 5). Accounting information is employed to develop one of two constructs: a machine rental cost or a variable burden rate. In the former, the costs of the capital, energy, and labor required to operate production equipment is summed and then divided by the time they are used to produce parts, yielding a "machine rent," or cost per unit time to operate. In the latter, the capital (and other nonmaterial and nonlabor) costs are distributed over the total number of labor hours (rather than machine hours) that are employed in part production, yielding a "variable burden" rate that essentially can be thought of as a "markup" on labor.

While useful for managerial control, both accounting approaches have important flaws when manufacturing costs of alternative designs are being developed. Most obviously, both approaches are based upon historical data, like the pure accounting method. As such, one is assuming that future costs will be similar to past costs--not a very good assumption when new processes and materials are under explicit consideration! However, the concepts of machine rent and variable burden are apparent attempts to overcome this limitation by introducing parameters that enable consideration of some limited ideas of change; machine rent allows one to consider that the time to produce a part may change, while variable burden allows one to consider that the amount of labor required may change.

Unfortunately, these two concepts still embed strong assumptions that limit their utility for product design. Both the concept of machine rent and variable burden imply that aggregating costs that are otherwise difficult to apportion correctly will still yield cost estimates that can be used to make economic decisions. However, these gross measures of cost essentially assume that all processes are equally capital intensive per unit time, in the case of machine rents, or that all labor requires equal amounts of capital to be effective, in the case of variable burden. Naturally, these measures can be refined by subdividing the accounting data employed, but this approach fails to address the key failure of the underlying assumptions of the method. Each process requires unique combinations of resources, and averaging limits the ability of decision makers to manage these combinations effectively.

In response to this objection, the accounting community has been working to develop a new approach to cost accounting known as activity-based costing (Ref 5). In this approach, the first objective of the cost accountant is to identify each of the activities that the firm undertakes and then to allocate costs according to the activity, rather than the capital or labor within that activity. In this way, managers receive cost information that emphasizes the relationship between what the firm is doing and how it is being achieved, rather than the more gross measures of traditional accounting tools. This approach has been under development for over a decade now, and it has been used to demonstrate that the focus upon business activity, or process, is a key to developing good measures of economic performance.

Analytical Methods

Rules of thumb and traditional accounting techniques offer limited powers for estimating the effect of changes in the material or processing parameters. Activity-based cost accounting is a technique more suited to cost estimation of plants and facilities, not products and processes. As such, it is quite useful in analyzing the cost drivers for a given manufacturing facility, but is incapable of predicting the costs arising from new materials or processes.

However, activity-based costing does demonstrate that consideration of the process is the key factor when attempting to characterize costs. While activity-based costing examines processes from the perspective of how best to manage a process, the designer requires a different emphasis: how does design choice--be it material, processing, or geometry--influence cost, and how is the resulting performance of the product balanced best against that cost. In effect, a more robust, process-based cost-estimation methodology is necessary to analyze these situations. An approach to cost estimation at an early stage in the design process is described in the article "Design for Manufacture and Assembly" in this Volume.

A process-based approach, called technical cost modeling, was developed at MIT in the late 1970s (Ref 6, 7, 8, 9, 10). Technical cost modeling requires that the different cost elements for each processing step be estimated separately based on engineering principles, the manufacturing process, and specified economic and accounting assumptions. The relationships between individual elements of cost and the underlying technical and engineering characteristics of each unit operation can be brought into the cost estimate in a way that enables considerable flexibility when exploring the implications of changes in the product design.

Technical Cost Modeling

In the technical cost modeling technique, variable and fixed costs are calculated separately. These categories are further subdivided into the variable costs of material, direct labor, and energy, and the capital costs associated with the main machine, the auxiliary equipment, the tooling, the building, maintenance and overhead on the labor. These individual elements reflect the line items of classical accounting methods in order to maintain consistency with conventional views of cost. However, the elements that underlie these line items are a reflection of how engineering process knowledge influences these conventional cost accounts.

The following paragraphs discuss the basic considerations that go into the development of estimates for each of these elements of cost based on a generic process flow diagram. More detailed descriptions of specific production processes are found in Ref 11, 12, 13, 14, 15, 16.

Variable Costs. The terms *variable costs* and *fixed costs* are historically derived and correspond to a simple bifurcation of costs into identifiable categories. Variable costs are those costs that can be directly associated with the production of a unit of output and whose total increases roughly linearly with the total number of units produced. For example, material costs are variable costs since a doubling of the total number of parts produced requires a doubling of the amount of material that will be consumed. Variable costs are contrasted with fixed costs, which are costs that do not increase linearly with total production. For example, the amount of capital equipment required to produce parts does not increase linearly with production. Instead, total capital equipment cost remains fixed until its production capacity is exceeded, whereupon more equipment is required. The perverse consequence of these definitions is that, when considering costs on a per piece basis, the variable costs remain constant as the production volume changes, while the fixed costs change. However, when total costs of producing X parts are considered, the variable costs vary with X, while the fixed costs generally do not vary with X for small changes in X.

The material cost can be estimated as a function of the price of the raw materials, the design of the component, and scrap considerations associated with the process. Essentially, the problem is one of determining the total amount of material actually required by each part, realizing that there will be material losses due to the process and part losses due to quality control. Part mass, process scrap rates, and net production yields can be used to calculate the total material input to the process, while each of these processing parameters can either be a direct input to the model or a more complex function of other engineering parameters.

Direct labor costs are a function of the wages paid (including all costs to the manufacturer of employing a worker), the number of workers necessary to run the process, and the time required to produce the part. Typically, only direct workers are included in this calculation, with the remainder accounted for in the overhead calculation (see below).

Energy consumption can be calculated from the theoretical energy requirements of processing the part. However, it is very difficult to compute this requirement since direct metering of energy consumption is rarely done, and then only for major consumers of energy (furnaces, etc.). Instead, energy costs are often estimated from the consumption requirements of the processing equipment and, again, the time required to produce the part.

Fixed costs are those that are expected to remain essentially constant for a given annual production volume. These include capital expenses for plant, equipment, and tooling, as well as maintenance and overhead labor costs.

Capital costs for machines can be analyzed as a function of factors, such as materials to be processed, the required production volume, and the design of the part (e.g., geometry). Usually, one calculates the number of parallel processing lines needed to manufacture a specified number of parts. Since only an integral number of parallel streams is possible, there are two approaches. One is to round the number of lines to the next highest integer and allocate all of the capital cost of the equipment to that part. This is called the dedicated equipment approach. Often, the machines can be used to manufacture more than one part. For instance, stamping dies can be changed within a matter of minutes to use the stamping press for another part run. In this case, it is appropriate to use a nondedicated assumption, allocating the cost on the basis of the fraction of machine time needed for the annual production volume.

It can be generally assumed that a given level of investment in the primary equipment requires a fixed level of investment in auxiliary equipment. Consequently, in the absence of detailed process information, auxiliary equipment costs can be estimated as a fixed percent of the main machine cost. For certain processes, parameters such as the degree of automation or types of equipment can also be related to the costs of auxiliary equipment.

Tooling cost is possibly the most difficult component of cost to estimate, largely because each set of tools is unique, reflecting design choices and available production equipment. This uniqueness also arises from the fact that tools are largely handmade, requiring considerable craft and special skills that are not widely available. Generally, the total cost of tooling is treated in two parts--the cost of a single set of tools and the number of parts that this tool can be used to produce before it is no longer serviceable. A reasonable approach is to estimate tooling cost based on empirical data that relate various tool types to certain types of components and to previous tooling costs. While such estimates (usually regression models) are imperfect, they can yield good first-order approximations. Tooling costs are always dedicated costs because they apply to specific parts.

Building costs are relatively easy to calculate. Prices per square meter of building space are readily available, and the space requirement can be estimated based on the size of the equipment and conventional practices (e.g., materials handling requirements, safety specifications, etc.).

Maintenance costs are often little understood and would require a complete understanding of the probability of breakdowns occurring on the production line. For the purposes of cost estimation, it is generally sufficient to assume that more expensive equipment requires additional expenditures for maintenance. Consequently, maintenance costs are estimated as a percent of the capital equipment cost.

Overhead labor costs present a similar problem. It is difficult to allocate the costs of supervisors, janitors, etc. across the different aspects of the production facility. Instead this cost is estimated using a burden rate, which is applied to the direct labor requirement. The idea is that a given level of direct labor requires a fixed amount of supervision, janitorial services, and other support staffing. Such a simplistic treatment of maintenance and overhead labor is usually acceptable when the goal is to analyze relative costs of using alternative materials and processes.

Process Engineering Variables. The time to produce a part, or cycle time, is a particularly important feature of technical cost models. Although cycle time is an intermediate variable and does not show up directly in the input or outputs of the models, it is an important determinant of most of the elements of the manufactured part cost. Fixed costs associated with equipment and tooling are affected because the cycle time influences the number of parallel streams necessary to manufacture a specified production volume. Variable costs are also affected. Labor and energy requirements are dependent on the time it takes to complete the production process.

Example: Estimating Cycle Times for Plastic Injection Molding.

In general there are two ways to estimate the cycle time for a given manufacturing process, product design, and materials: theoretical and statistical. For example, consider a relatively simple process, plastic injection molding. The injection molding cycle can be broken into the steps shown in Fig. 1 (Ref 17).

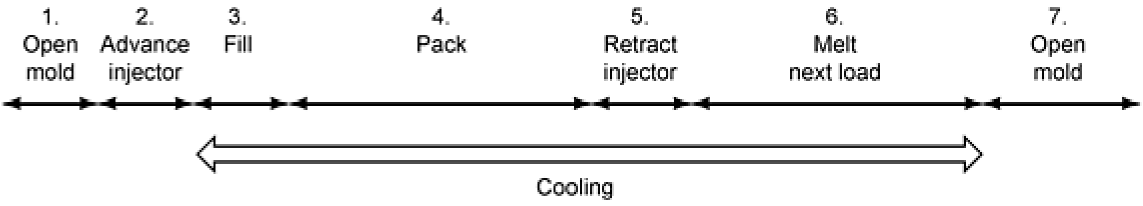

Fig. 1 Plastic injection molding cycle

The packing and cooling stages are most suited to theoretical modeling. Packing refers to the injection of additional material into the mold even after the mold is filled. This is done to compensate for shrinkage due to cooling. Packing stops when the material in the injection sprue solidifies, preventing any more material from entering. By computer modeling of the temperature profile in the sprue, one can simulate when this event happens.

A proprietary computer program, MoldFlow (Ref 18), also models the pressure that develops throughout the part during this phase by using a finite element methodology. MoldFlow also models cooling with a finite difference methodology.

If detailed designs (e.g., computer-aided design, CAD, drawings) of the part are available, using theoretical simulation models to simulate the cycle time of the crucial packing and cooling stages is possible. If these designs are not available, it is possible to predict the cycle time using an empirical approach, usually involving statistical estimation.

The statistical approach requires that data be collected from a number of production sites and an equation be fitted to that data using regression analysis. In one study (Ref 19), it was postulated that the cycle time depends primarily on two factors: the time to fill and pack, and the time to cool. Filling and packing are assumed to be a function of the part volume and therefore (through the density) are proportional to the weight of the part.

The form of the equation was:

$$\text{cycle time} = (a + b)\,(\text{cooling time} + c)\,(\text{weight}) \qquad \textbf{(Eq 1)}$$

The coefficients (a, b, c) were estimated regression analysis using data from 33 manufacturing operations, representing parts weighing between 5 and 2780 g.

Once the materials and simple part geometry are known, it is easy to calculate the part weight. The cooling time can be estimated using transport theory (Ref 20). In this case, it was assumed that the injection molded parts of interest conform to a slab geometry because they usually have relatively thin and uniform wall thicknesses. The cooling time for a semi-infinite slab is given by the relationship:

$$\text{cooling time} = \left(\frac{d^2 \rho C_p}{\Pi^2 k}\right) \ln\left[\frac{8(T_{melt} - T_{mold})}{\Pi^2 (T_{eject} - T_{mold})}\right] \qquad \textbf{(Eq 2)}$$

where d is the nominal wall thickness, ρ is the density, C_p is the specific heat, k is the thermal conductivity, T_{melt} is the process melt temperature, T_{mold} is the temperature at the tool surface, and T_{eject} is the ejection temperature. These data are available in Volumes of the *ASM Handbook* and other materials references. The wall thickness will be known from the part geometry.

The regression estimates cannot be expected to be precise because the estimation of the cooling time represents the minimum time for cooling and does not take into account the information of hot melt during packing or any curved (not slab like) sections in the part. Moreover, each plant is usually operated differently. Nevertheless, the statistical results are relatively good, with the cycle time equation explaining 90% of the variation in the data, and each independent variable statistically significant with a 99% level of confidence. Agreement between the empirical/statistical approach and MoldFlow simulations is within 5% for wall thicknesses between 1 and 5 mm. At wall thicknesses of 10 mm, the approaches result in cooling time estimates that differ by about 20%.

Case Study: Cost Estimation for the Automotive Body-in-White

The cost methods discussed so far are useful for analyzing manufacturing costs. Although manufacturing costs are of greatest importance to product designers, other costs are becoming increasingly relevant. These can be divided into two categories: private costs (those borne by individuals or firms) and social costs (those borne by society). In addition to manufacturing costs, private costs include the costs of using and disposing of (or recycling) the product. Social costs include the cost to society of emissions resulting from extraction, processing, using, and disposing of the materials/products.

These various elements of cost are introduced in the following section with a case study concerned with the manufacture, use, and disposal of the automobile body-in-white. The body-in-white consists of the structural components of the automobile, not including closures (e.g., doors, hood, trunk). Currently a number of designs employing combinations of steel, aluminum, and polymer composites are under consideration by automotive companies.

Technical Cost Modeling of the Body-in-White

The technical cost modeling method has been used extensively to determine manufacturing cost for many production processes, including those involved in the production of automobiles. Body-in-white manufacture begins with the production of individual components, typically metal stampings, but in some cases extrusions and castings are used as well. The parts are assembled using several joining techniques into a complete body-in-white. The choice of joining technique is dependent on the design and material used.

The case study presented here includes several alternative designs; a traditional steel unibody, as well as an aluminum unibody and three aluminum space-frame designs (Ref 16, 21). The unibody designs are based on Ford Taurus. The space-frame designs were chosen to represent a comparable automobile.

In general, an aluminum space-frame design is composed of extrusions, stampings, and castings. In most cases, the extrusions form the predominant load transmitting paths. The frame structure consists of straight and curved extruded profiles, which are primarily joined by cast nodes. These nodes enhance the local rigidity of the structure. Furthermore, castings can be used in areas where the complexity of the design prohibits the use of extrusions, such as in the case of the grill opening. Finally, stamped panels complete the design, in some cases providing some additional structure while in others they are simply "hang-ons." This is entirely different from the unibody design where the stamped panels make up the complete structure of the vehicle.

The availability of part forming operations and joining methods leads to numerous viable design choices for an all aluminum space frame. This case study considered three actual designs developed by aluminum companies for different production volumes (Ref 21). The first design (SF-1) has a high number of aluminum extrusions and no castings. Consequently it is better suited for low production volume applications. The second design (SF-2) consists of a limited number of casting, while the third design (SF-3) uses castings extensively.

Cost models of numerous manufacturing processes were used for this study. All of the designs require the stamping of sheet metal into body panels. Furthermore, in the case of aluminum space frames, many parts are extruded or cast and then machined. Finally, each of the individual components must be assembled using potentially different joining methods into a complete body-in-white.

A typical steel unibody contains more than 100 stampings. It is usually unnecessary to estimate the cost of producing each of these parts. Instead, stampings may be grouped into categories of similar parts, for which materials cost will constitute the same percent of their total costs. This means that it is necessary to model only one part of each type and then to extrapolate the results to all similar components based on the part weight.

Two considerations were used to determine the part classifications: appearance versus nonappearance parts, and complex versus simple geometries. Complex geometries consist of either a deep draw or a large cut out. The roof panel and quarter panel outer were chosen as indicative of the appearance parts. The roof constitutes a simple geometry, while the quarter panel outer is a more complex stamping. The rear floor pan and the quarter panel inner were chosen for the nonappearance parts. The quarter panel inner has a simple geometry, and the rear floor pan has a complex geometry due to the deep draw, which is necessary for the spare tire wheel well (Ref 16).

A metal stamping technical cost model was used to determine the total and material cost of the four characteristic parts. A separate manufacturing model was used to extrapolate these results to all of the parts in the body-in-white. For the aluminum space-frame designs, extrusion, casting, and machining models were used to estimate the costs of parts that were not produced by traditional metal stamping processes.

The body-in-white manufacturing costs were estimated using the results from the various parts fabrication models and the manufacturing extrapolation model in conjunction with a vehicle assembly model, assuming combinations of spot welding and adhesive bonding.

At low production volumes, some of the aluminum space-frame designs could hold a cost advantage over the steel unibody:

Body type	Cost per unit, $, for a total annual production volume of:		
	20,000	**100,000**	**300,000**

Steel unibody	5774	2000	1205
Aluminum unibody	7249	2510	1788
SF-1	4471	. . .	. . .
SF-2	. . .	2926	. . .
SF-3	6073	2792	2404

Source: Ref 21

Figure 2 shows the effect of production volume on cost for each alternative. In this case, the cost of the three space-frame alternatives is represented as a single function, which includes only the lowest cost design at each production volume.

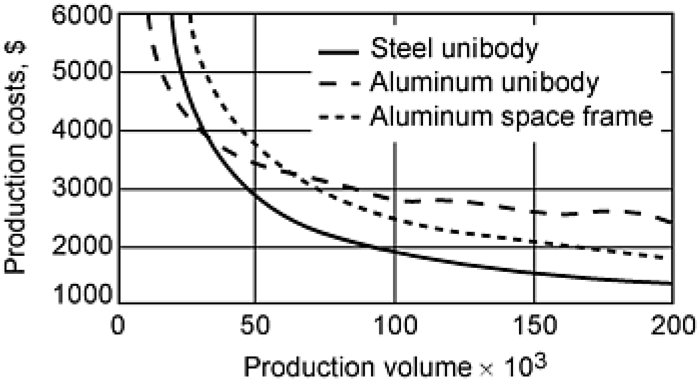

Fig. 2 Production cost comparisons for alternative vehicle designs. Source: Ref 21

At high production volumes, the space-frame designs cannot compete on a cost basis with steel (or even with the aluminum unibody). The two monocoque designs are manufactured using stampings and spot welding, both of which are very capital intensive and depend on economies of scale to be cost effective. The main production techniques used for the space-frame designs do not exhibit the same economies of scale and, therefore, are not cost competitive at high volumes.

Life Cycle Cost Analysis of the Body-in-White

In addition to the direct manufacturing costs, it is also possible to analyze the costs borne by the consumer (i.e., the cost of driving and disposal/recycling). This section discusses the life cycle costs of the alternative body-in-white designs. This article also includes a discussion of life cycle analysis (LCA), which is a separate, but related, concept (see the section "Life Cycle Analysis").

The cost of fuel is a strong function of fuel economy. For the steel unibody design, the fuel economy is based on the Ford Taurus: 18 and 26 miles per gallon (mpg) in the city and on the highway, respectively. Using the EPA 55/45 cycle mix of these two driving modes, the steel unibody has a fuel economy of 21.6 mpg (Ref 16). The fuel economy of the aluminum designs is dependent on the weight of the vehicle.

The effects of lightweighting on fuel consumption have been analyzed extensively (Ref 16, 21, 22, 23, 24). These studies do not yield identical results. Figure 3 shows that the varying results give a bounded region of possible gains in fuel economy for a given body-in-white weight. For the purposes of this study, an average value was used.

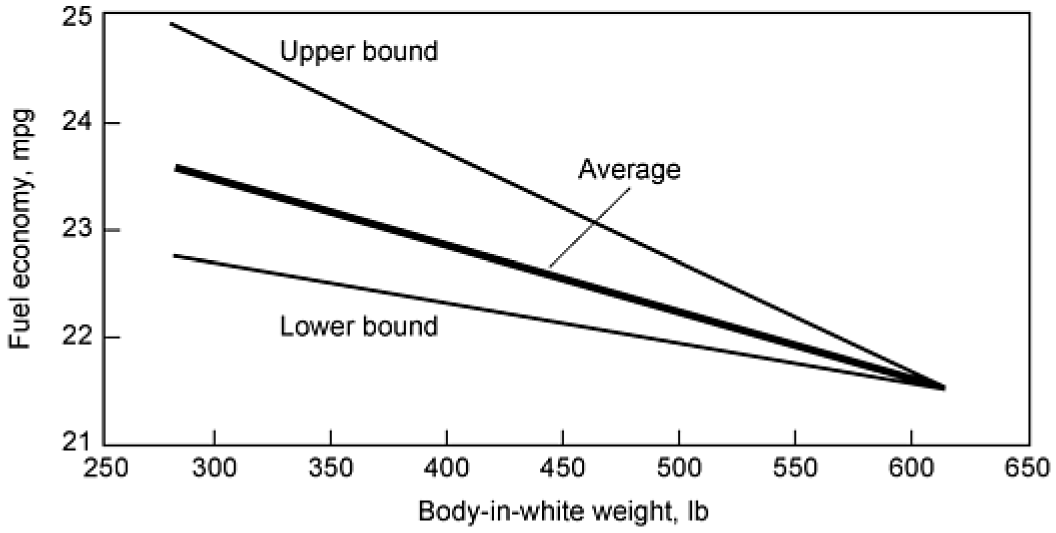

Fig. 3 Effect of vehicle lightweighting on fuel economy

Using the fuel economies as provided by the average line in Fig. 3, it is possible to calculate the cost of powering the vehicle for a given body-in-white weight:

Body type	Lifetime fuel cost, $
Steel unibody	3961
Aluminum unibody	3656
SF-1	3651
SF-2	3630
SF-3	3679

Source: Ref 21

The fuel cost of the vehicle depends on the fuel economy (mpg), the number of miles driven over the lifetime of the vehicle, and the price of gasoline. In the United States, recent Motor Vehicle Manufacturers' Association data show that people drive an average of 10,250 miles per year and cars last an average of 12.5 years (Ref 21). These data were used with a gasoline price of $1.20/gal. A discount rate of 10% was used to convert future dollars to a present value.

Since each of the aluminum designs weighs about 300 lb less than the steel unibody (some more, some less), they offer some cost advantages in the use phase of the life of the vehicle. The vehicle lightweighting achieved in each of the aluminum designs results in use cost savings of approximately $300.

The final phase in the life of the automobile is the disposal stage. At this point, the vehicle has no more transportation value to the owner and has to be discarded. The monetary effects of this stage are restricted to the salvage value of the body-in-white. For this case study, scrap prices were assumed to be $0.05 for steel and $0.30 for aluminum (Ref 16). A discount rate of 10% was used to give the value of the disposed vehicle in present dollars. The net present value (NPV) is:

Body type	NPV, $
Steel unibody	7
Aluminum unibody	20
SF-1	20
SF-2	18
SF-3	22

Source: Ref 21

The aluminum designs have more recoverable value at the end of their useful life. However, in the case of aluminum versus steel, the magnitude of the disposal value is insignificant when compared with the costs arising from the manufacture or use stages.

The total life cycle cost of each design is the sum of its costs through the previously mentioned stages: manufacturing, use, and disposal. Figure 4 shows the effect of production volume on lifetime cost for each alternative. Once again, the cost of the three space-frame alternatives is represented as a single function, which includes only the lowest cost design at each production volume.

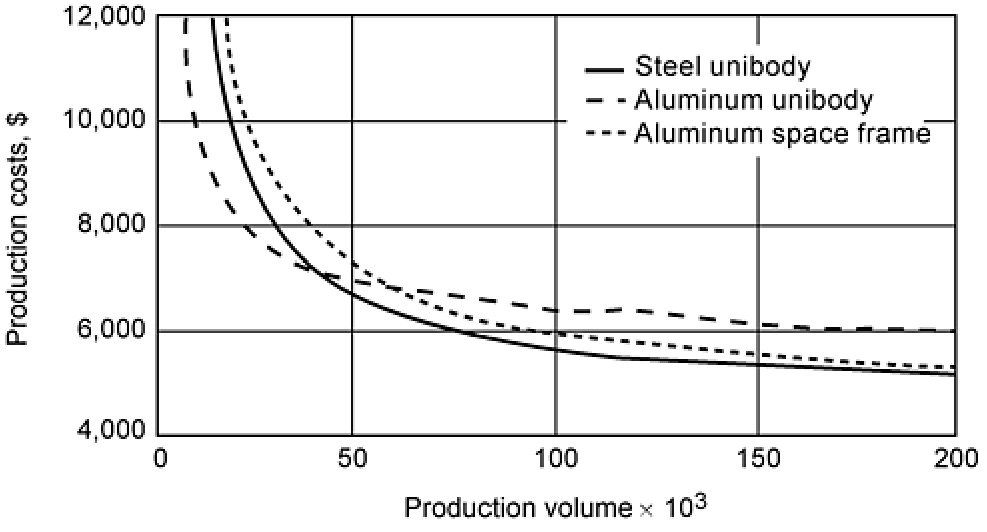

Fig. 4 Life cycle cost comparison for alternative vehicle designs

At all but the lowest production volumes, the steel unibody is the lowest cost design. However, steel has a diminished cost advantage when compared with the results of the analysis based strictly on manufacturing costs (see Fig. 2). Furthermore, the cross over production volume is shifted up. Based strictly on manufacturing costs, the steel unibody is the low cost design at production volumes down to only 34,000 vehicles per year. However, when total life cycle costs are included, the production volume must rise to above 40,000. Furthermore, the life cycle costs are based on a U.S. gasoline price of $1.20/gal. If this were to rise, or a price more typical of Europe were used, the cost advantage of aluminum in the use phase would be further enhanced, thus increasing its ability to compete at higher production volumes.

Recycling Economics of the Body-in-White

In the previous analysis, the disposal stage costs of each vehicle were estimated by looking simply at the market for the materials in the body-in-white. However in reality, the economics of recycling is quite a bit more complicated (Ref 25). There are costs associated with the disassembly of the vehicle, shredding of the hulk, separating out the valuable metals, and landfilling the remainder. All of these costs must be considered to get a true understanding of the costs/benefits arising from the disposal stage. Figure 5 shows the typical stages in automotive recycling and disposal.

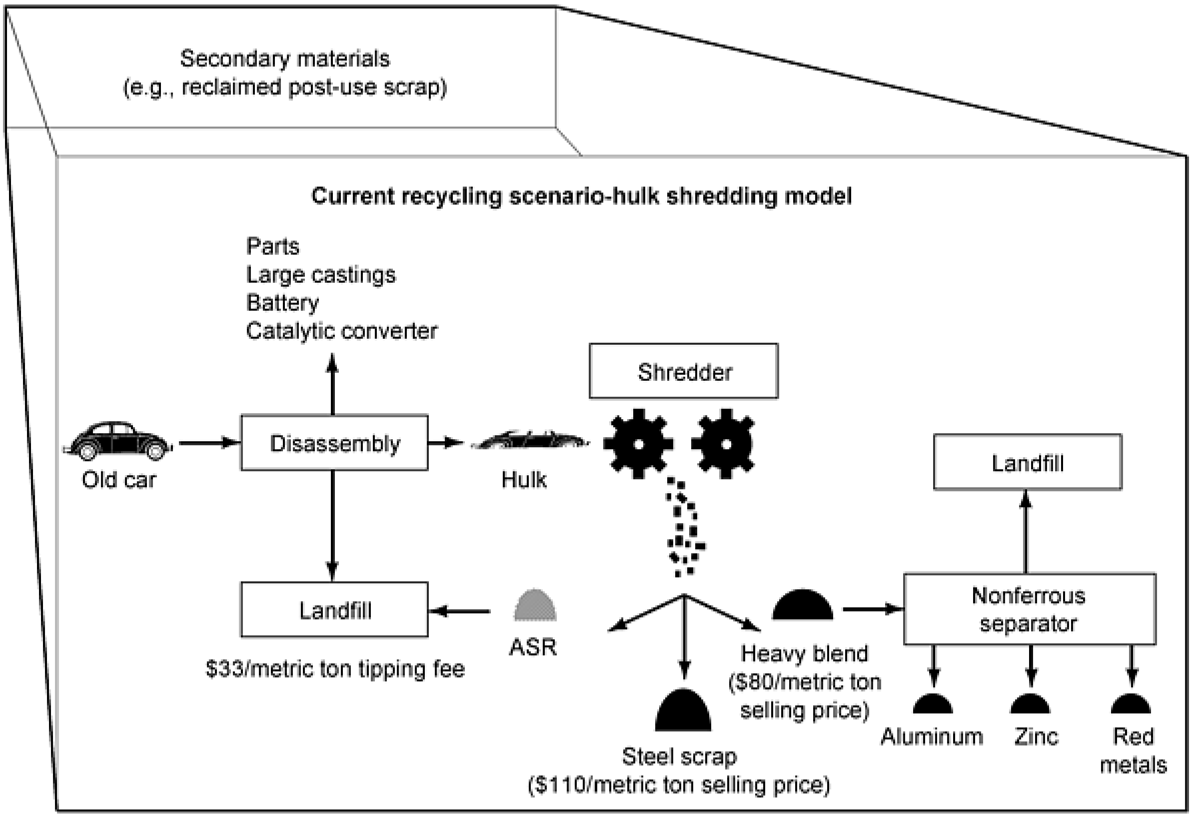

Fig. 5 Current automobile recycling infrastructure. Source: Ref 25

Figure 5 illustrates just one possible process scenario for reclaiming post-use consumer scrap. In fact, this hulk shredding scheme is currently the dominant recycling procedure. Dismantlers typically pay the last owner of the vehicle $50 or more, depending on its condition. Reusable components and valuable materials are removed prior to shredding. Additional parts, such as tires and fluids, may also be removed, not so much for their resale value, but to ensure that the vehicle hulk is acceptable to the downstream shredder. However, complete vehicle disassembly is not economically advisable since there are diminishing returns associated with the process.

At the shredding facility, hulks are mechanically reduced into fist-sized chunks. Magnetic and specific gravity separation techniques are used to segregate the material into ferrous, nonferrous, and mainly nonmetallic automotive shredder residue fractions. The ferrous fraction is sold to electric arc furnace mini-mills. The nonferrous fraction is sold to specialized shops where aluminum, zinc, and copper can be segregated and resold to their secondary markets. The automotive shredder residue (ASR) is usually sent to a landfill.

Recycling Cost Estimation. The technical cost modeling methodology was applied to the recycling infrastructure to examine the major economic forces at work in this industry (Ref 26, 27). Each process within the recycling infrastructure was divided into its component process steps, and the costs (and revenues) for each of these were estimated. The analysis was based on a polymer intensive vehicle, for which the costs incurred during the disposal phase of the vehicle life may be significant.

Shredder Costs. The first baseline simulation was aimed at understanding the economics of the shredding process. A 1990 model year vehicle was used. In this case shredding resulted in 0.28 metric tons of ASR, 0.66 metric tons of ferrous scrap, and 0.05 metric tons of nonferrous scrap per hulk (Ref 26). The costs estimated with the use of a technical cost model and revenue of this process are shown in Fig. 6.

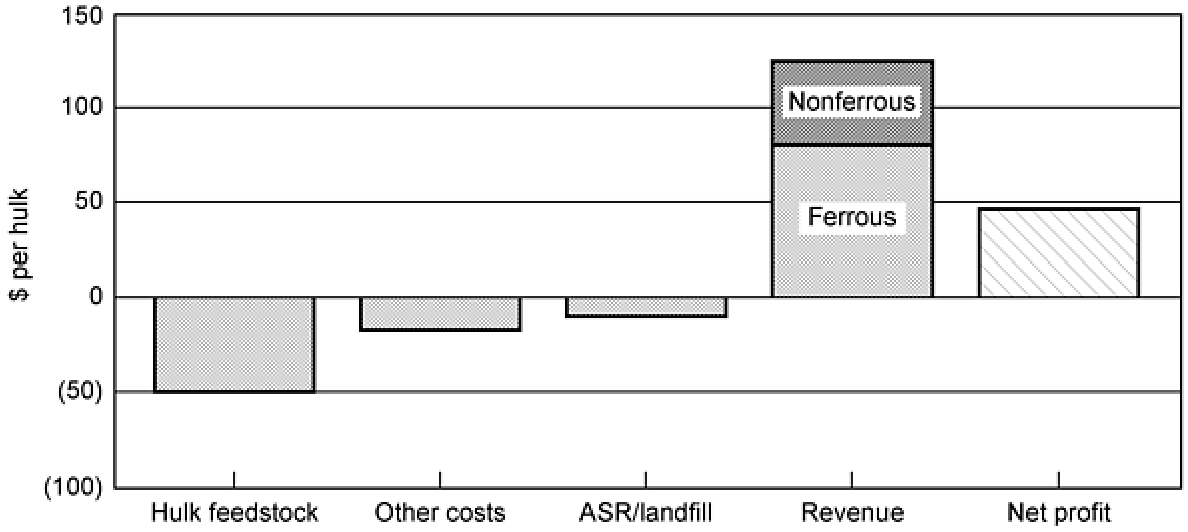

Fig. 6 Cost breakdown for the automobile shredding process (1990 model year). Source: Ref 26

Given the relatively low disposal tipping fees in the United States, the landfill cost is a small fraction of the total operating cost. The high market value of the metallic fraction, accounting for approximately 71% by weight of the hulk, more than compensates for ASR's relatively small cost liability. The major cost contributor is the purchase of the hulk.

Industry profitability can be affected by changing market conditions such as landfill prices, material content of the hulk, and the feedstock price. Figure 7 demonstrates the extent to which the shredder profit is affected by rising landfill tipping fees and increasing polymer content in the hulk.

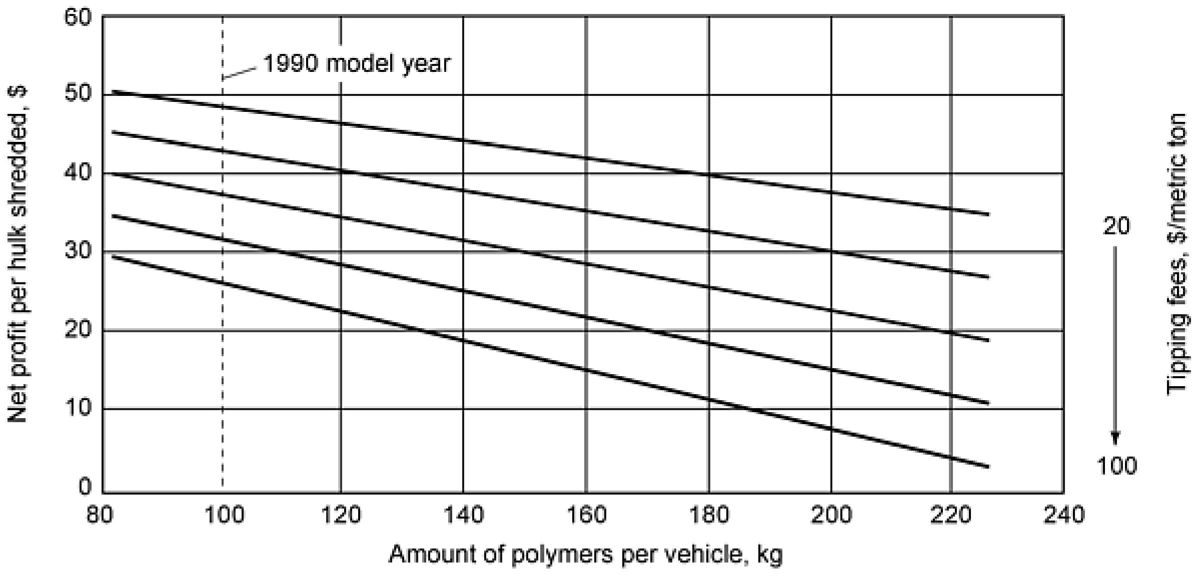

Fig. 7 Effect of polymer content and landfill tipping fee on profit per hulk. Based on price per metric ton of $110 for ferrous scrap and $880 for nonferrous scrap

Figure 7 shows that only under the extreme conditions of high landfill fees and greatly increased polymer content would the shredder operate at a loss. At tipping fees as high as $100/metric ton, the shredder is still profitable. In fact, net loss for the hulk shredding process will not occur until tipping fees climb to nearly $200/metric ton. Currently, landfill prices in the United States are about $35 to $50 per ton. In Germany, landfill prices are in the $100 to 120/ton range and could rise to $200/ton in the next 5 to 10 years.

Despite the current profitability and robustness of the infrastructure, increasing attention is being focused on looking for alternative recycling schemes. One reason is that the preconditions for collapse of the infrastructure may be realized. Landfill prices are on an upward trend, especially in other countries, and the material content of the vehicle is changing. Furthermore, the hulk transfer price is a key cost to the shredder and is subject to changes in the materials scrap prices and landfill prices. Decreasing metal scrap prices could lower the price the shredder is willing to pay for the hulk. This will have consequences on the dismantler, who may then seek alternative disposal routes for the hulk. The dismantler could in turn transfer this cost on to the last user of the vehicle. This could result in the dismantler charging the vehicle owner for disposal of the car rather than paying for the used vehicle. Vehicle owners may then seek alternate disposal routes, thus bypassing the current recycling infrastructure.

ASR Treatment. Another approach to the vehicle disposal issue involves treatment of the shredder residue. A major advantage of these approaches is their compatibility with the current recycling infrastructure, which is based on shredder processing. The goal of these methods is to recover more of the value imbedded in the ASR, which is currently landfilled, and the concomitant reduction in landfill costs.

Consider two ASR treatment processes, pyrolysis and selective precipitation. Pyrolysis brings the recyclate back to the feedstock stage as petroleum products. Selective precipitation brings the recyclate back to the intermediate product stage as polymer resins (Ref 26, 27).

Pyrolysis is the thermal decomposition of organic materials into oil, gas, and solid residue. Energy is required to start the reaction, but is not necessary to sustain it due to the generation of gas by the process. The resulting oil can be sold, and the solid residue can either be landfilled or sold for its fillers and metal scrap content. A schematic of the ASR pyrolysis process is given in Fig. 8.

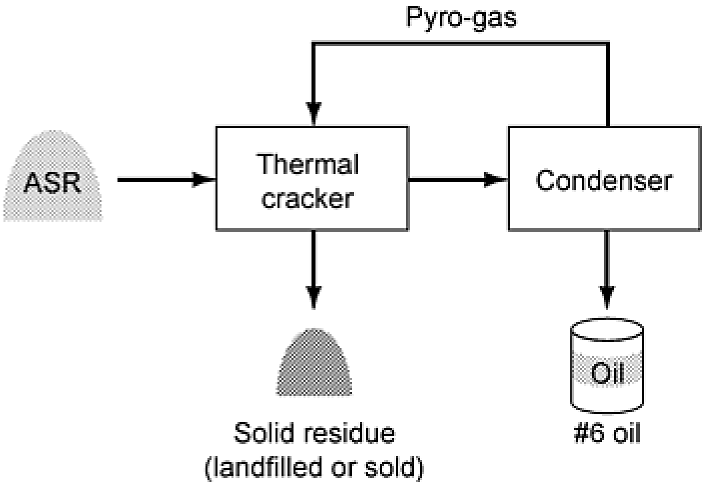

Fig. 8 Schematic diagram of the ASR pyrolysis process

The selective precipitation process is aimed at collecting higher valued recyclates. Mechanical separation is used to remove any fluids and obtain both a polymer rich stream and "fines." Fines are small particles (less than 0.6 cm in diameter), which are rich in iron oxide and silica. These can be sold as feedstock for cement making. The selective precipitation process then uses extracting solvents at elevated temperatures to remove specific thermoplastic polymers. In this case study, acrylonitrile-butadiene-styrene (ABS), polyvinyl chloride (PVC), and a polyolefin mix of polyethylene (PE) and polypropylene (PP) were considered. Figure 9 shows a schematic of this process, which was developed at Argonne National Laboratory (Ref 26).

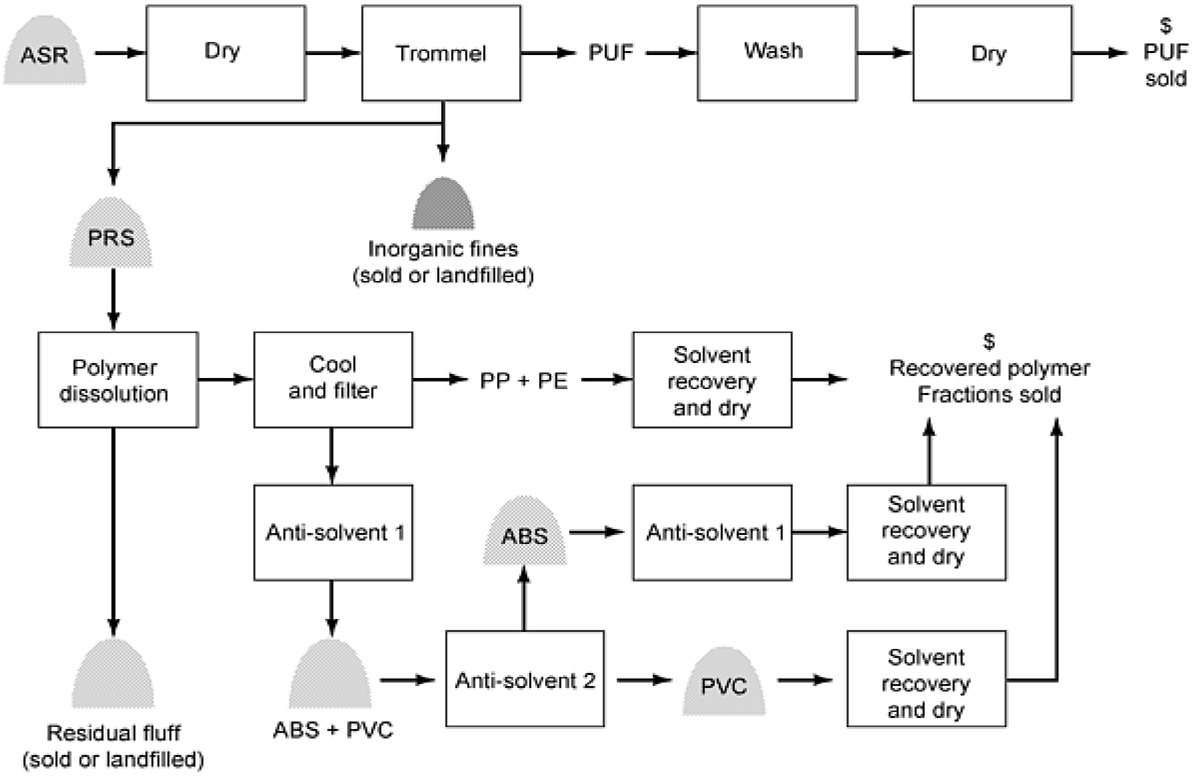

Fig. 9 Flow diagram of the ASR mechanical separation/selective precipitation process. ABS, acrylonitrile-butadiene-styrene; PE, polyethylene; PP, polypropylene; PRS, polymer-rich stream; PUF, polyurethane foam; PVC, polyvinyl chloride. Source: Ref 26

Cost models were developed for each of the two ASR treatment processes. The results are shown in Fig. 10 and 11.

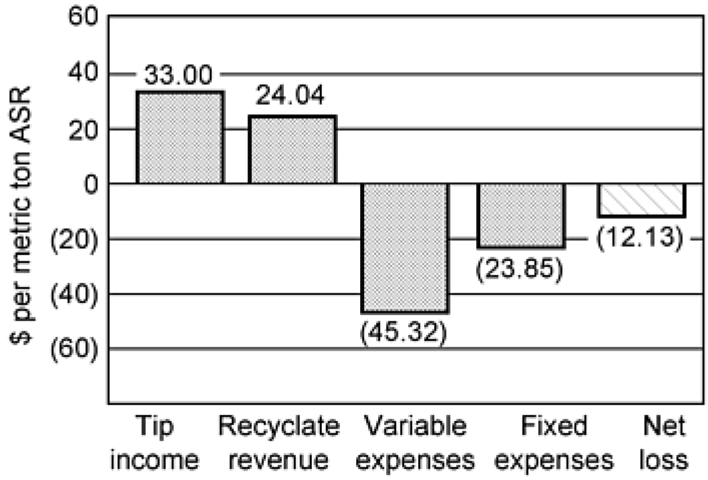

Fig. 10 ASR pyrolysis cost breakdown. Source: Ref 26

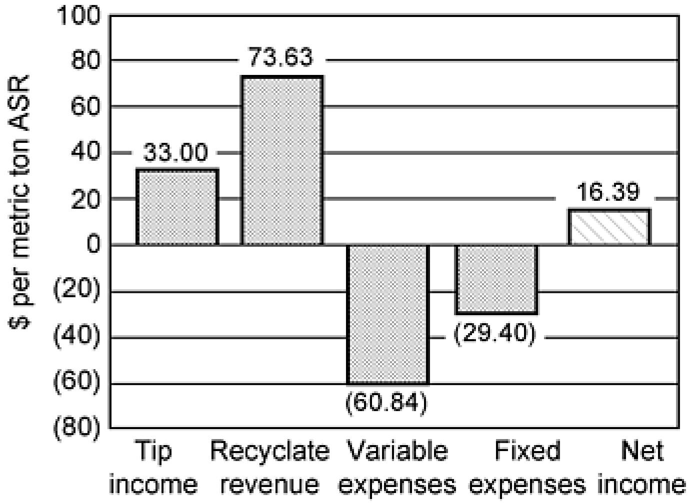

Fig. 11 ASR mechanical separation/selective precipitation cost breakdown. Source: Ref 26

The selective precipitation process has a potential profit of $16/metric ton, while the pyrolysis process has a projected loss of $12/metric ton of processed ASR. This difference is a consequence of the reclamation of higher valued recyclates in the selective precipitation technique. In fact, these higher valued products more than offset the increased labor and capital cost associated with the process. The recyclate revenues from each process are critical factors, which affect the relative profitability of the processes.

Both of the above two cost projections assume a near 100% capacity utilization. As can be seen, there is a limit to how greater recycling economies of scale can lead to lower recyclate costs. While greater plant utilization certainly leads to a lower per unit fixed cost, the processes modeled still cannot independently achieve profitability. The tipping fee is an important revenue source for either process even at the low values representative of the U.S. prices. In Germany, where tipping fees are about four times those in the United States, landfill prices are the critical variable. Variable costs, such as energy and labor, together with fundamental physical and chemical constraints of materials processing, ultimately impose a financial asymptote.

An additional critical factor for the economics of these processes is the material throughput. Figure 12 shows the net profit of each process for varying levels of ASR throughput.

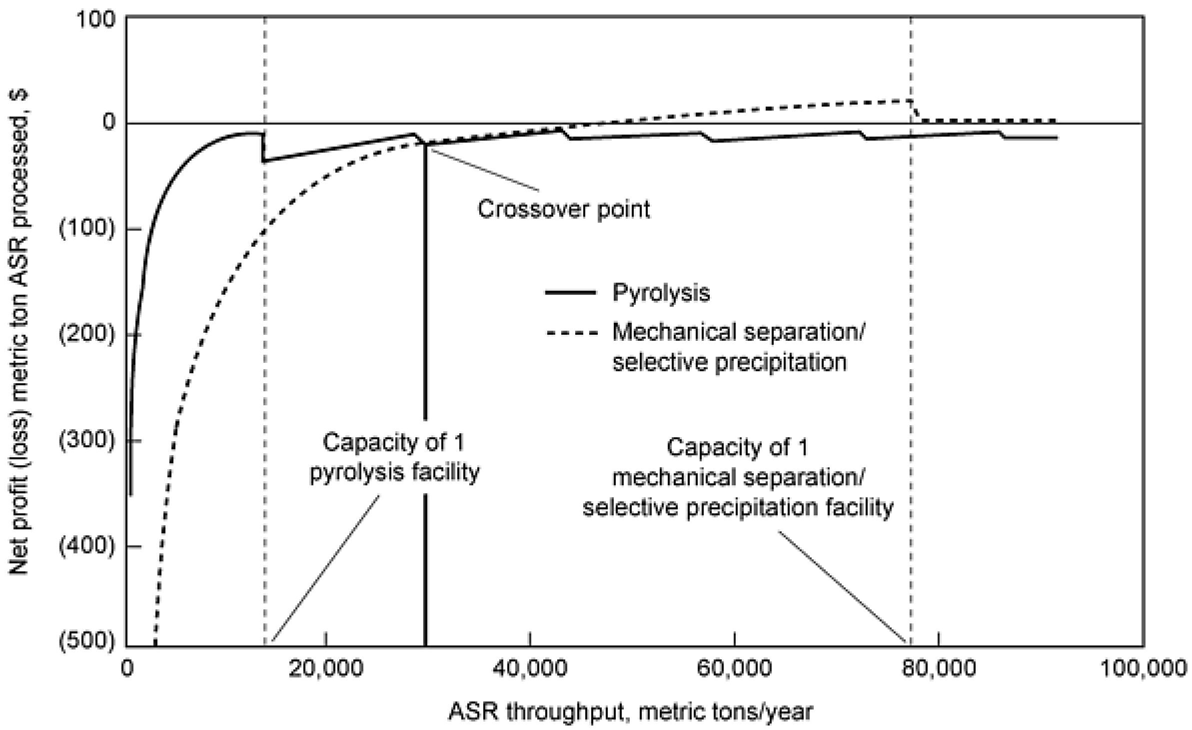

Fig. 12 Throughput implications in alternative recycling processes. Source: Ref 26

Regardless of the throughput, pyrolysis results in a net loss, while it is possible for selective precipitation to achieve a profit at high volumes. Another interesting view is based on the availability of shredder fluff in a given region. If less than 30,000 metric tons of ASR (100,000 to 110,000 shredded hulks) can be collected, pyrolysis may be the more economical alternative. There is still a net loss associated with this process, but it is small relative to the selective precipitation technique.

Techno-Economic Issues in Materials Selection

Joel P. Clark, Richard Roth, and Frank R. Field III, Massachusetts Institute of Technology

Environmental and Social Costs

Public concern for the environment is increasing, and thus "environmental performance" is becoming the newest strategic objective in materials selection for automotive design. This objective overlaps with weight reduction, but it is more complex when manufacturing and recycling issues arise. How should designers measure total "environmental performance," and how can they integrate those measures into the whole materials selection problem?

Life Cycle Analysis

Life cycle analysis (LCA) is one of the most actively considered methods for the study and analysis of strategies to meet environmental challenges. Its strengths derive from its roots in traditional process analysis, and from the recognition, implicit in its formulation, that the consequences of technological undertakings are not limited to the performance of a single process or change. Instead, the majority of the effects deriving from an action may only be perceived when the entire range of consequences of that action are taken into account.

The objective of LCA is to provide decision makers, whether consumers, industrialists, or government policy makers, with information that will allow them to understand the environmental impacts of their actions. In order to meet their needs, this tool must be used in alliance with traditional bases for decision making, including economic, engineering, and social objectives.

Life cycle analysis is frequently characterized as a three-step process (Ref 28):

1. *Inventory analysis:* The identification and quantification of energy and resource use and environmental releases to air, water, and land
2. *Impact analysis:* The technical qualitative and quantitative characterization and assessment of the consequences on the environment of these changes
3. *Improvement analysis:* The evaluation and implementation of opportunities to reduce environmental burdens

Inventory. Airborne emissions of carbon dioxide (CO_2), carbon monoxide (CO), particulates, nitrogen oxides (NO_x), sulfur dioxide (SO_2), and other hydrocarbons (HC) are usually considered to be of greatest importance in the automotive body life cycle. The emissions arise from the energy required in each of the stages in the lifetime of the product. In addition, emissions arise from chemical reactions, mainly during the material mining and refining processes. These are strictly related to the material chosen for the production of components for the vehicle. Finally, emissions also arise during the use phase due to the combustion of gasoline.

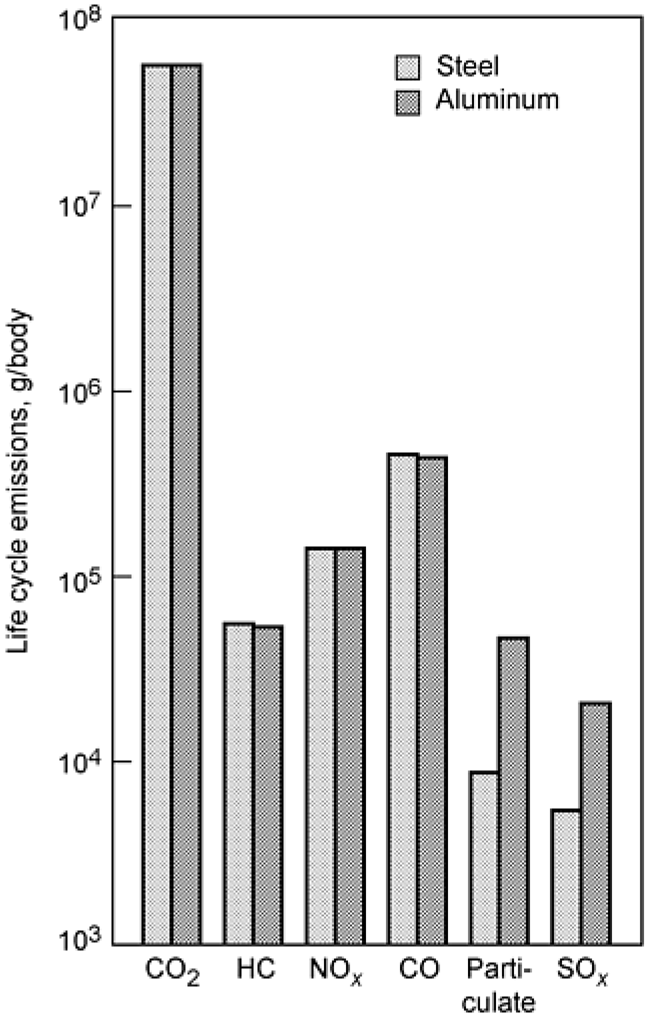
Table 1 lists the emissions generated for a steel unibody and an average aluminum design over the life cycle of the vehicle. It is important to note that emissions from each of the four aluminum designs do not vary substantially. This is a consequence of the fact that they are similar in weight and have similar emissions released in the use phase. The fact that they are all aluminum designs also means that the emissions generated in the mining and refining stage will also be quite similar.

Table 1 Percentage of emissions generated during each stage of the vehicle life cycle for a steel unibody and an average aluminum design

Emission type	Emissions produced, %			
	Mining/refining	**Production**	**Use**	**Post-use**
Steel unibody				
CO_2	2.32	0.05	97.63	~0
HC	0.10	~0	99.90	0
NO_x	2.21	0.04	97.74	~0
CO	0.05	~0	99.95	~0
Particulate	23.30	0.50	76.20	~0
SO_x	97.78	1.97	0	0.25
Aluminum body				
CO_2	8.65	0.09	91.26	0
HC	0.40	~0	99.60	0
NO_x	8.27	0.08	91.64	~0
CO	0.21	0	99.79	0
Particulate	84.10	0.05	15.85	0
SO_x	98.98	0.99	0	0.04

Results show that the aluminum designs perform better in the pollutant categories that dominate during the use phase (CO_2, hydrocarbons, NO_x, and CO). However, for particulates and sulfur oxides, the steel design is more competitive. Emissions associated with the aluminum design are greater for the mining and refining stage (sulfur oxides and particulates). For the categories that arise predominantly during vehicle use (CO_2, hydrocarbons, NO_x, and CO), the lightweighting achieved in the aluminum designs pays off.

Analysis of the inventory data does not lead to an unambiguous result. On a cost basis, even with a life cycle approach, the steel unibody is most competitive. However, if the goal is to reduce greenhouse gases and smog precursors, one of the aluminum designs may be preferred (Fig. 13).



Emission Type	Change when using aluminum, %
CO_2	-1.24
HC	-7.71
NO_x	-1.50
CO	-7.50
Particulate	+438
SO_x	+264

Fig. 13 Emissions throughout the entire product life cycle for steel and aluminum automobile bodies

Impact and Evaluation. Most efforts to develop the LCA technique have focused on constructing a complete set of procedures for the collection and organization of the information that must be developed in the course of a LCA. However, determining what to do with this information, once it is collected, has so far been only imperfectly addressed. Although the reason for employing LCA is to develop activities that reduce environmental impact, establishing how this mass of data informs specific problems has proven to be extremely difficult for all but the simplest of situations.

In particular, the most problematic aspect of LCA has been the final, "improvement analysis" component. Improvement analysis implicitly assumes that it is possible to choose (and implement) a "best" action from the set of possible actions, thus yielding improvement. Aside from simple cases where it is possible to find an action that leads to reductions in all impacts on the environment, this choice depends upon the relative importance placed upon each of the possible consequences that are indicated by the analysis. This relative rating of importance is a reflection of the strategic objectives of the user--objectives that are not necessarily shared by all interested stakeholders.

Example: Method for Estimating the "Environmental Load" of Materials.

To illustrate the potential and limitations of LCA method, the Swedish Environmental Priority Strategies (EPS), under development by the Swedish Environmental Research Institute, Chalmers Institute of Technology, and the Federation of Swedish Industries, are discussed (Ref 29). EPS translates emissions into a single monetary metric that allows the direct costs of manufacturing, use, and recycling/disposal to be compared with the social costs generated by emissions.

EPS is specifically constructed to associate an "environmental load" with individual activities or processes on a per unit of material consumed or processed basis. For example, EPS might associate X units of environmental load (ELUs) per kilogram of steel produced and Y units of environmental load per kilogram of steel components stamped. Thus, the environmental load of stamping a 5 kg automobile component, requiring 5.3 kg of steel, would be (5.3 X + 5 Y). This load could then be compared to the load associated with a different process stream or with using a different material. The interesting questions are: how are these environmental loads established and what do they mean.

Based on the environmental objectives of the Swedish Parliament, EPS relates all of the physical consequences of the processes under consideration to their impact on five environmental "safeguard subjects": biodiversity, production (i.e., reproduction of biological organisms), human health, resources, and aesthetic values. Because the impacts on any one safeguard subject by a process may take several forms, EPS allows for individual consideration of each of these consequences, called "unit effects." Two criteria are applied when establishing which impacts will become unit effects: the importance of the impact on the sustainability of the environment and the existence of an ability to establish a quantitative value for that impact within traditional economic grounds. Examples of unit effects for human health include: mortality due to increased frequency of cancer; mortality due to increased maximum temperatures; food production decreases (and, hence, increased incidence of starvation) due to global warming.

Once the individual unit effects are established, their value must be determined. This valuation is accomplished by expressing each unit effect in terms of its economic worth and associated risk factors. Formally, the value of each unit effect is set equal to the product of five factors, F1 through F5. F1 is a monetary measure of the total cost of avoiding the unit effect. The extent of affected area (F2), the frequency of unit effect in the affected area (F3), and the duration of the unit effect (F4), represent "risk factors" similar to those employed in toxicological risk evaluations. F5 is a normalizing factor, constructed so that the product F1 × F5 is equal to the cost of avoiding the unit effect that would arise through the use or production of one kilogram of material. The product of all five factors yields the contribution of a particular unit effect to environmental load. Summing the value of each unit effect yields the "environmental load index" (ELI) in units of environmental load per unit of material consumed or processed (ELU/kg). Since these unit effects were specified according to their relevance to the five safeguard subjects, the ELI represents the total environmental load (or impact) of the process.

While this formulation of valuation raises important questions of scientific feasibility (insofar as the ability to characterize fully the unit effects of every process or activity that might be developed is debatable), the crucial valuation questions arise from two other aspects of this scheme: (a) the nature of the economic measures used in calculating the cost of avoiding a unit effect, and (b) the assumption that the value of the total environmental impact of an action (the "environmental load") is equal to the sum of each individual environmental load weighted by the size of each unit effect.

The first of these valuation questions relates to the distinction between "cost" and "worth." While the theory of competitive markets argues that prices are the worth of an object, the theory rests upon assumptions that are difficult to support in the case of environment. In the first place, perfect markets assume the availability of perfect information to all

participants, which clearly is not the case, or there would be no need to develop life cycle analysis in the first place. Furthermore, the theory of markets routinely discusses "consumer surplus," which can roughly be defined as the difference in the prevailing market price and the higher price that some consumers would have been willing to pay (recall that demand curves slope downward). Finally, there is the critical question how to establish these costs/prices when markets do not exist. While litigators are prepared to place a value on wrongful death or pain and suffering during a civil suit, there are no markets for pain, clean air, or future well-being. Generally, most environmental attributes are "external" to markets; many of the classical examples of market externalities are based on environmental issues.

Where markets exist, EPS uses market prices to establish the costs of avoidance. Where market prices do not exist, EPS relies upon two alternatives. If there are governmental funds allocated to resolve specific problems (e.g., funds to protect a particular species), these funds are normalized and extrapolated to obtain a cost figure (e.g., the value of maintaining biodiversity is established by normalizing the annual budget of the Swedish government for species protection). If relevant financial allocations do not exist, then the method of contingent valuation is employed. This method (or set of methods) is based on direct inquiries of representative populations to determine their willingness to pay to avoid specific effects. As might be expected, this last approach to establishing the appropriate costs of avoidance is somewhat controversial, since it is hard (both conceptually and practically) to design questions that demonstrably extract the "correct" measure of value.

The second of these valuation questions is a reflection of the fact that the mathematical structure of the value function is a consequence of critical assumptions about the nature of the subject's preferences. The valuation employed in the EPS system is an example of a linear, additive preference structure. Each unit effect is reduced to a monetary value, normalized for risk/exposure and for material quantity. Thereafter, the net impact of each increment in unit effect is the same, regardless of how large the effect is, and regardless of the size of any other unit effect. While such value functions are simple to represent and employ (linear combinations of linear functions), it is difficult to argue that they are an accurate, general purpose formulation of value functions for environmental impact. Although the appropriate form of the value function may be linear, EPS does not explicitly make this assumption. Rather, the linearity of EPS valuation is based on the assumption that, because monetization reduces all effects to a common metric, the resulting metrics should be additive. In fact, most individuals do not even exhibit linear preferences for money, much less for more subjective attributes. (For example, most individuals would consider paying $0.50 to play a game offering a 50:50 chance of winning $1.00, while rejecting out of hand paying $5,000 to get a 50:50 chance of winning $10,000). In practice, preferences usually reflect nonlinearities in both individual effects and in substitution between effects.

The first two issues (money as a measure of value and linear additive preferences) are not necessarily crippling assumptions when considering the development of value functions for the environment. While difficult, it may be possible for someone to establish the dollar value that exactly offsets a particular unit effect. Similarly, linear additive preferences may be able to model the behavior of an individual over a restricted range. However, it is impossible to state that the same dollar value, or the same linearization of preferences, will be agreeable to every individual in the affected population in the case of environmental considerations. And, if individuals cannot agree on the value or the structure of their preferences, then no single value function can be constructed to represent their wants.

A recent methodology developed at MIT (Ref 30) is similar to EPS, but provides a set of broad ranges of value, in dollars per kilogram of each emission, based on estimates of willingness to pay to avoid the environmental impacts of each pollutant. These ranges reflect scientific uncertainty, variation in context or location, and large variations of possible values for parameters that have a subjective component. The dollars per kilogram ranges can be applied to the life cycle inventories of products to compare material or process alternatives.

The methodology was used to analyze the life cycle costs of three material alternatives for automotive fenders produced at low volumes (60,000/year). The three materials under consideration were steel, aluminum, and Noryl (Noryl is a trademark of General Electric Company for a polyphenylene oxide blend thermoplastic). The results of the base case, employing "best guess" for scientific data and economic valuation, are shown in Fig. 14.

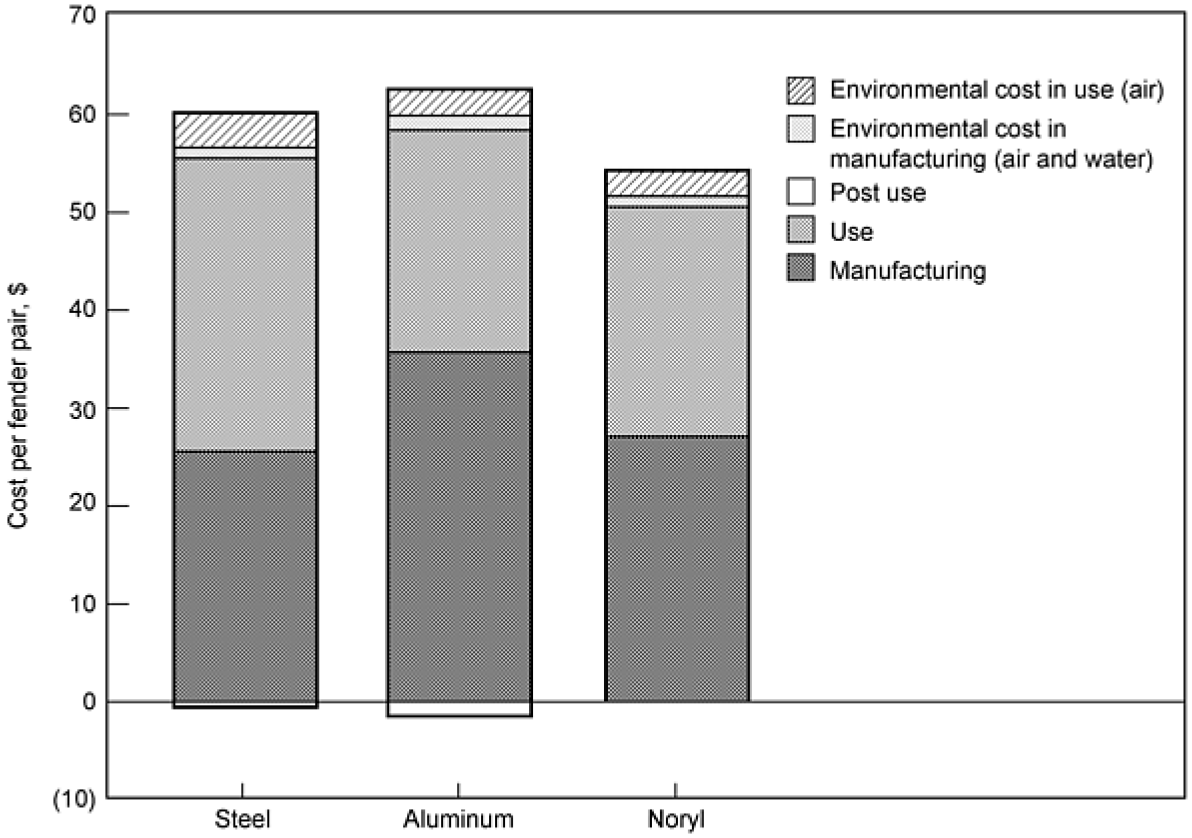


Fig. 14 Estimated life cycle costs by life phase for competing materials for an automobile fender application

In this scenario, the private costs of manufacturing and use (with German gasoline prices) are significantly greater than the social costs from emissions to the environment. Figure 15 shows the implications of allowing the scientific and economic assumptions to take on the highest and lowest values possible, based on a review of published estimates.

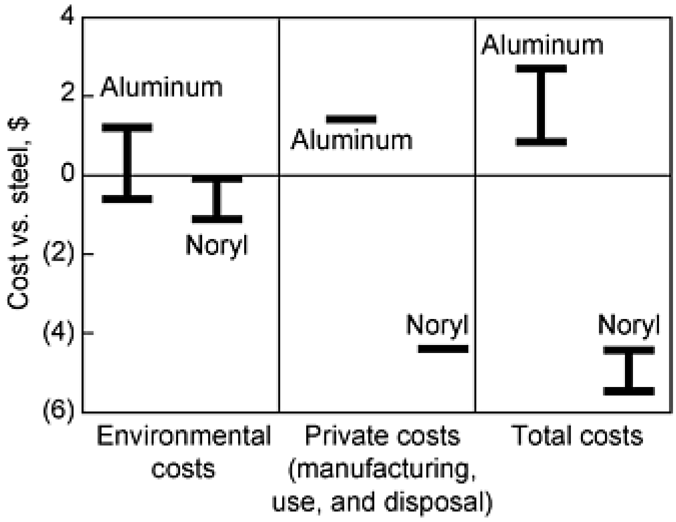

Fig. 15 Total costs relative to steel of competing materials for an automobile fender application

The externalities are the environmental costs of emissions from the extraction to the manufacturing and use stages. The private costs include manufacturing, use, and disposal. The specific assumptions employed in this case study lead to a

lower total cost for Noryl, although no clear winner arises under this set of assumptions. Even when no clear choice emerges, the environmental cost drivers can be identified. For instance, the fender case study shows that only 4 or 5 emissions categories account for more than 95% of the total environmental cost for each material.

The EPS system is a commendable attempt at simplifying the enormous detail of inventory data to a representative environmental load. The developers of EPS have pointed out that this system is based on their subjective value judgments, which are not necessarily supportable in all situations worldwide. The ultimate goals for improvement analysis based on life cycle inventories are laudable, but can only be realized by some kind of consensus on the values for avoiding environmental degradation. This suggests that achieving the ultimate stage of LCA will require the development of a basis for devising (and revising) this consensus. In the absence of a common strategic objective, it will be impossible to use LCA to designate ways to achieve environmental improvement beyond straightforward pollution prevention/precautionary principle strategies, because a strategic consensus is required to trade off competing environmental, economic, and engineering goals.

Uses of LCA. In summary, life cycle analysis is a technique that has already shown great promise for improving our understanding of the wider implications and relationships that must be taken into consideration when incorporating environmental concerns into technical decision making. As these concepts diffuse into industrial and technical decision making, LCA will enable industry and government to find ways to be both more efficient and less harmful to the environment.

However, practitioners and proponents must guard against using LCA to determine "best" modes of action when the consequences of the alternatives expose conflicting objectives and values within the group of decision makers. In these cases, no amount of analysis will directly resolve the conflict. Rather, the role of LCA should be to articulate clearly the consequences of each alternative and to provide a framework for the necessary negotiations.

Additional information about LCA is provided in the articles "Life-Cycle Engineering and Design" and "Environmental Aspects of Design" in this Volume.

Conclusions

There is an ever growing need for consistent methodologies for analyzing the use of new materials, designs, and technologies in many applications. Advances in materials science and in the development of new processing technologies have presented product designers with a wide array of choices previously unavailable to them. This has made the selection of a material for a given application a far more challenging task.

The difficulty confronting designers is compounded by the increasing number of objectives that product designers must satisfy. In the past, the designer simply had to meet a set of performance criteria, at or below a specified cost, from a very limited set of design alternatives. The current situation is much more complicated. In addition to the increasing number of design choices, there are potentially conflicting performance, cost, and environmental characteristics.

Central to all product evaluations is a consideration of the economic consequences of design and materials choice. Cost is one of the key strategic elements of product competitiveness, and an early appreciation of the relationship between major design choices and the cost of the resulting product is a vital element of effective product development. However, cost remains an elusive element of design evaluation. The tools are largely outside the control of the design engineers. The results suggest only a limited number of ways in which cost can be changed, and the costs tend to focus only upon the cost consequences to the firm itself. Unfortunately, designers require a far more comprehensive appreciation of cost, particularly as the number and complexity of design objectives have increased.

The combined technical cost modeling and life cycle analysis methodology offers the product designer a much needed systematic approach for analyzing the trade-offs associated with various choices of materials and technologies. Technical cost modeling enables designers to estimate the manufacturing costs of alternative designs. Its main advantages lie in the fact that it is predictive and allows one to investigate the sensitivity of the outcome to changes in the input parameters. Because it is predictive, it can be used with new processes for which there is no past experience upon which to base cost estimates. The ability to do sensitivity analysis enables the product designer to look at the effects of unknown or uncertain model parameters, capturing the scope and consequences of important processing and market assumptions.

The advantages of the life cycle approach are also two-fold. First, life cycle analysis enables one to look at cost over the entire life of the product, not just the manufacturing phase. For many products, cost can be quite substantial during other parts of the product life, especially the use phase. Second, life cycle analysis is useful for looking at issues relevant to environmental concerns, such as tracking selected emissions throughout the product life. While valuation techniques are rather imperfect, they provide a means for translating these diverse parameters into a common metric, as well as a context for analyzing the implications of distinctions in the strategic objectives of all parties affected by the product and design choice.

The integrated approach provided by technical cost modeling and life cycle analysis is particularly important in industries such as the automotive sector, where both consumer and regulatory pressures are causing the producers to continuously innovate. The combined life cycle cost and emissions methodology offers a systematic and predictive method for addressing some of the fundamental considerations involved in selecting materials and designs for specific products.

Techno-Economic Issues in Materials Selection

Material Property Charts

M.F. Ashby, Engineering Design Centre, Cambridge University

Introduction

MATERIAL PROPERTIES limit performance. However, it is seldom that the performance of a component depends on just one property. Almost always it is a combination (or several combinations) of properties that matter: one thinks, for instance, of the strength-to-weight ratio, σ_f/ρ, or the stiffness-to-weight ratio, E/ρ, which are important in design of lightweight products. This suggests the idea of plotting one property against another, mapping out the fields in property-space occupied by each material class, and the subfields occupied by individual materials.

The resulting charts are helpful in several ways. They condense a large body of information into a compact but accessible form, they reveal correlations between material properties that aid in checking and estimating data, and they lend themselves to a performance-optimizing technique (developed in the article "Performance Indices" following in this Section of the Handbook), which becomes the basis of the selection procedure.

The idea of a materials-selection chart is developed below. Further information about the charts and their uses can be found in Ref 1, 2, 3 and in the article "Performance Indices."

Acknowledgements

The charts reproduced as Fig. 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, and 13 first appeared in Ref 1, where more details about their use can be found.

The author wishes to thank Dr. David Cebon for helpful discussions. The support of the Royal Society, the EPSRC through the Engineering Design Centre at Cambridge, and the Advance Research Project Agency through the University Research Initiative under Office of Naval Research Contract No. N-00014092-J-1808 are gratefully acknowledged.

Material Property Charts

M.F. Ashby, Engineering Design Centre, Cambridge University

Displaying Material Properties

Each property of an engineering material has a characteristic range of values. The values are conveniently displayed on materials selection charts, illustrated by Fig. 1. One property (the modulus, *E*, in this case) is plotted against another (the density, ρ) on logarithmic scales. The range of the axes is chosen to include all materials, from the lightest foams to the heaviest metals. It is then found that data for a given class of materials (polymers for example) cluster together on the chart; the subrange associated with one material class is, in all cases, much smaller than the full range of that property. Data for one class can be enclosed in a property-envelope, as shown in Fig. 1. The envelope encloses all members of the class.

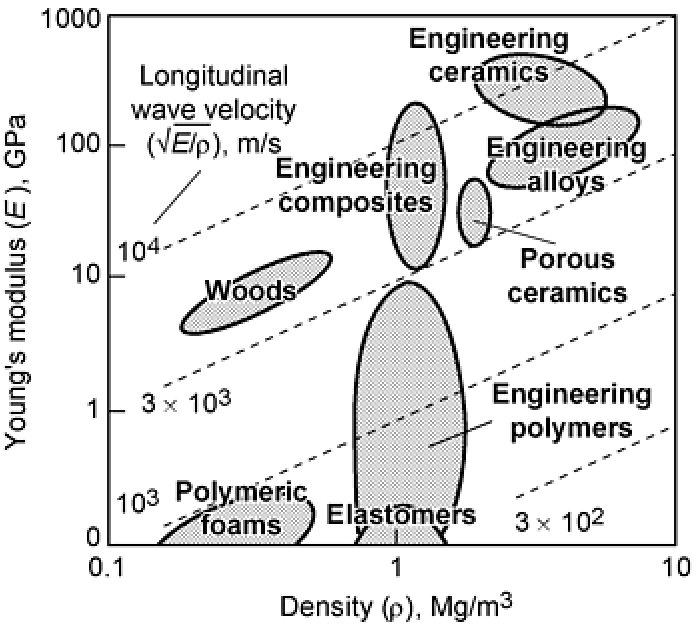

Fig. 1 The idea of a Materials Property Chart: Young's modulus, *E*, is plotted against the density, ρ, on log scales. Each class of material occupies a characteristic part of the chart. The log scales allow the longitudinal elastic wave velocity *v* = $(E/\rho)^{1/2}$ to be plotted as a set of parallel contours.

All this is simple enough--just a helpful way of plotting data. However, by choosing the axes and scales appropriately, more can be added. The speed of sound in a solid depends on the modulus, *E*, and the density, ρ; the longitudinal wave speed *v*, for instance, is

$$v = \left(\frac{E}{\rho}\right)^{1/2}$$

or (taking logs)

$$\log E = \log \rho + 2 \log v$$

For a fixed value of *v*, this equation plots as a straight line of slope 1 on Fig. 1. This allows the addition of contours of constant wave velocity to the chart: They are the family of parallel diagonal lines linking materials in which longitudinal waves travel with the same speed. All the charts allow additional fundamental relationships of this sort to be displayed.

A number of mechanical and thermal properties characterize a material and determine its use in engineering design; they include density, modulus, strength, toughness, damping coefficient, thermal conductivity, diffusivity, and expansion. The charts display data for these properties for the nine classes of materials listed in Table 1. Within each class, data are plotted for a representative set of materials, chosen both to span the full range of behavior for the class and to include the most common and most widely used members of it. In this way the envelope for a class encloses data not only for the materials listed in Table 1, but for virtually all other members of the class as well.

Table 1 Engineered material classes included in the material property charts (Fig. 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13)

Engineering alloys

- Aluminum (Al) alloys
- Copper (Cu) alloys
- Lead (Pb) alloys
- Magnesium (Mg) alloys
- Molybdenum (Mo) alloys
- Nickel (Ni) alloys
- Steels (MS, mild steels and SS, stainless steels)
- Cast irons
- Tin (Sn) alloys
- Titanium (Ti) alloys
- Tungsten (W) alloys
- Zinc (Zn) alloys
- Beryllium (Be)
- Boron (B)
- Germanium (Ge)
- Silicon (Si)

Engineering plastics (thermoplastics and thermosets)

- Epoxies (EP)
- Melamines (MEL)
- Polycarbonate (PC)
- Polyesters (PEST)
- High-density polyethylene (HDPE)
- Low-density polyethylene (LDPE)
- Polyformaldehyde (PF)
- Polymethyl methacrylate (PMMA)
- Polypropylene (PP)
- Polytetrafluoroethylene (PTFE)
- Polyvinyl chloride (PVC)
- Polyimides

Elastomers

- Natural rubber
- Hard butyl rubber
- Polyurethanes (PU)
- Silicone rubber
- Soft butyl rubber

Polymer foams

- Cork
- Polyester
- Polystyrene (PS)
- Polyurethane (PU)

Engineering composites (polymer-matrix composites)[(a)]

- Carbon-fiber-reinforced polymer (CFRP)
- Glass-fiber-reinforced polymer (GFRP)
- Kevlar-fiber-reinforced polymer (KFRP)

Engineering ceramics

Alumina (Al_2O_3)
Diamond
Sialons
Silicon carbide (SiC)
Silicon nitride (Si_3N_4)
Zirconia (ZrO_2)
Beryllia (BeO)
Mullite
Magnesia (MgO)

Porous ceramics (traditional ceramics)

Brick
Cement
Common rocks
Concrete
Porcelain
Pottery

Glasses

Borosilicate glass
Soda glass
Silica (SiO_2)

Cermets

Tungsten carbide/cobalt (WC-Co)

Woods[(b)]

Ash
Balsa
Fir
Oak
Pine
Wood products (laminates)

(a) A distinction is drawn in the charts between the properties of uniply and laminated (laminates) composites.

(b) Separate property envelopes describe properties of wood parallel, $\parallel$, and perpendicular, $\perp$, to the grain.

The charts show a range of values for each property of each material. Sometimes the range is narrow; the modulus of copper, for instance, varies by only a few percent about its mean value, influenced by purity, texture, and the like. Sometimes the range is wide; the strength of alumina-ceramic can vary by a factor of 100 or more, influenced by porosity, grain size, and so on. Heat treatment and mechanical working have a profound effect on yield strength, damping, and the toughness of metals. Crystallinity and degree of cross-linking greatly influence the modulus of polymers, and so on.

These structure-sensitive properties appear as elongated bubbles within the envelopes on the charts. A bubble encloses a typical range for the value of the property for a single material (see Fig. 2). Envelopes (heavier lines) enclose the bubbles for a class.

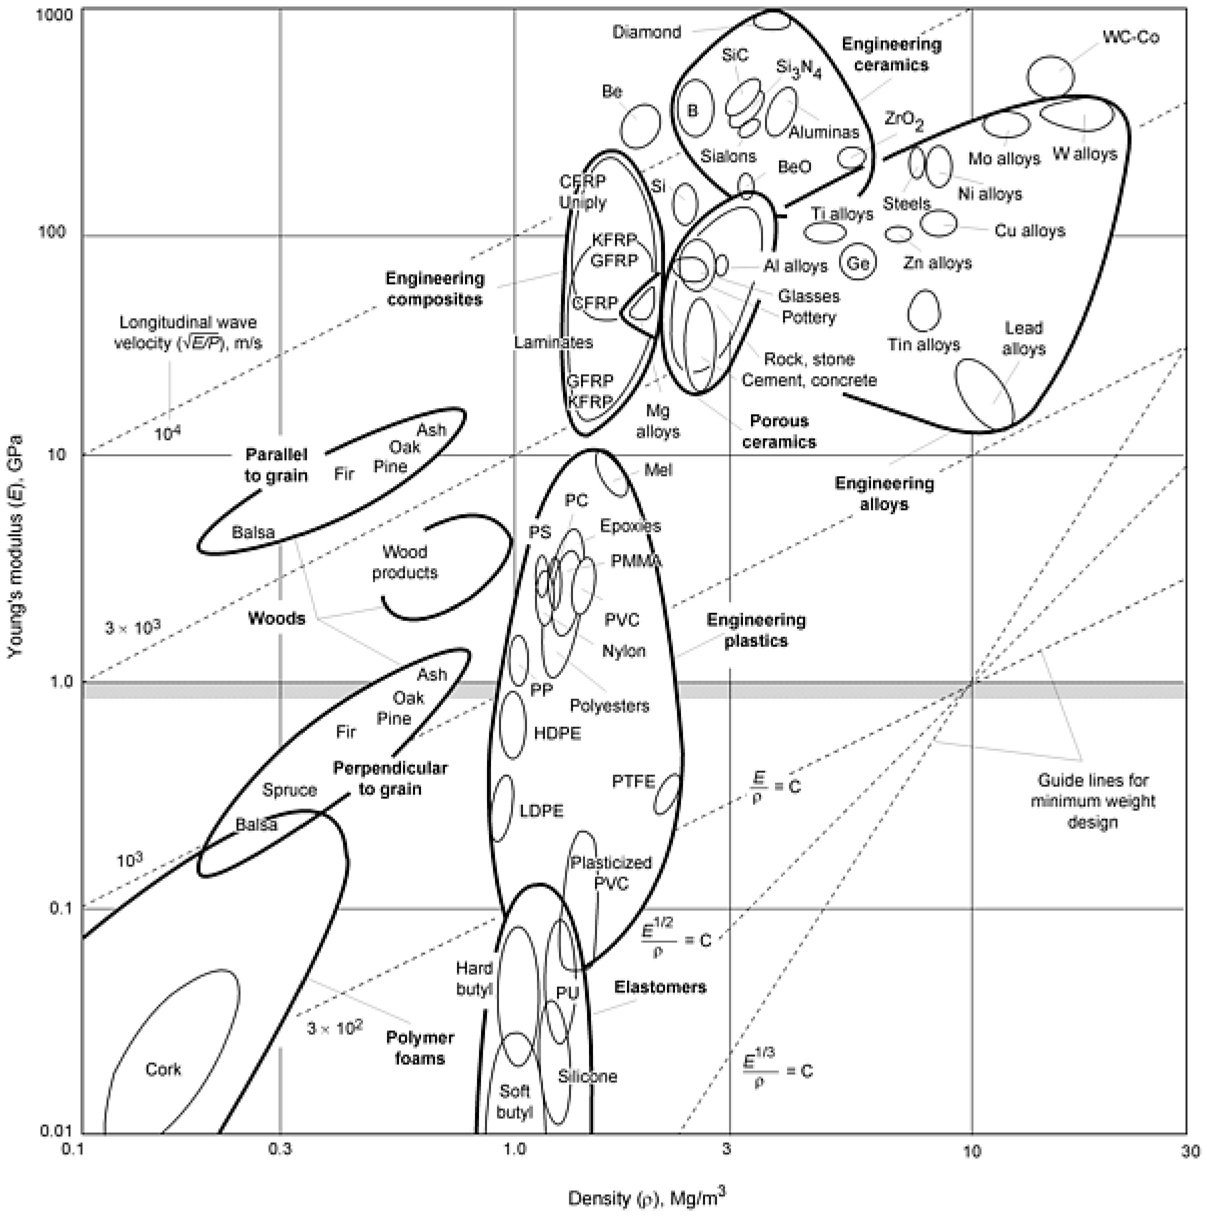

Fig. 2 Young's modulus, *E*, plotted against density, ρ, for various engineered materials. The heavy envelopes enclose data for a given class of material. The diagonal contours show the longitudinal wave velocity. The guide lines of constant E/ρ, $E^{1/2}/\rho$, and $E^{1/3}/\rho$ allow selection of materials for minimum weight, deflection-limited, design.

The data plotted on the charts have been assembled from a variety of sources, the most accessible of which are listed as Ref 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, and 40.

Types of Material Property Charts

The Modulus-Density Chart (Fig. 2). Modulus and density are familiar properties. Steel is stiff, rubber is compliant: these are effects of modulus. Lead is heavy; cork is buoyant: these are effects of density. Figure 2 shows the full range of Young's modulus, E, and density, ρ, for engineering materials. Data for members of a particular class of material cluster together and can be enclosed by an envelope (heavy line). The same class-envelopes appear on all the diagrams, corresponding to the main headings in Table 1.

The density of a solid depends on three factors: the atomic weight of its atoms or ions, their size, and the way they are packed. Metals are dense because they are made of heavy atoms, packed densely; polymers have low densities because they are largely made of carbon (atomic weight: 12) and hydrogen in a linear, 2-, or 3-dimensional network. Ceramics, for the most part, have lower densities than metals because they contain light oxygen, nitrogen, or carbon atoms. Even the lightest atoms, packed in the most open way, give solids with a density of around 1 Mg/m^3 (60 lb/ft^3). Materials with lower densities than this are foams--materials made up of cells containing a large fraction of pore space.

The moduli of most materials depend on two factors: bond stiffness, and the density of bonds per unit area. An interatomic bond is like a spring: it has a spring constant, S (units: N/m). Young's modulus, E, is roughly

$$E = \frac{S}{r_0} \qquad \textbf{(Eq 1)}$$

where r_o is the "atom size" (r_o^3 is the mean atomic or ionic volume). The wide range of moduli is largely caused by the range of values of S. The covalent bond is stiff (S = 20 to 200 N/m, or 0.1 to 1 lb/in.); the metallic and the ionic a little less so (S = 15 to 100 N/m, or 0.075 to 0.5 lb/in.). Diamond has a very high modulus because the carbon atom is small (giving a high bond density), and its atoms are linked by very strong springs (S = 200 N/m, or 1 lb/in.). Metals have high moduli because close packing gives a high bond density and the bonds are strong, though not as strong as those of diamond. Polymers contain both strong diamondlike covalent bonds and weak hydrogen or Van der Waals bonds (S = 0.5 to 2 N/m, or 0.0025 to 0.01 lb/in.); it is the weak bonds that stretch when the polymer is deformed, giving low moduli.

But even large atoms ($r_o = 3 \times 10^{-10}$ m, or 1.2×10^{-8} in.) bonded with weak bonds (S = 0.5 N/m, 0.0025 lb/in.) have a modulus of roughly

$$E = \frac{0.5}{3 \times 10^{-10}} \approx 1 \text{ GPa (200 ksi)} \qquad \textbf{(Eq 2)}$$

This is the lower limit for true solids. The chart shows that many materials have moduli that are lower than this, but these are not true solids; they are either elastomers or foams. Elastomers have a low E because the weak secondary bonds have melted (their glass transition temperature, T_g, is below room temperature), leaving only the very weak "entropic" restoring force associated with tangled, long-chain molecules. Foams have low moduli because the cell walls bend (allowing large displacements) when the material is loaded.

The chart shows that the modulus of engineering materials spans five decades, from 0.01 GPa (0.5 ksi) (low-density foams) to 1000 GPa (1.5×10^5 ksi) (diamond); the density spans a factor of 2000, from less than 0.1 to 20 Mg/m^3 (6 to 1200 lb/ft^3). At the level of precision of interest here (that required to reveal the relationship between the properties of materials classes) the shear modulus, G, by $3E/8$ and the bulk modulus, K, by E, for all materials except for elastomers (for which $G = E/3$ and $K \gg E$), may be approximated so the G-ρ chart and the K-ρ chart both look almost identical to Fig. 2.

The log scales allow more information to be displayed. The velocity of elastic waves in a material, and the natural vibration frequencies of a component made of it, are proportional to $(E/\rho)^{1/2}$; the quantity $(E/\rho)^{1/2}$ itself is the velocity of longitudinal waves in a thin rod of the material. Contours of constant $(E/\rho)^{1/2}$ are plotted on the chart, labeled with the longitudinal wave speed, which varies from less than 50 m/s (160 ft/s) (soft elastomers) to a little more than 10^4 m/s (33,000 ft/s) (fine ceramics). Note that aluminum and glass, because of their low densities, transmit waves quickly despite their low moduli. One might have expected the sound velocity in foams to be low because of the low modulus; however, the low density almost compensates. The sound velocity in wood is low across the grain, but along the grain, it is high--roughly the same as steel--a fact made use of in the design of musical instruments.

The modulus-density chart helps in the common problem of material selection for applications in which weight must be minimized. Guide lines corresponding to three common geometries of loading are drawn on the diagram; they correspond to the three indices for stiffness-limited minimum-weight design listed in Table 5(a) in the article "Performance Indices" in this Volume, in which their use in selecting materials is explained.

The Strength-Density Chart (Fig. 3). The modulus of a solid is a well-defined quantity with a sharp value. The strength is not. The word "strength" needs definition. For metals and polymers, it is the yield strength, but because the range of materials includes those that have been worked, the range extends from initial yield to ultimate strength; for most practical purposes it is the same in tension and compression. For brittle ceramics, it is the crushing strength in compression, not that in tension which is about 15 times smaller; the envelopes for brittle materials are shown as broken lines as a reminder of this. For elastomers, strength means the tear strength. For composites, it is the tensile failure strength (the compressive strength can be less, because of fiber buckling).

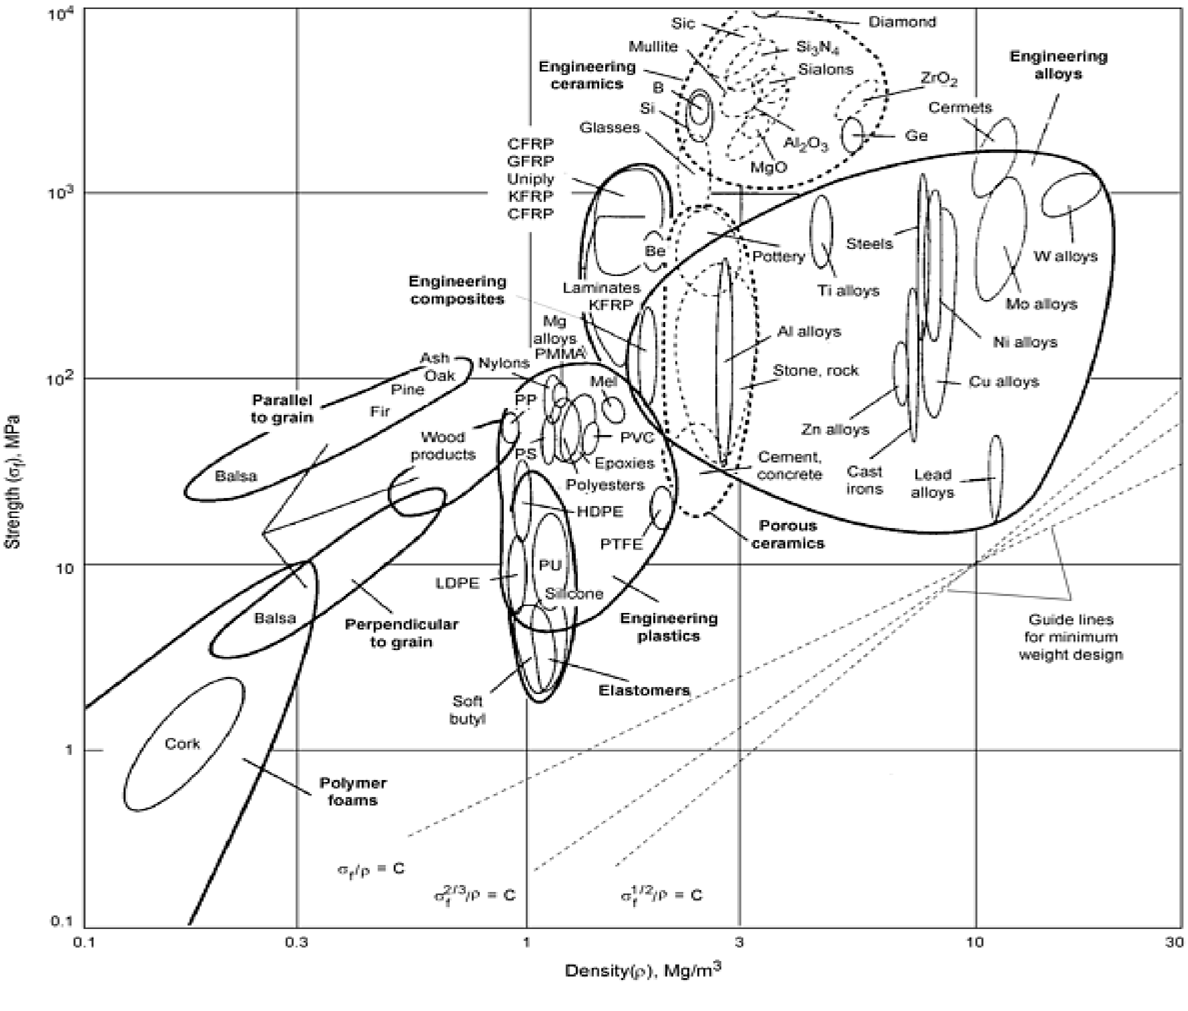

Fig. 3 Strength, σ_f, plotted against density, ρ, for various engineered materials. Strength is yield strength for metals and polymers, compressive strength for ceramics, tear strength for elastomers, and tensile strength for composites. The guide lines of constant σ_f/ρ, $\sigma_f^{2/3}/\rho$, and $\sigma_f^{1/2}/\rho$ are used in minimum weight, yield-limited,

design.

Figure 3 shows these strengths, using the symbol σ_f despite the different failure mechanisms involved, plotted against density, ρ. The considerable vertical extension of the strength bubble for an individual material reflects its wide range, caused by degree of alloying, work hardening, grain size, porosity, and so forth. As before, members of a class cluster together and can be enclosed in an envelope (heavy line). Each envelope occupies a characteristic area of the chart.

The range of strengths for engineering materials, like that of their moduli, spans about five decades: from less than 0.1 MPa (15 psi) (foams, used in packaging and energy-absorbing systems) to 104 MPa (1500 ksi) (the strength of diamond, exploited in the diamond-anvil press). The single most important concept in understanding this wide range is that of the lattice resistance or Peierls stress, which is the intrinsic resistance of the structure to plastic shear. Plastic shear in a crystal involves the motion of dislocations. Metals are soft because the nonlocalized metallic bond does little to prevent dislocation motion, whereas ceramics are hard because their more localized covalent and ionic bonds, which must be broken and reformed when the structure is sheared, lock the dislocations in place. In noncrystalline solids, on the other hand, the energy is associated with the unit step of the flow process: the relative slippage of two segments of a polymer chain, or the shear of a small molecular cluster in a glass network. Their strength has the same origin as that underlying the lattice resistance: if the unit step involves breaking strong bonds (as in an inorganic glass), the materials will be strong; if it only involves the rupture of weak bonds (the Van der Waals bonds in polymers for example), it will be weak. Materials that fail by fracture do so because the lattice resistance or its amorphous equivalent is so large that fracture happens first.

When the lattice resistance is low, the material can be strengthened by introducing obstacles to slip: in metals, by adding alloying elements, particles, grain boundaries, and even other dislocations ("work hardening"); and in polymers by cross-linking or by orienting the chains so that strong covalent as well as weak Van der Waals bonds are broken. When, on the other hand, the lattice resistance is high, further hardening is superfluous--the problem becomes that of suppressing fracture (see the Section "The Fracture Toughness-Density Chart" in this article).

An important use of the strength-density chart is in materials selection in lightweight plastic design. The guide lines performance indices (Table 5b in the article "Performance Indices," which follows in this Section of the Handbook) for materials selection in the minimum-weight design of ties, columns, beams, and plates, and for yield-limited design of moving components in which inertial forces are important.

Aspects of fatigue--the endurance limit, for example--can be displayed in a similar way. Charts relating to fatigue can be found in Ref 41.

The Fracture Toughness-Density Chart (Fig. 4). Increasing the plastic strength of a material is useful only as long as it remains plastic and does not fail by fast fracture. The resistance to the propagation of a crack is measured by the fracture toughness, K_{Ic}. It is plotted against density in Fig. 4. The range is large: from 0.01 to over 100 MPa$\sqrt{m}$ (0.01 to 100 ksi$\sqrt{in.}$). At the lower end of this range are brittle materials that, when loaded, remain elastic until they fracture. For these, linear elastic fracture mechanics works well, and the fracture toughness itself is a well-defined property. At the upper end lie the supertough materials, all of which show substantial plasticity before they break. For these the values of K_{Ic} are approximate, derived from critical J-integral (J_c) and critical crack-opening displacement (δ_c) measurements (by writing $K_{Ic} = (EJ_c)^{1/2}$, for instance). They are helpful in providing a ranking of materials, but must be used as an indicator only. Guide lines for minimum weight design are based on the indices listed in Table 5(e) in the article "Performance Indices," which follows in this Section of the Handbook. The figure shows one reason for the dominance of metals in engineering; they almost all have values of K_{Ic} above 20 MPa$\sqrt{m}$ (20 ksi$\sqrt{in.}$), a value often quoted as a minimum for conventional design.

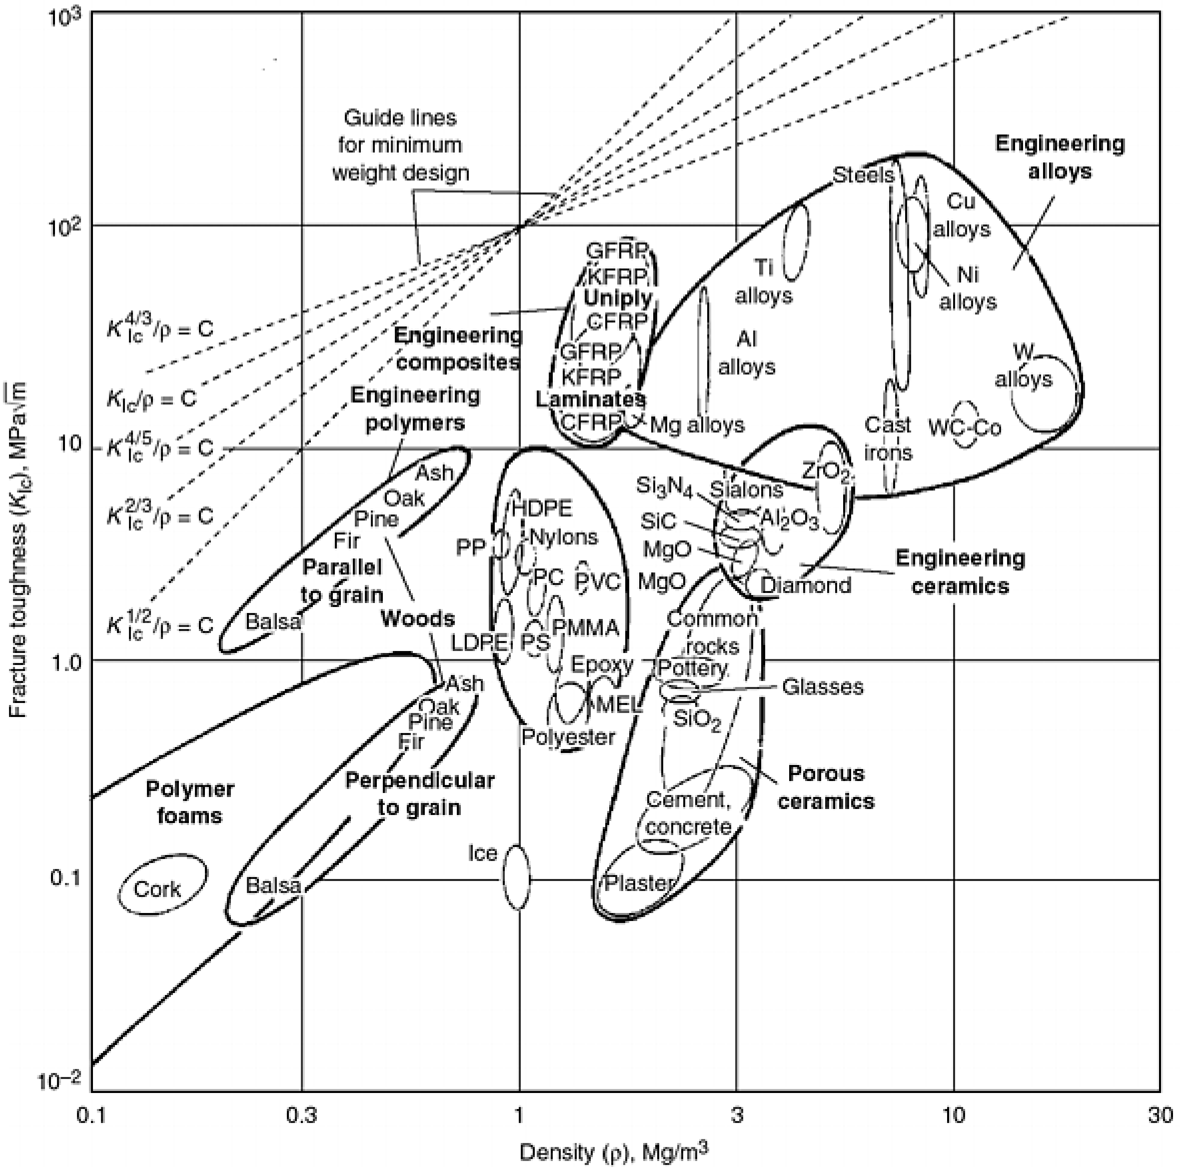

Fig. 4 Fracture toughness, K_{Ic}, plotted against density, ρ. The guide lines of constant K_{Ic}, $K_{Ic}^{2/3}/\rho$, and $K_{Ic}^{1/2}/\rho$, and so forth, help in minimum weight, fracture-limited design. Data for K_{Ic} are valid below 10 MPa$\sqrt{m}$; data above 10 MPa$\sqrt{m}$ are for ranking only.

The Modulus-Strength Chart (Fig. 5). High tensile steel makes good springs. But so does rubber. How is it that two such different materials are both suited for the same task? This and other questions are answered by Fig. 5, the most useful of all the charts.

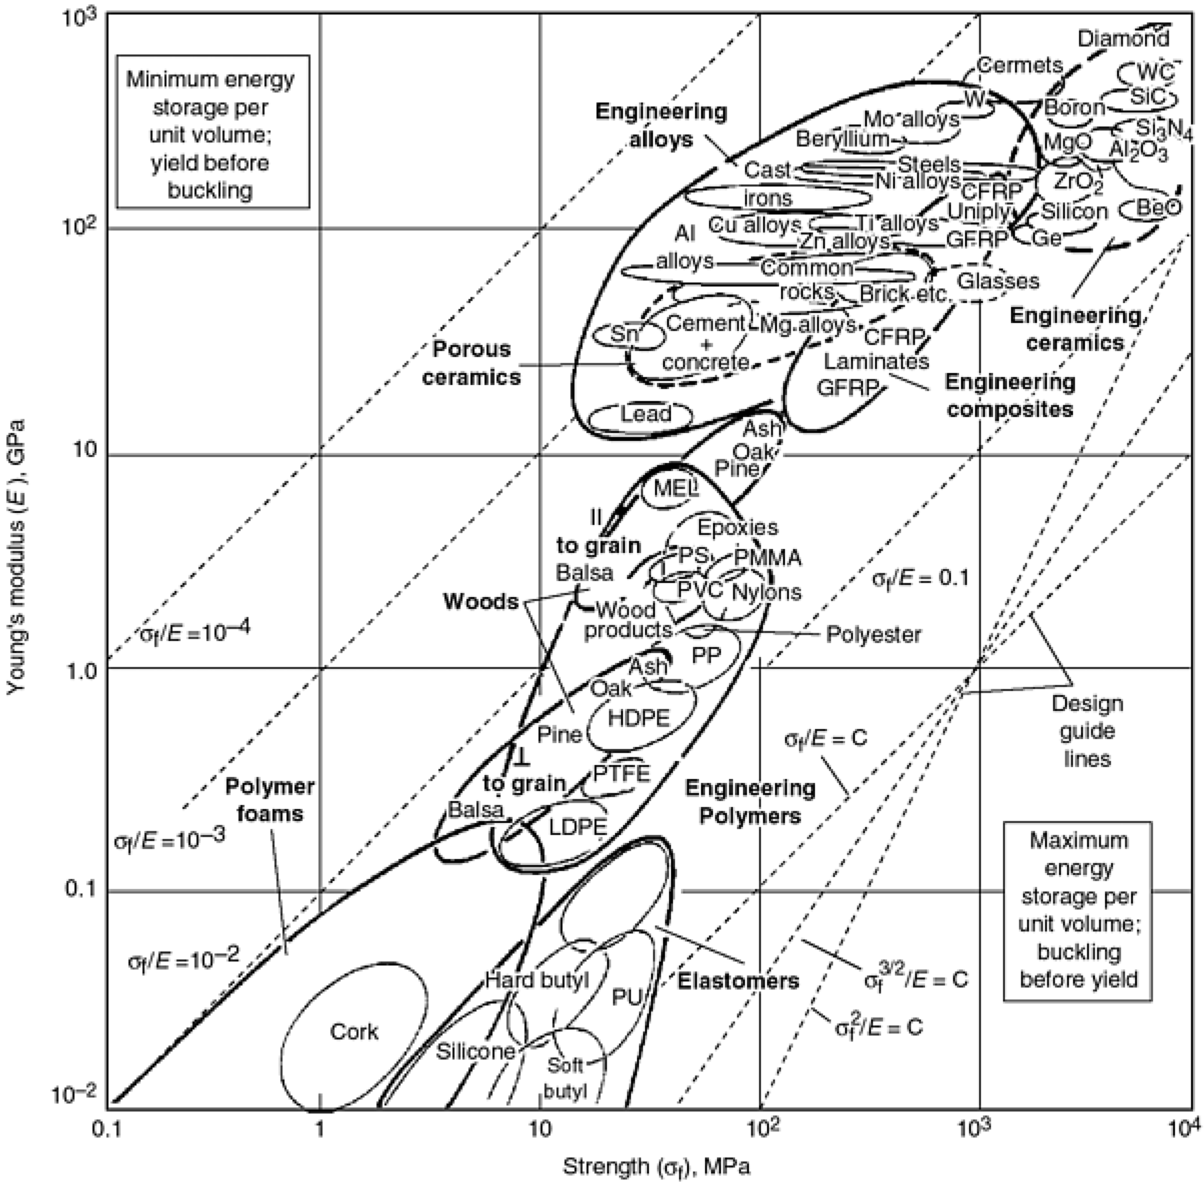

Fig. 5 Young's modulus, *E*, plotted against strength, σ_f, for various engineered materials. Strength is yield strength for metals and polymers, compressive strength for ceramics, tear strength for elastomers, and tensile strength for composites. The design guide lines help with the selection of materials for springs, pivots, knife edges, diaphragms, and hinges.

It shows Young's modulus, *E*, plotted against strength, σ_f. The qualifications on "strength" are the same as before: yield strength for metals and polymers, compressive crushing strength for ceramics, tear strength for elastomers, and tensile strength for composites and woods; the symbol σ_f is used for them all. The ranges of the variables, too, are the same. Contours of normalized strength, σ_f/E, appear as a family of straight parallel lines.

Examine these first. Engineering polymers have normalized strengths between 0.01 and 0.1. In this sense they are remarkably strong; the values for metals are at least a factor of 10 smaller. Even ceramics, in compression, are not as strong, and in tension they are far weaker (by a further factor of 15 of so). Composites and woods lie on the 0.01 contour, as good as the best metals. Elastomers, because of their exceptionally low moduli, have values of σ_f/E larger than any other class of material: 0.1 to 10.

The distance over which interatomic forces act is small--a bond is broken if it is stretched to more than about 10% of its original length. So the force needed to break a bond is roughly

$$F = \frac{S r_o}{10} \qquad \textbf{(Eq 3)}$$

where *S*, as before, is the bond stiffness. If shear breaks bonds, the strength of a solid should be roughly

$$\sigma_y \approx \frac{F}{r_o^2} = \frac{S}{10 r_o} = \frac{E}{10} \qquad \textbf{(Eq 4)}$$

The chart shows that for some polymers it is. Most solids are weaker, for two reasons.

First, nonlocalized bonds (those in which the cohesive energy derives from the interaction of one atom with large number of others, not just with its nearest neighbors) are not broken when the structure is sheared. The metallic bond, and the ionic bond for certain directions of shear, are like this; very pure metals, for example, yield at stresses as low as *E*/10,000, and strengthening mechanisms are needed to make them useful in engineering. The covalent bond ***is*** localized, and for this reason covalent solids have yield strengths which, at low temperatures, are as high as *E*/10. It is hard to measure them (though it can sometimes be done by indentation) because of the second reason for weakness: They generally contain defects--concentrators of stress--from which shear or fracture can propagate, often at stresses well below the "ideal" *E*/10. Elastomers are anomalous (they have strengths of about *E*) because the modulus does not derive from bond stretching, but from the change in entropy of the tangled molecular chains when the material is deformed.

The performance index for selecting materials for springs (Table 5c in the article "Performance Indices," which follows in this Section of the Handbook) is

$$M = \frac{\sigma_f^2}{E}$$

A guide line for this index is shown on the chart. Using it in the way explained in the article "Performance Indices" reveals that elastomers, high-strength steels, and glass-fiber-reinforced polymer (GFRP) all make good springs.

Equivalent charts for the endurance limit can be found in Ref 41.

The Specific Stiffness-Specific Strength Chart (Fig. 6). Many designs--particularly those for things that move--call for stiffness and strength at minimum weight. To help with this, the data of the modulus-strength chart (Fig. 5) are replotted in Fig. 6 after dividing, for each material, by the density; it shows E/ρ plotted against σ_f/ρ.

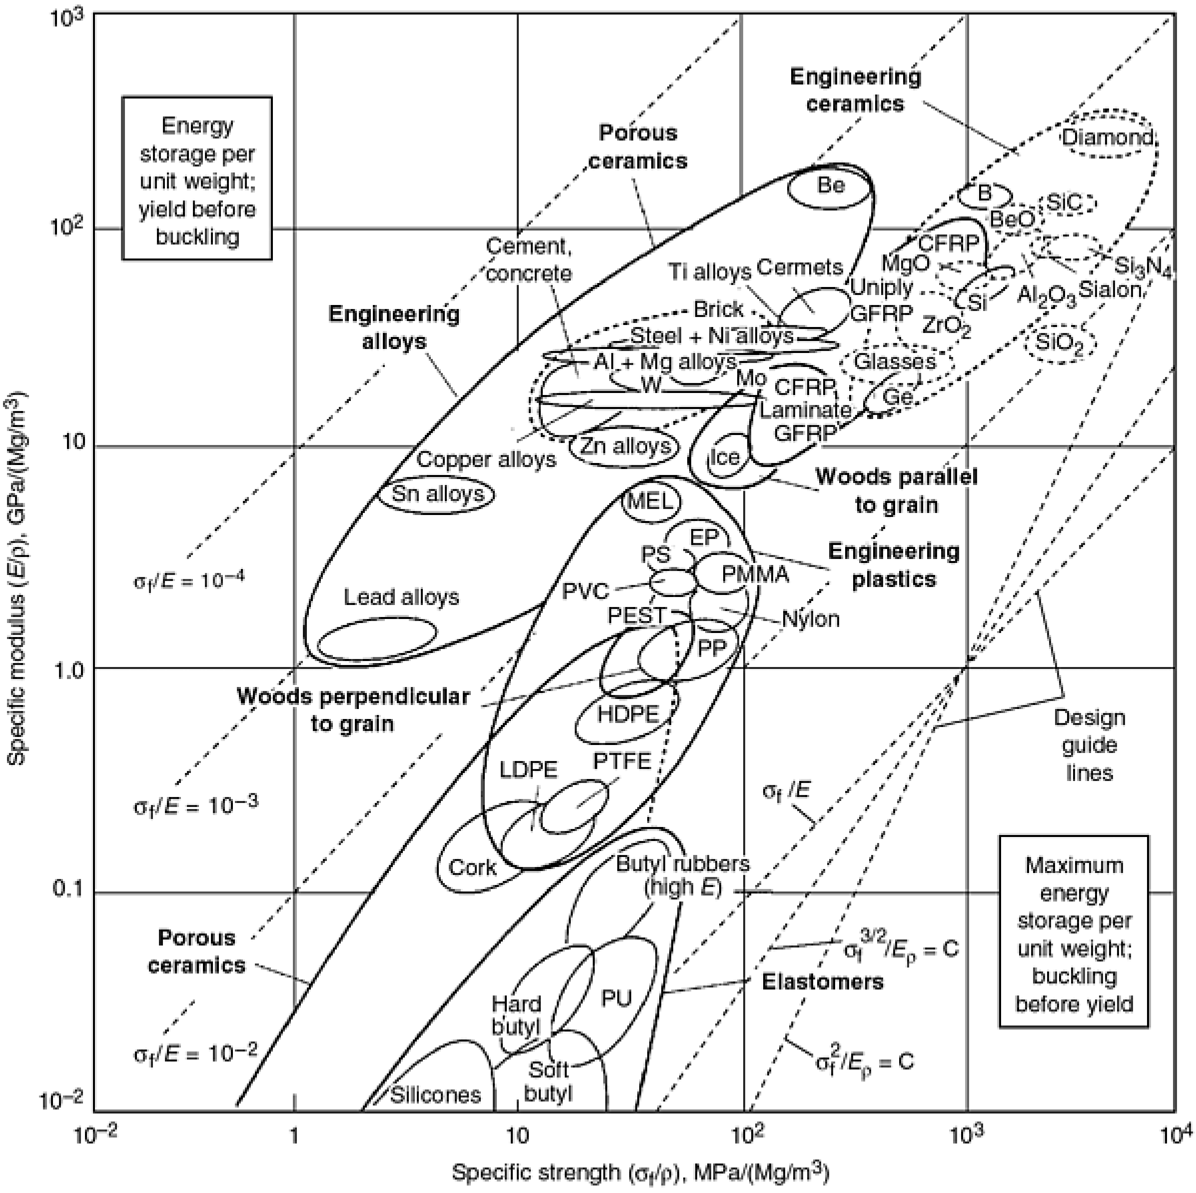

Fig. 6 Specific modulus, E/ρ, plotted against specific strength σ_f/ρ for various engineered materials. Strength is yield strength for metals and polymers, compressive strength for ceramics, tear strength for elastomers, and tensile strength for composites. The design guide lines help with the selection of materials for lightweight springs and energy-storage systems.

Ceramics lie at the top right: they have exceptionally high stiffness and strength per unit weight. The same restrictions on strength apply as before. The data shown here are for compression strengths; the tensile strengths are about 15 times smaller. Composites then emerge as the material class with the most attractive specific properties, one of the reasons for their increasing use in aerospace. Metals are penalized because of their relatively high densities. Polymers, because their densities are low, are favored.

The chart has application in selecting materials for light springs and energy-storage devices (Table 5c in the article "Performance Indices," which follows in this Section of the Handbook). Equivalent charts for the endurance limit are contained in Ref 41.

The Fracture Toughness-Modulus Chart (Fig. 7). As a general rule, the fracture toughness of polymers is less than that of ceramics. Yet polymers are widely used in engineering structures; ceramics, because they are "brittle," are treated with much more caution. Figure 7 helps resolve this apparent contradiction. It shows the fracture toughness, K_{Ic},

plotted against Young's modulus, *E*. The restrictions described earlier apply to the values of K_{Ic}: When small, they are well defined; when large, they are useful only as a ranking for material selection.

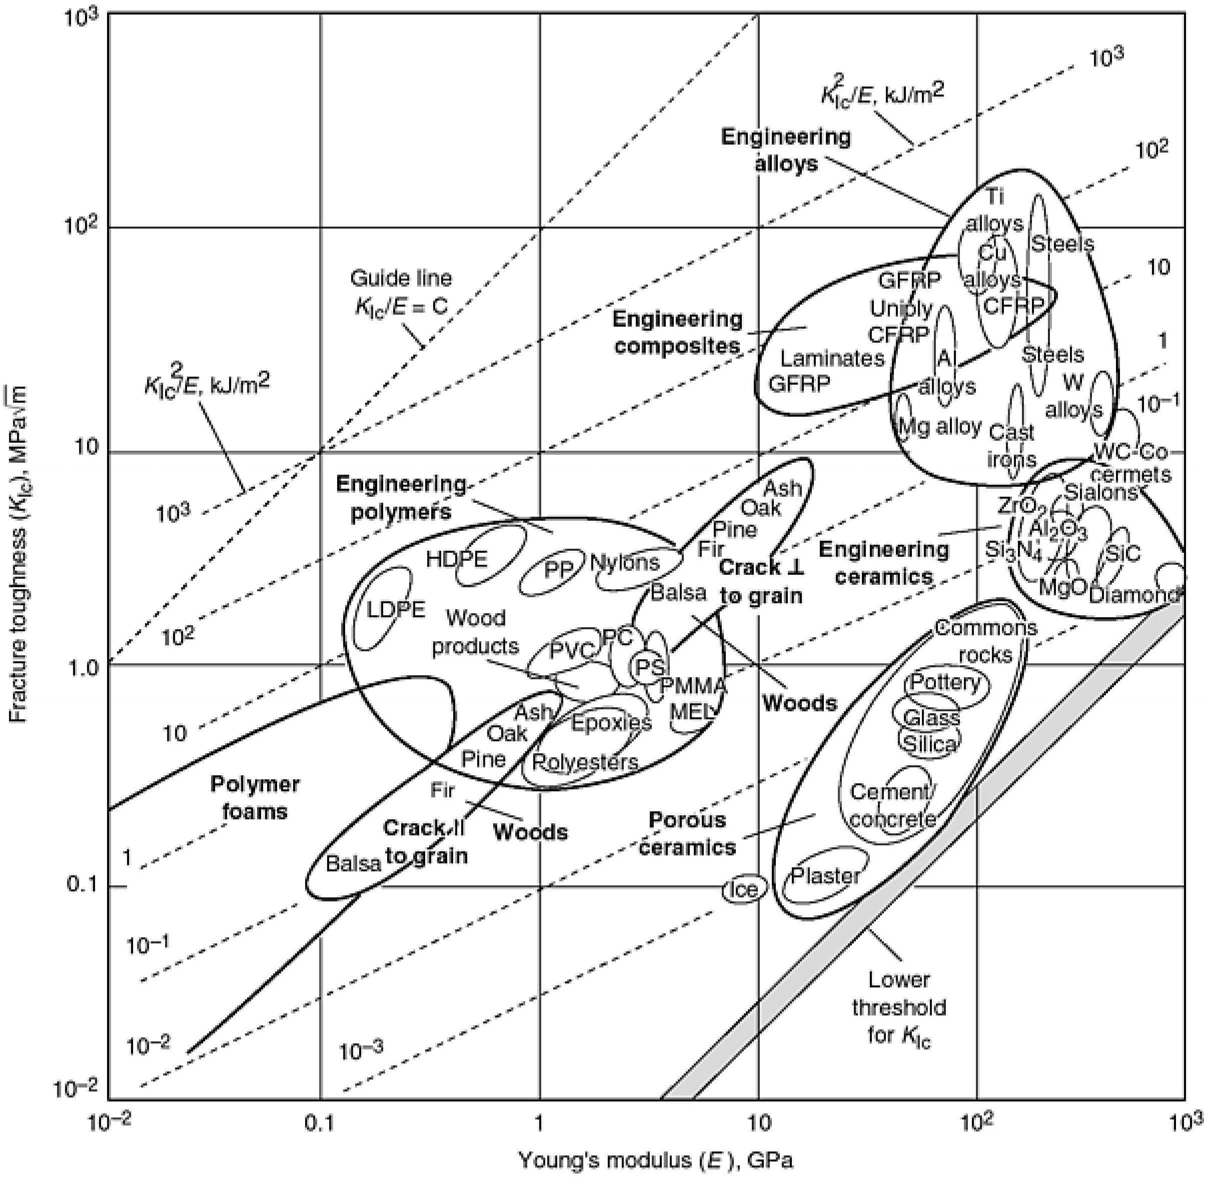

Fig. 7 Fracture toughness, K_{Ic}, plotted against Young's modulus, *E*. The family of lines are of constant K_{Ic}^2/E (approximately G_{Ic}, the fracture energy). These, and the guide line of constant K_{Ic}/E, help in design against fracture. The shaded band shows the "necessary condition" for fracture. Fracture can, in fact, occur below this limit under conditions of corrosion, or cyclic loading.

Consider first the question of the necessary condition for fracture. It is that sufficient external work be done, or elastic energy released, to supply the surface energy (2γ per unit area) of the two new surfaces that are created. This is written as:

$$G \geq 2\gamma \quad \textbf{(Eq 5)}$$

where *G* is the elastic energy release rate. Using the standard relation $K \sim (EG)^{1/2}$ between *G* and stress intensity *K*, then

$$K \geq (2E\gamma)^{1/2} \quad \textbf{(Eq 6)}$$

Now the surface energies, γ, of solid materials scale as their moduli; to an adequate approximation $\gamma = Er_o/20$, where r_o is the atom size, giving

$$K \geq E\left(\frac{r_o}{20}\right)^{1/2} \qquad \textbf{(Eq 7)}$$

The right-hand side of this equation is identified with a lower-limiting value of K_{Ic}, when, taking r_o as 2×10^{-10} m (8×10^{-9} in.),

$$\frac{(K_{Ic})_{min}}{E} = \left(\frac{r_o}{20}\right)^{1/2} \approx 3 \times 10^{-6}\sqrt{m}\ (2 \times 10^{-5}\sqrt{in.}) \qquad \textbf{(Eq 8)}$$

This criterion is plotted on the chart as a shaded, diagonal band near the lower right corner (the width of the band reflects a realistic range of r_o and of the constant C in $\gamma = r_o/C$). It defines a lower limit on values of K_{Ic}: It cannot be less than this unless some other source of energy (such as a chemical reaction, or the release of elastic energy stored in the special dislocation structures caused by fatigue loading) is available, when it is given a new symbol such as $(K_{Ic})_{scc}$. Note that the most brittle ceramics lie close to the threshold; when they fracture, the energy absorbed is only slightly more than the surface energy. When metals, polymers, and composites fracture, the energy absorbed is vastly greater, usually because of plasticity associated with crack propagation. This is discussed in the following Section of this article.

Plotted on Fig. 7 are contours of toughness, G_{Ic}, a measure of the apparent fracture surface energy ($G_{Ic} \approx K^2_{Ic}/E$). The true surface energies, γ, of solids lie in the range 10^{-4} to 10^{-3} kJ/m^2 (10^{-2} to 10^{-1} ft · lbf/ft^2). The diagram shows that the values of the toughness start at 10^{-3} kJ/m^2 (10^{-1} ft · lbf/ft^2) and range through almost six decades to 10^3 kJ/m^2 (10^5 ft · lbf/ft^2). On this scale, ceramics (10^{-3} to 10^{-1} kJ/m^2, or 10^{-2} to 10 ft · lbf/ft^2) are much lower than polymers (10^{-1} to 10 kJ/m^2, or 10 to 1000 ft · lbf/ft^2); this is part of the reason polymers are more widely used in engineering than ceramics.

The Fracture Toughness-Strength Chart (Fig. 8). The stress concentration at the tip of a crack generates a process zone: a plastic zone in ductile solids, a zone of microcracking in ceramics, a zone of delamination, debonding, and fiber pullout in composites. Within the process zone, work is done against plastic and frictional forces; it is this that accounts for the difference between the measured fracture energy G_{Ic} and the true surface energy 2γ. The amount of energy dissipated must scale roughly with the strength of the material, with the process zone, and with its size, d_y. This size is found by equating the stress field of the crack ($\sigma = K/\sqrt{2\pi r}$) at $r = d_y/2$ to the strength of the material, σ_f, giving

$$d_y = \frac{K^2_{Ic}}{\pi \sigma^2_f} \qquad \textbf{(Eq 9)}$$

Figure 8 (fracture toughness versus strength) shows that the size of the zone, d_y (broken lines) varies enormously, from atomic dimensions for very brittle ceramics and glasses to almost 1 meter for the most ductile of metals. At a constant zone size, fracture toughness tends to increase with strength (as expected); it is this that causes the data plotted in Fig. 8 to be clustered around the diagonal of the chart.

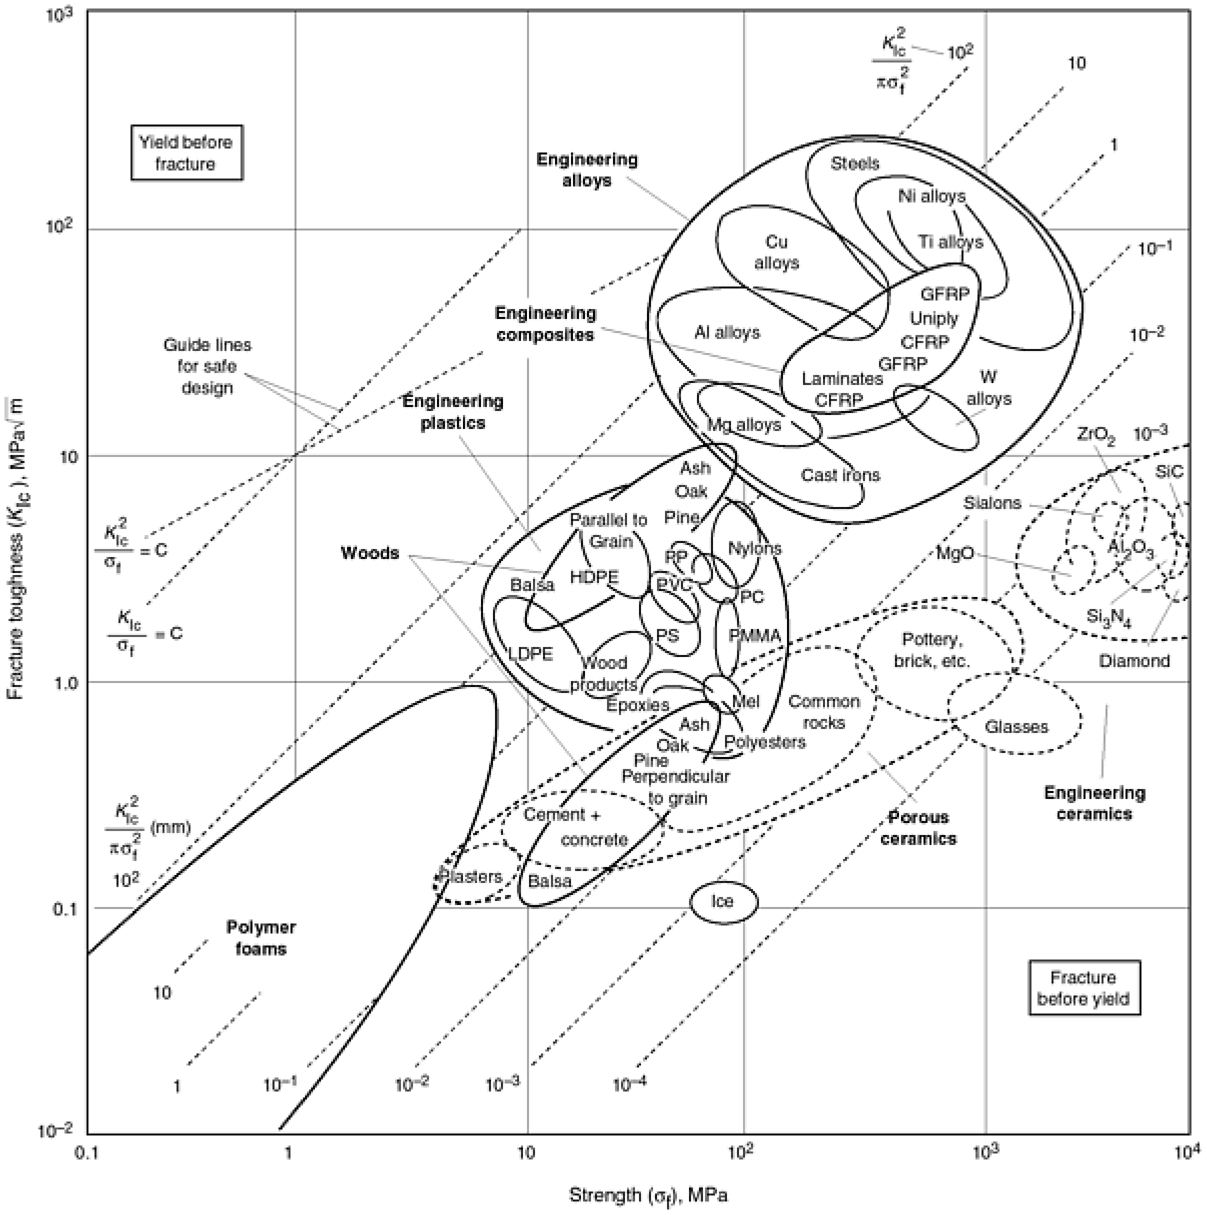

Fig. 8 Fracture toughness, K_{Ic}, plotted against strength, σ_f, for various engineered materials. Strength is yield strength for metals and polymers, compressive strength for ceramics and glasses, and tensile strength for composites. The contours show the value of $K_{Ic}^2/\pi\sigma_f$--roughly, the diameter of the process-zone at a crack tip. The design guide lines are used in selecting materials for damage-tolerant design.

The fracture toughness-strength diagram has application in selecting materials for the safe design of load-bearing structures using the indices described in Table 5(e) in the article "Performance Indices," which follows in this Section of the Handbook.

The Loss Coefficient-Modulus Chart (Fig. 9). Bells are traditionally made of bronze. They can be (and sometimes are) made of glass; and they could (if one could afford it) be made of silicon carbide. Metals, glasses, and ceramics all, under the right circumstances, have low intrinsic damping or "internal friction," an important material property when structures vibrate. Intrinsic damping is measured by the loss coefficient, η, which is plotted in Fig. 9.

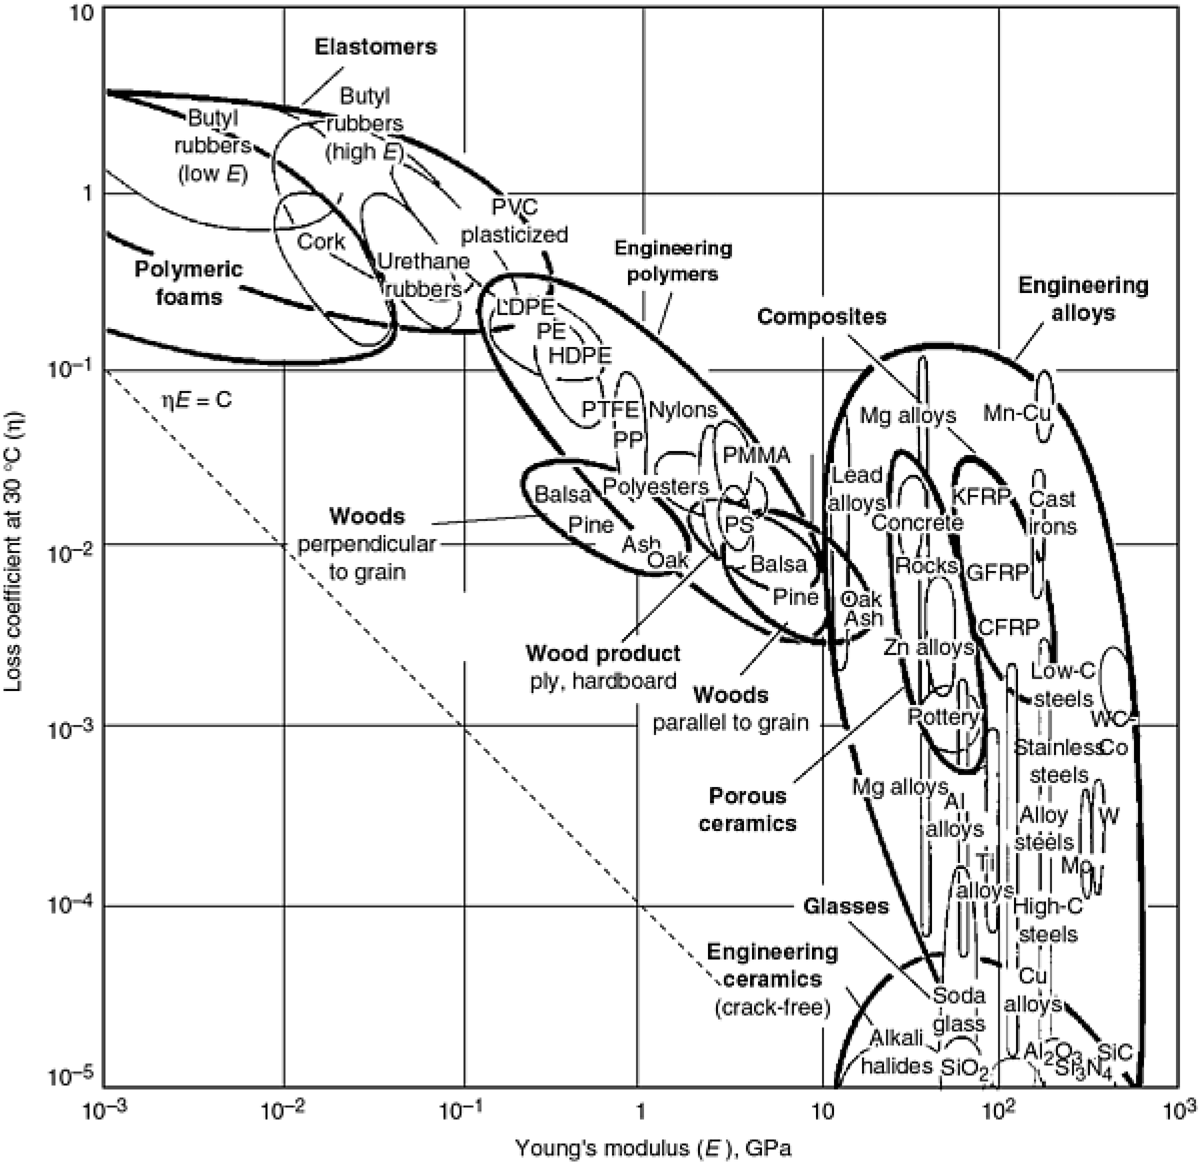

Fig. 9 The loss coefficient, η, plotted against Young's modulus, *E*, for various engineered materials. The guide line corresponds to the condition $\eta = C/E$.

The loss coefficient, a dimensionless number, measures the degree to which a material dissipates vibrational energy. If a material is loaded elastically to a stress σ_{max}, it stores an elastic energy

$$U = \int_0^{\sigma_{max}} \sigma d\varepsilon = \frac{1}{2}\frac{\sigma_{max}^2}{E}$$

per unit volume. If it is loaded and then unloaded, it dissipates an energy

$$\Delta U = \int \sigma d\varepsilon$$

The loss coefficient is

$$\eta = \frac{\Delta U}{2 \pi U}$$

The cycle can be applied in many different ways--some fast, some slow. The value of η usually depends on the time scale or frequency of cycling. Other measures of damping include the specific damping capacity, $D = (\Delta U)/U$; the log decrement, Δ (the log of the ratio of successive amplitudes of natural vibrations); the phase lag, δ, between stress and strain; and the "*Q*"-factor or resonance factor, *Q*. When damping is small ($\eta < 0.01$), these measures are related by

$$\eta = \frac{D}{2 \pi} = \frac{\Delta}{\pi} = \tan \delta = \frac{1}{Q}$$

but when damping is large, they are no longer equivalent.

There are many mechanisms of intrinsic damping and hysteresis. Some (the "damping" mechanisms) are associated with a process that has a specific time constant; then the energy loss is centered about a characteristic frequency. Others (the "hysteresis" mechanisms) are associated with time-independent mechanisms; they absorb energy at all frequencies.

In metals a large part of the loss is hysteretic, caused by dislocation movement: it is high in soft metals like lead and pure aluminum. Heavily alloyed metals like bronze and high-carbon steels have low loss because the solute pins the dislocations; these are the materials for bells. Exceptionally high loss is found in the manganese-copper alloys, because of a strain-induced martensite transformation, and in magnesium, perhaps because of reversible twinning. The elongated bubbles for metals span the large range accessible by alloying and working. Engineering ceramics have low damping because the enormous lattice resistance pins dislocations in place at room temperature. Porous ceramics, on the other hand, are filled with cracks, the surfaces of which rub, dissipating energy, when the material is loaded; the high damping of some cast irons has a similar origin. In polymers, chain segments slide against each other when loaded; the relative motion dissipates energy. The ease with which they slide depends on the ratio of the temperature (in this case, room temperature) to the glass transition temperature, T_g, of the polymer. When $T/T_g < 1$, the secondary bonds are "frozen"; the modulus is high and the damping is relatively low. When $T/T_g > 1$, the secondary bonds have melted, allowing easy chain slippage; the modulus is low and the damping is high. This accounts for the obvious inverse dependence of η on *E* for polymers in Fig. 9; indeed, to a first approximation,

$$\eta = \frac{4 \times 10^{-2}}{E} \quad \textbf{(Eq 10a)}$$

with *E* in GPa, or

$$\eta = \frac{6}{E} \quad \textbf{(Eq 10b)}$$

with *E* in ksi.

The Thermal Conductivity-Thermal Diffusivity Chart (Fig. 10). The material property governing the flow of heat through a material at steady state is the thermal conductivity, λ (units: W/m · K or Btu/h · ft · F); that governing transient heat flow is the thermal diffusivity, *a* (units: m^2/s or $in.^2/s$). They are related by

$$a = \frac{\lambda}{\rho C_p} \quad \textbf{(Eq 11)}$$

where ρ is the density and C_p the specific heat, measured in J/kg · K; the quantity ρC_p is the volumetric specific heat. Figure 10 relates thermal conductivity, diffusivity, and volumetric specific heat, at room temperature.

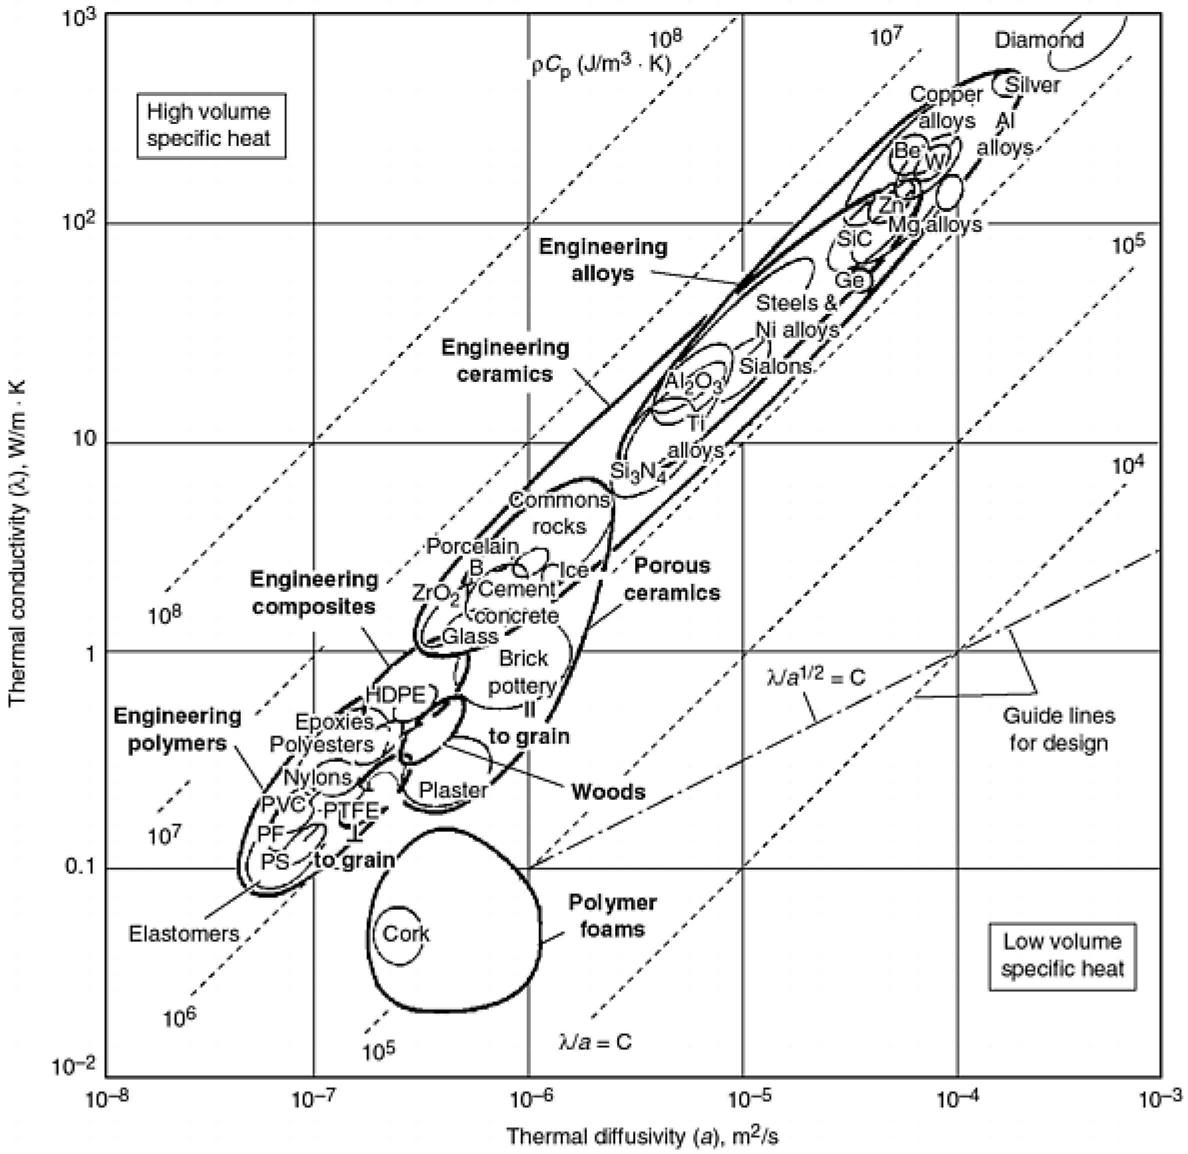

Fig. 10 Thermal conductivity, λ, plotted against thermal diffusivity, *a*. The contours show the volume specific heat, ρC_p. All three properties vary with temperature; the data here are for room temperature.

The data span almost five decades in λ and *a*. The highest conductivities are those of diamond, silver, copper, and aluminum. The lowest are shown by highly porous materials like firebrick, cork, and foams, in which conductivity is limited by that of the gas in their cells.

Solid materials are strung out along the line

$$\rho C_p \approx 3 \times 10^6 \text{ J/m}^3 \cdot \text{K (45 Btu/ft}^3 \cdot \text{F)} \qquad \textbf{(Eq 12)}$$

This can be understood by noting that a solid containing *N* atoms has 3*N* vibrational modes. Each (in the classical approximation) absorbs thermal energy k*T* at the absolute temperature *T*, and the vibrational specific heat is $C_p \sim C_v = 3N\text{k}$ where k is Boltzmann's constant. The volume of *N* atoms is ($N\Omega$) m³, where Ω is the volume per atom; for almost all solids Ω lies within a factor of two of 1.4×10^{-29} m³ (8.5×10^{-25} in.³). The volume specific heat is then (as Fig. 10 shows):

$$\rho C_v \cong 3Nk/N\Omega = \frac{3k}{\Omega} = 3 \times 10^6 \text{ J/m}^3 \cdot \text{K} \; (45 \text{ Btu/ft}^3 \cdot \text{F}) \qquad \text{(Eq 13)}$$

Some materials deviate from this rule: they have lower-than-average volumetric specific heat. For a few, such as diamond, it is low because their Debye temperatures lie well above room temperature; then heat absorption is not classical, some modes do not absorb kT and the specific heat is less than 3Nk. The largest deviations are shown by porous solids: foams, low density firebrick, woods, and so on. Their low density means that they contain fewer atoms per unit volume and, averaged over the volume of the structure, ρC_v is low. The result is that, although foams have low conductivities (and are widely used for insulation because of this), their thermal diffusivities are not necessarily low: They may not transmit much heat, but they reach a steady state quickly, an important consideration in selecting materials for thermal insulation.

The Thermal Expansion-Thermal Conductivity Chart (Fig. 11). Almost all solids expand on heating. The bond between a pair of atoms behaves like a linear elastic spring when the relative displacement of the atoms is small; but when it is large, the spring is nonlinear. Most bonds become stiffer when the atoms are pushed together and less stiff when they are pulled apart, that is, when they are anharmonic. The thermal vibration of atoms, even at room temperature, involves large displacements; as the temperature is raised, the anharmonicity of the bond pushes the atoms apart, increasing their mean spacing. The effect is measured by the linear expansion coefficient

$$\alpha = \frac{1}{l}\frac{dl}{dT} \qquad \text{(Eq 14)}$$

where l is a linear dimension of the body.

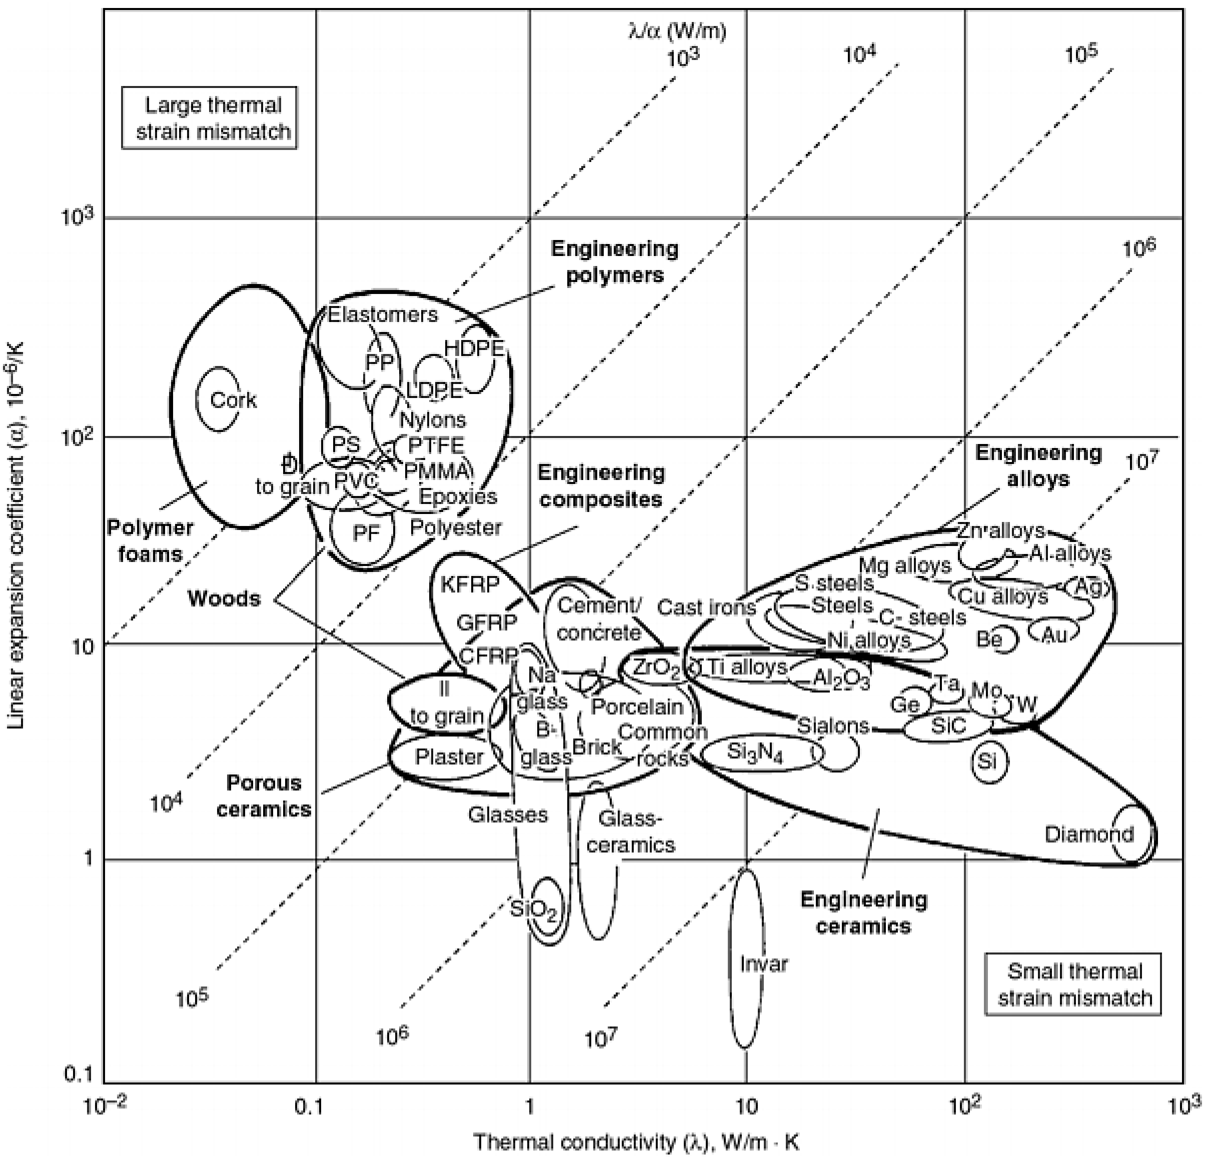

Fig. 11 The linear expansion coefficient, α, plotted against the thermal conductivity, λ. The contours show the thermal distortion parameter λ/α.

The expansion coefficient is plotted against the conductivity in Fig. 11. It shows that polymers have large values of α, roughly 10 times greater than those of metals and almost 100 times greater than those of ceramics. This is because the Van der Waals bonds of the polymer are very anharmonic. Diamond, silicon, and silica (SiO_2) have covalent bonds that have low anharmonicity (that is, they are almost linear-elastic even at large strains), giving them low expansion coefficients. Composites, even though they have polymer matrices, can have low values of αbecause the reinforcing fibers, particularly carbon, expand very little.

The thermal expansion-thermal conductivity chart shows contours of λ/α, a quantity important in designing against thermal distortion.

The Thermal Expansion-Modulus Chart (Fig. 12). Thermal stress is the stress that appears in a body when it is heated or cooled, but prevented from expanding or contracting. It depends on the expansion coefficient, α, of the material and on its modulus, *E*. A development of the theory of thermal expansion leads to the relation

$$\alpha = \frac{\gamma_G \rho C_v}{3E} \qquad \textbf{(Eq 15)}$$

where γ_G is Gruneisen's constant; its value ranges between about 0.4 and 4, but for most solids it is near 1. Since ρC_v is almost constant (Eq 12), the equation shows that α is proportional to 1/*E*. Figure 12 shows that this is so. Diamond, with the highest modulus, has one of the lowest coefficients of expansion; elastomers with the lowest moduli expand the most. Some materials with a low coordination number (silica and some diamond-cubic or zinc-blend structured materials) can absorb energy preferentially in transverse modes, leading to very small (even a negative) value of γ_G and a low expansion coefficient; that is why SiO_2 is exceptional. Others, like Invar, contract as they lose their ferromagnetism when heated through the Curie temperature and, over a narrow range of temperature, they too show near-zero expansion, which is useful in precision equipment and in glass-metal seals.

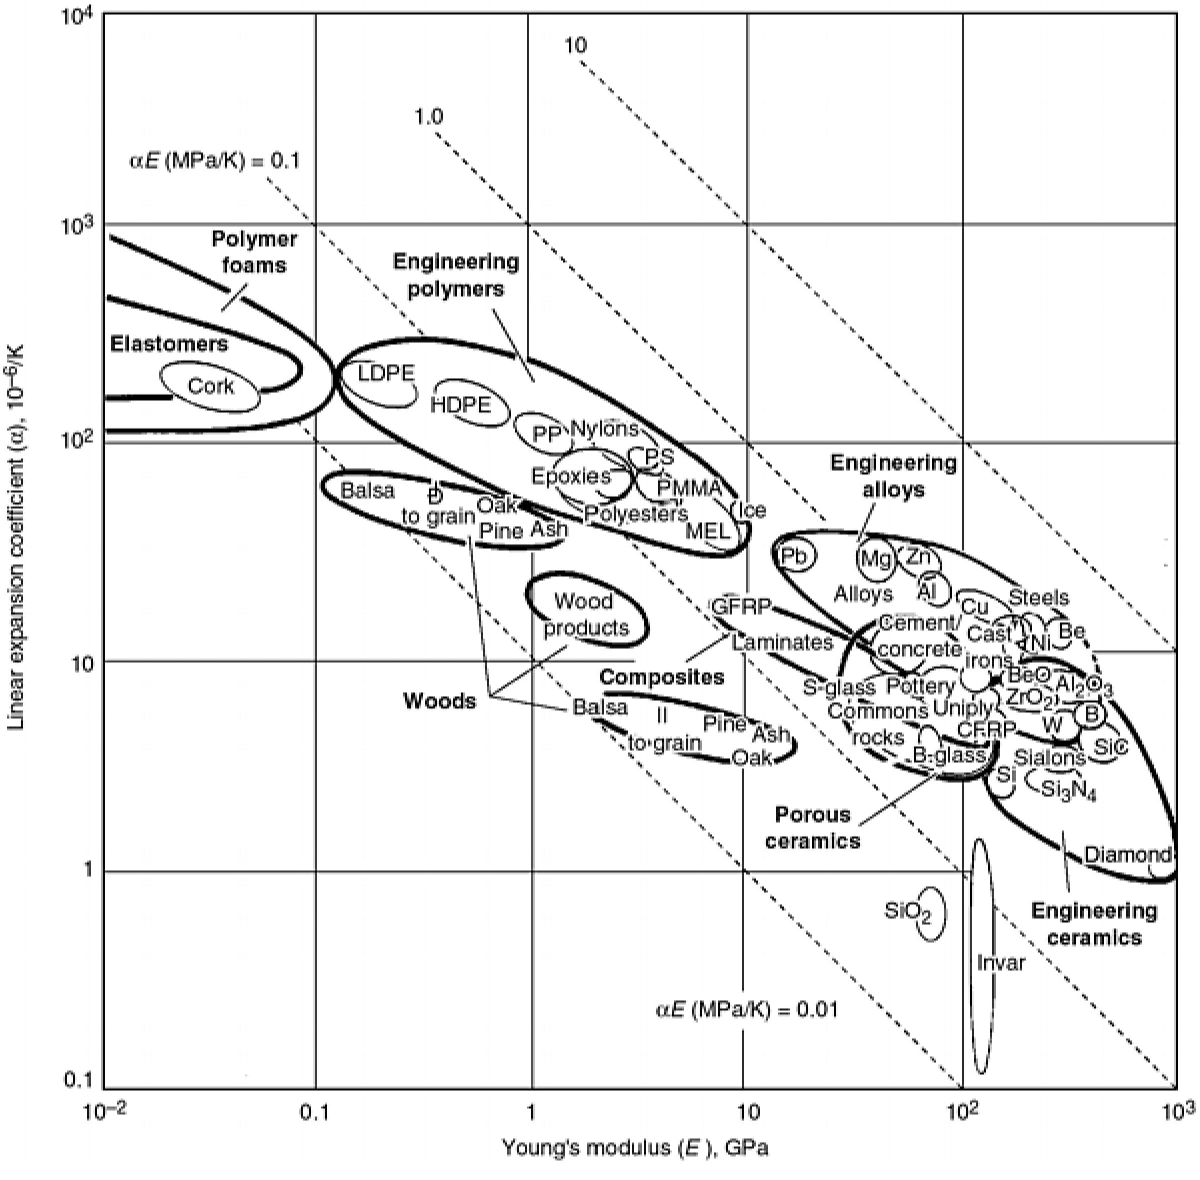

Fig. 12 The linear expansion coefficient, α, plotted against Young's modulus, *E*. The contours show the thermal stress created by a temperature change of 1 °C if the sample is axially constrained. A correction factor *C* is applied for biaxial or triaxial constraint (see text).

One more useful fact: the moduli of materials scale approximately with their melting point, T_m:

$$E \approx \frac{100\,k\,T_m}{\Omega} \qquad \text{(Eq 16)}$$

where k is Boltzmann's constant and Ω the volume-per-atom in the structure. Substituting this and Eq 13 for ρC_v into Eq 15 for α gives

$$\alpha = \frac{\gamma_G}{100\, T_m} \qquad \textbf{(Eq 17)}$$

The expansion coefficient varies inversely with the melting point, or (equivalently stated) for all solids the thermal strain, just before they melt, depends only on γ_G, and this is roughly a constant. The result is useful for estimating and checking expansion coefficients.

Whenever the thermal expansion or contraction of a body is prevented, thermal stresses appear that--if large enough--cause yielding, fracture, or elastic collapse (buckling). It is common to distinguish between thermal stress caused by external constraint (a rod, rigidly clamped at both ends, for example) and that which appears without external constraint because of temperature gradients in the body. All scale as the quantity αE, shown as a set of diagonal contours in Fig. 12. More precisely: the stress $\Delta\sigma$ produced by a temperature change of 1 °C in a constrained system, or the stress per °C caused by a sudden change of surface temperature in one that is not constrained, is given by

$$C\,\Delta\sigma = \alpha E \qquad \textbf{(Eq 18)}$$

where C = 1 for axial constraint, (1 - ν) for biaxial constraint or normal quenching, and (1 - 2ν) for triaxial constraint, where ν is Poisson's ratio. These stresses are large: typically 1 MPa/K; they can cause a material to yield, crack, spall, or buckle when it is suddenly heated or cooled. The resistance of materials to such damage is the subject of the following section.

The Normalized Strength-Thermal Expansion Chart (Fig. 13). The ability of a material to withstand such thermal stress is measured by its thermal shock resistance ΔT_s. It depends on its thermal expansion coefficient, α, and its normalized tensile strength, σ_t/E. They are the axes of Fig. 13, on which contours of constant $\sigma_t/\alpha E$ are plotted. The tensile strength, σ_t, requires definition, just as σ_f did. For brittle solids, it is the tensile fracture strength (roughly equal to the modulus of rupture, or MOR). For ductile metals and polymers, it is the tensile yield strength; for composites it is the stress that first causes permanent damage in the form of delamination, matrix cracking, or fiber debonding.

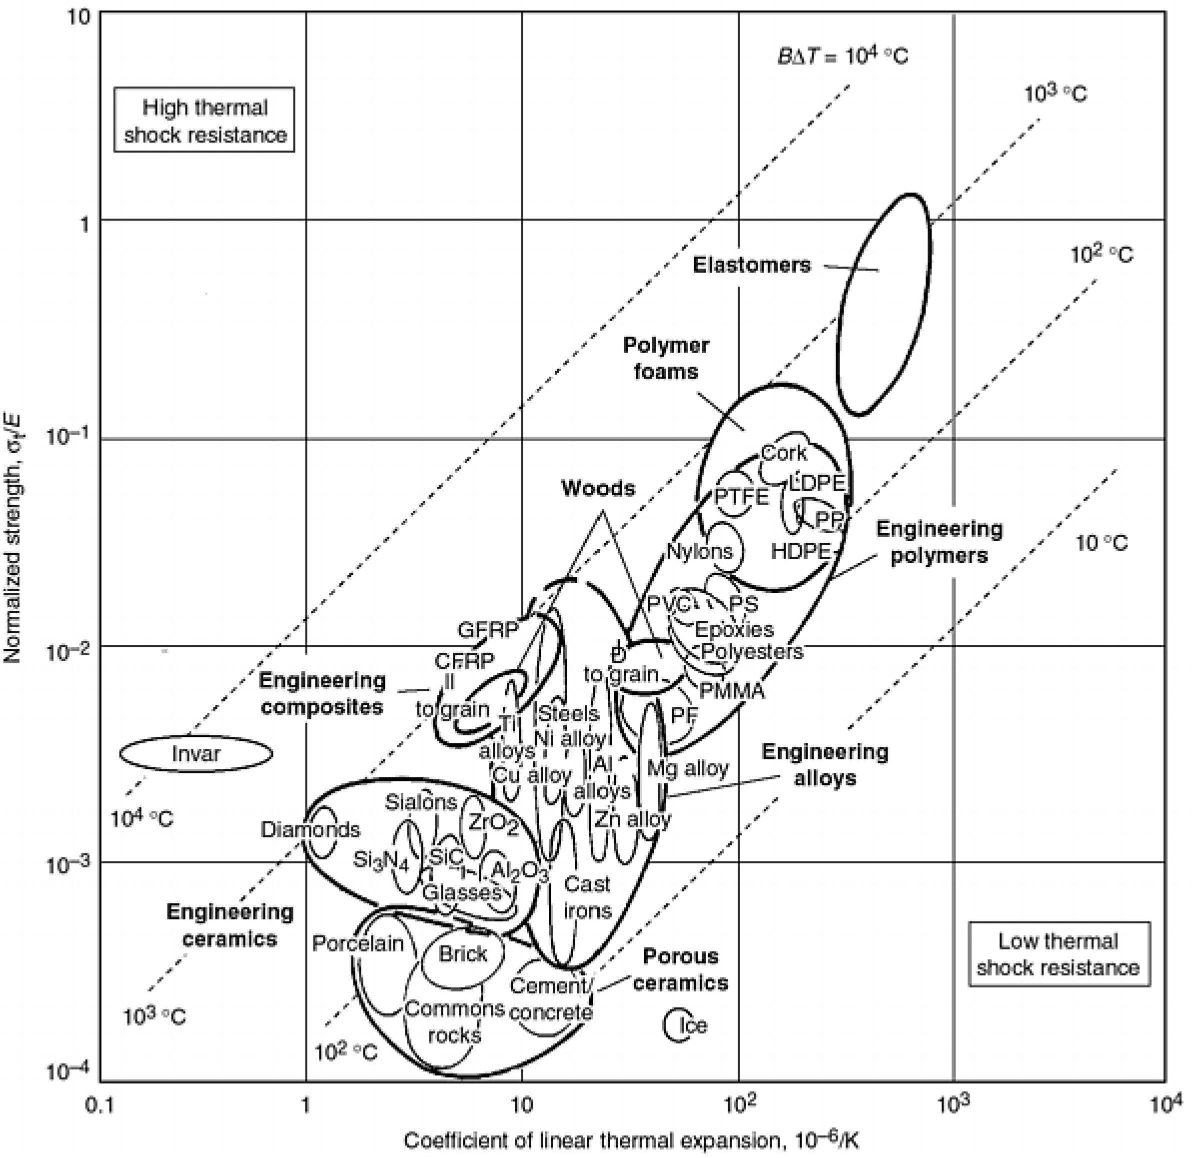

Fig. 13 The normalized tensile strength, σ_t/E, plotted against coefficient of linear thermal expansion, α (see text for strengths). The contours show a measure of the thermal shock resistance, ΔT. Corrections must be applied for constraint and to allow for the effect of thermal conduction during quenching.

To use the chart, note that a temperature change of ΔT, applied to a constrained body--or a sudden change ΔT of the surface temperature of a body that is unconstrained--induces a stress

$$\sigma = \frac{E\alpha\Delta T}{C} \quad \textbf{(Eq 19)}$$

where C was defined in the previous section. If this stress exceeds the local strength σ_t of the material, yielding or cracking results. Even if it does not cause the component to fail, it weakens it. Then a measure of the thermal shock resistance is given by

$$\frac{\Delta T_s}{C} = \frac{\sigma_t}{\alpha E} \quad \textbf{(Eq 20)}$$

This is not quite the whole story. When the constraint is internal, the thermal conductivity of the material becomes important. "Instant" cooling when a body is quenched requires an infinite rate of heat transfer at its surface. Heat transfer

rates are measured by the heat transfer coefficient, *h*, and are never infinite. Water quenching gives a high *h*, and then the values of ΔT_s calculated from Eq 20 give an approximate ranking of thermal shock resistance. However, when heat transfer at the surface is poor and the thermal conductivity of the solid is high (thereby reducing thermal gradients) the thermal stress is less than that given by Eq 20 by a factor *A*, which, to an adequate approximation, is given by

$$A = \frac{th/\lambda}{1 + th/\lambda} \quad \textbf{(Eq 21)}$$

where *t* is a typical dimension of the sample in the direction of heat flow; the quantity th/λ is usually called the Biot modulus. Table 2 gives typical values of *A* for each class using a section size *t* of 10 mm.

Table 2 Values for the factor *A* of Eq 21

Section thickness *t* = 10 mm

Conditions	Foams	Polymers	Ceramics	Metals
Slow air flow (h = 10 W/m^2 · K)	0.75	0.5	3×10^{-2}	3×10^{-3}
Black body radiation 500 to 0 °C (h = 40 W/m^2 · K)	0.93	0.6	0.12	1.3×10^{-2}
Fast air flow ($h = 10^2$ W/m^2 · K)	1	0.75	0.25	3×10^{-2}
Slow water quench ($h = 10^3$ W/m^2 · K)	1	1	0.75	0.23
Fast water quench ($h = 10^4$ W/m^2 · K)	1	1	1	0.1-0.9

The equation defining the thermal shock resistance, ΔT_s, now becomes

$$B\,\Delta T_s = \frac{\sigma_t}{\alpha E} \quad \textbf{(Eq 22)}$$

where $B = C/A$. The contours on the diagram are of $B\,\Delta T$. The table shows that, for rapid quenching, *A* is unity for all materials except the high-conductivity metals, for which the thermal shock resistance is simply read from the contours, with appropriate correction for the constraint (the factor *C*). For slower quenches, ΔT_s is larger by the factor 1/*A*, read from Table 2.

Use of Material Property Charts

The engineering properties of materials are usefully displayed as material selection charts. The charts summarize the information in a compact, easily accessible way, and they show the range of any given property accessible to the designer and identify the material class associated with segments of that range. By choosing the axes in a sensible way, more information can be displayed: A chart of modulus E against density ρ reveals the longitudinal wave velocity $(E/\rho)^{1/2}$; a plot of fracture toughness K_{Ic} against modulus E shows the fracture surface energy G_{Ic}; a diagram of thermal conductivity λ against diffusivity, a, also gives the volume specific heat ρC_v; expansion, α, against normalized strength, σ_t/E, gives thermal shock resistance ΔT_s.

The most striking feature of the charts is the way in which members of a material class cluster together. Despite the wide range of modulus and density associated with metals (as an example), they occupy a field that is distinct from that of polymers, or that of ceramics, or that of composites. The same is true of strength, toughness, thermal conductivity, and the rest: The fields sometimes overlap, but they always have a characteristic place within the whole picture.

The position of the fields and their relationship can be understood in simple physical terms: the nature of the bonding, the packing density, the lattice resistance, and the vibrational modes of the structure (themselves a function of bonding and packing), and so forth. It may seem odd that so little mention has been made of microstructure in determining properties. However, the charts clearly show that the first-order difference between the properties of materials has its origins in the mass of the atoms, the nature of the interatomic forces, and the geometry of packing. Alloying, heat treatment, and mechanical working all influence microstructure and, through this, properties, giving the elongated bubbles shown on many of the charts; yet the magnitude of their effect is less, by factors of 10, than that of bonding and structure.

The charts have numerous applications, among them: data checking, composite design, and identification of applications for new materials (Ref 1). But most important of all, the charts form the basis for a procedure for materials selection. This use is developed further in the following article in this Handbook, "Performance Indices," which contains two case studies to illustrate their use.

Performance Indices

M.F. Ashby, Engineering Design Centre, Cambridge University

Introduction

ANY ENGINEERING COMPONENT has one or more functions: to carry bending moments, to contain a pressure, to transmit heat, and so forth. In designing the component, the designer has an objective: to make it as inexpensive as possible, or as light, or as safe, perhaps. This must be achieved subject to constraints: that the component must carry the given loads without failure, that certain dimensions are fixed, that it can function in a certain range of temperature and in a given environment. Function, objective, and constraints (Table 1) define the boundary conditions for selecting a material and --in the case of load-bearing components--a shape for its cross section.

Table 1 Questions for determining function, objective, and constraints for a component

Function	"What does component do?"
Objective	"What is to be maximized or minimized?"
Constraints	"What nonnegotiable conditions must be met?"

From these are derived material property limits and indices that are the key to optimizing the selection. Property limits are bounding values within which certain properties must lie if the material is to be considered further; typically, these are limits on fracture toughness, on maximum service temperature, or on corrosion resistance in a given environment. Performance indices are groupings of material properties which, if maximized, maximize some aspect of the performance of the component. Some are familiar. The specific stiffness, E/ρ, (where E is Young's modulus and ρ is the density) is an index; materials with exceptionally large values of E/ρ are the best candidates for a light, stiff tie-rod. The specific strength, σ_y/ρ, is another; materials with extreme values of σ_y/ρ are good candidates for a light, strong tie-rod. There are many such indices, each characterizing a particular combination of function, objective, and constraint (Fig. 1). Their derivation (Ref 1, 2, 3, 4, 5) proceeds from a statement of the objective in the form of an objective function, that is, an equation describing the quantity to be maximized or minimized. It contains free variables: parameters of the problem that the designer is free to change, provided the constraints are met. By using the constraint(s) to eliminate the free variable(s), the objective function can be expressed in terms of design-specified quantities and material properties only. The group of material properties is the performance index.

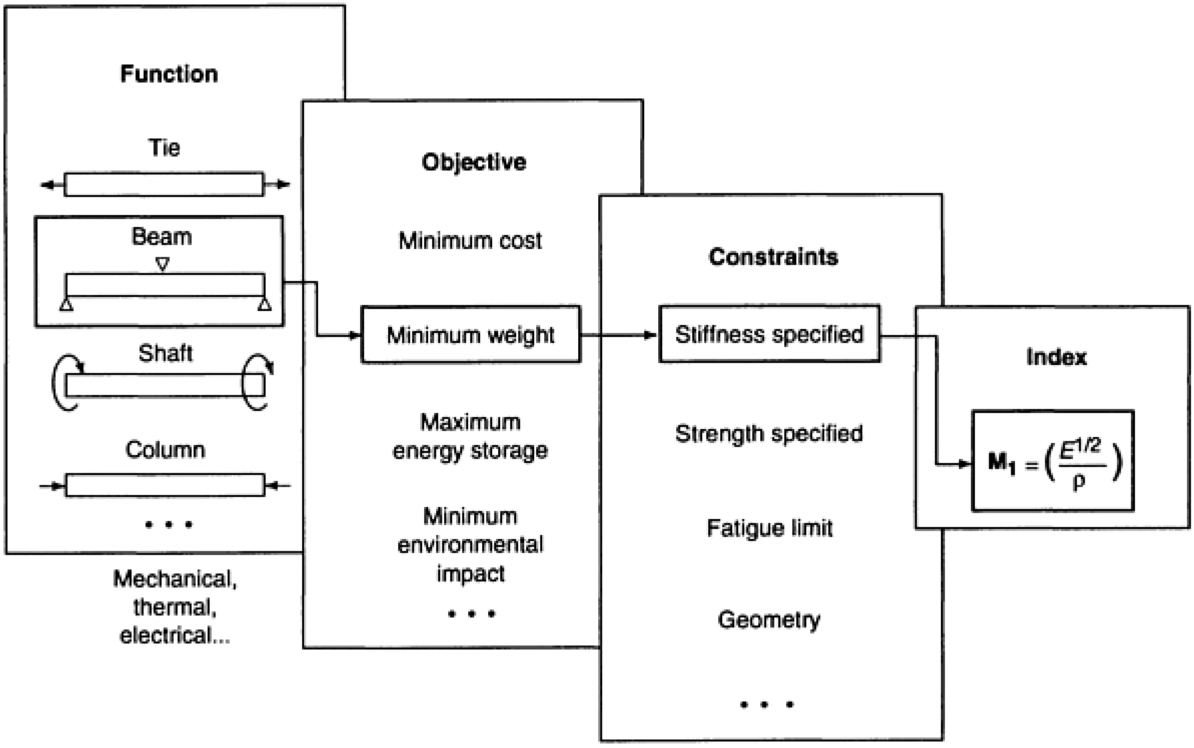

Fig. 1 The specification of function, objective, and constraint leads to a material index, M. The combination highlighted by the boxes leads to the index M - $E^{1/2}/\rho$.

The derivation of indices is described in this article. Their use is illustrated, and a catalog of indices is appended.

Acknowledgements

The charts shown as Fig. 8 and 10 first appeared in Ref 4, where further details about their use can be found.

The author wishes to thank Dr. David Cebon and Dr. P.M. Weaver for helpful discussions. Performance Indices and Material Property Charts

Two concepts are used in the "index-and-chart" selection procedure. The first is that of performance indices, which isolate the combination of material properties and shape information that maximize performance; the second is that of material property charts, described more fully in the article "Material Property Charts" in this Volume.

Development of Performance Indices

This article first defines performance indices in a formal way, then specifies how they are derived. The method is illustrated by two examples, one simple, the other--involving section shape as well as material--somewhat more advanced.

The design of a mechanical component is specified by three groups of variables: the functional requirements **F** (the need to carry loads, transmit heat, etc.); the specifications on geometry, **G**; and some combination **M** of the properties p of the material of which it is made (Ref 1 and 2). The performance **P** of the component can be described by an equation with the form

$$\mathbf{P} = f(\mathbf{F}, \mathbf{G}, p) \qquad \textbf{(Eq 1)}$$

where **P** is the quantity for which a maximum or minimum is sought (the mass of the component, or its volume, or cost, or life for example) and f means "a function of." Optimum design can be considered to be selection of the material and geometry that maximize (or minimize) **P**. This optimization is subject to constraints, some of them imposed by the material properties.

The three groups of parameters in Eq 1 are said to be "separable" when the equation can be written

$$\mathbf{P} = f_1(\mathbf{F}) \cdot f_2(\mathbf{G}) \cdot f_3(p) \qquad \textbf{(Eq 2)}$$

where f_1, f_2, and f_3 are functions. When the groups are separable, as they usually are, the optimum choice of material becomes independent of the many of the details of the design: it is the same for all geometries **G** and all values of the functional requirements **F**. Then the optimum material can be identified without solving the complete design problem, or even knowing all the details of **F** and **G**. This enables enormous simplification: the performance for all **F** and **G** is maximized by maximizing $\mathbf{M} = f_3(p)$, which is called the "merit index," or, better, "performance index."

The steps in deriving an index, shown schematically in Fig. 1, are as follows.

Step 1: Identify the *primary function* of the component for which a material is sought. A beam carries bending moments; a heat-exchanger tube transmits heat; a spring stores elastic energy.

Step 2: Write down an equation for the *objective;* it is called the "objective function." The objective is the first and most important quantity to be minimized or maximized. Commonly, it is weight or cost; but it could be energy stored per unit volume or per unit weight (a spring, a flywheel), or depth of dive (a submarine), or energy dissipated in i^2R heating (a bus bar)--it depends on the application.

Step 3: Identify the *constraints.* They are design requirements that must be met and which therefore limit the optimization process of step 2. Commonly these are: a required value for the stiffness S; a required value for the safe load F, moment M, torque T, or pressure p that can be supported; a limit on operating temperature T_{max}; or on resistance to sudden fracture, measured by the fracture toughness K_{Ic}.

It is essential to distinguish between objectives and constraints, and this requires a little thought. For example, in the performance-limited design of a racing bicycle frame, minimizing *weight* might be the objective with stiffness, strength, toughness, and cost as constraints ("as light as possible without costing more than $1000"). But in the design of an inexpensive "shopping" bicycle, minimizing *cost* becomes the objective, and weight becomes a constraint ("as inexpensive as possible, without weighing more than 22 kg").

Lay out the results as in Table 1.

Step 4: Eliminate the free variable(s) in the objective function by using the constraints. Read off the grouping of material properties called the "Performance Index," which maximizes (or minimizes) the value of the objective function. Performance indices are the basis for a method of optimal material selection.

Each combination of a function, an objective, and a constraint shown in Fig. 1 leads to a performance index. The index characterizes the combination. The particular combination in the boxes of Fig. 1 describes a light stiff beam; its index (derived below) is:

$$\mathbf{M} = \frac{E^{1/2}}{\rho} \qquad \textbf{(Eq 3)}$$

Indices are always denoted by a bold **M.** There are many others characterizing thermomechanical and electromechanical functions. They are cataloged in Table 5(f) and 5(g) of this article.

Performance Index for a Light, Strong Tie

The loading on a component can generally be decomposed into some combination of axial tension or compression, bending, and torsion. Almost always, one mode dominates. So common is this that the functional name given to the component describes the way it is loaded: ties carry predominantly tensile loads, beams carry bending moments, shafts carry torques, and columns carry compressive axial loads (Fig. 2).

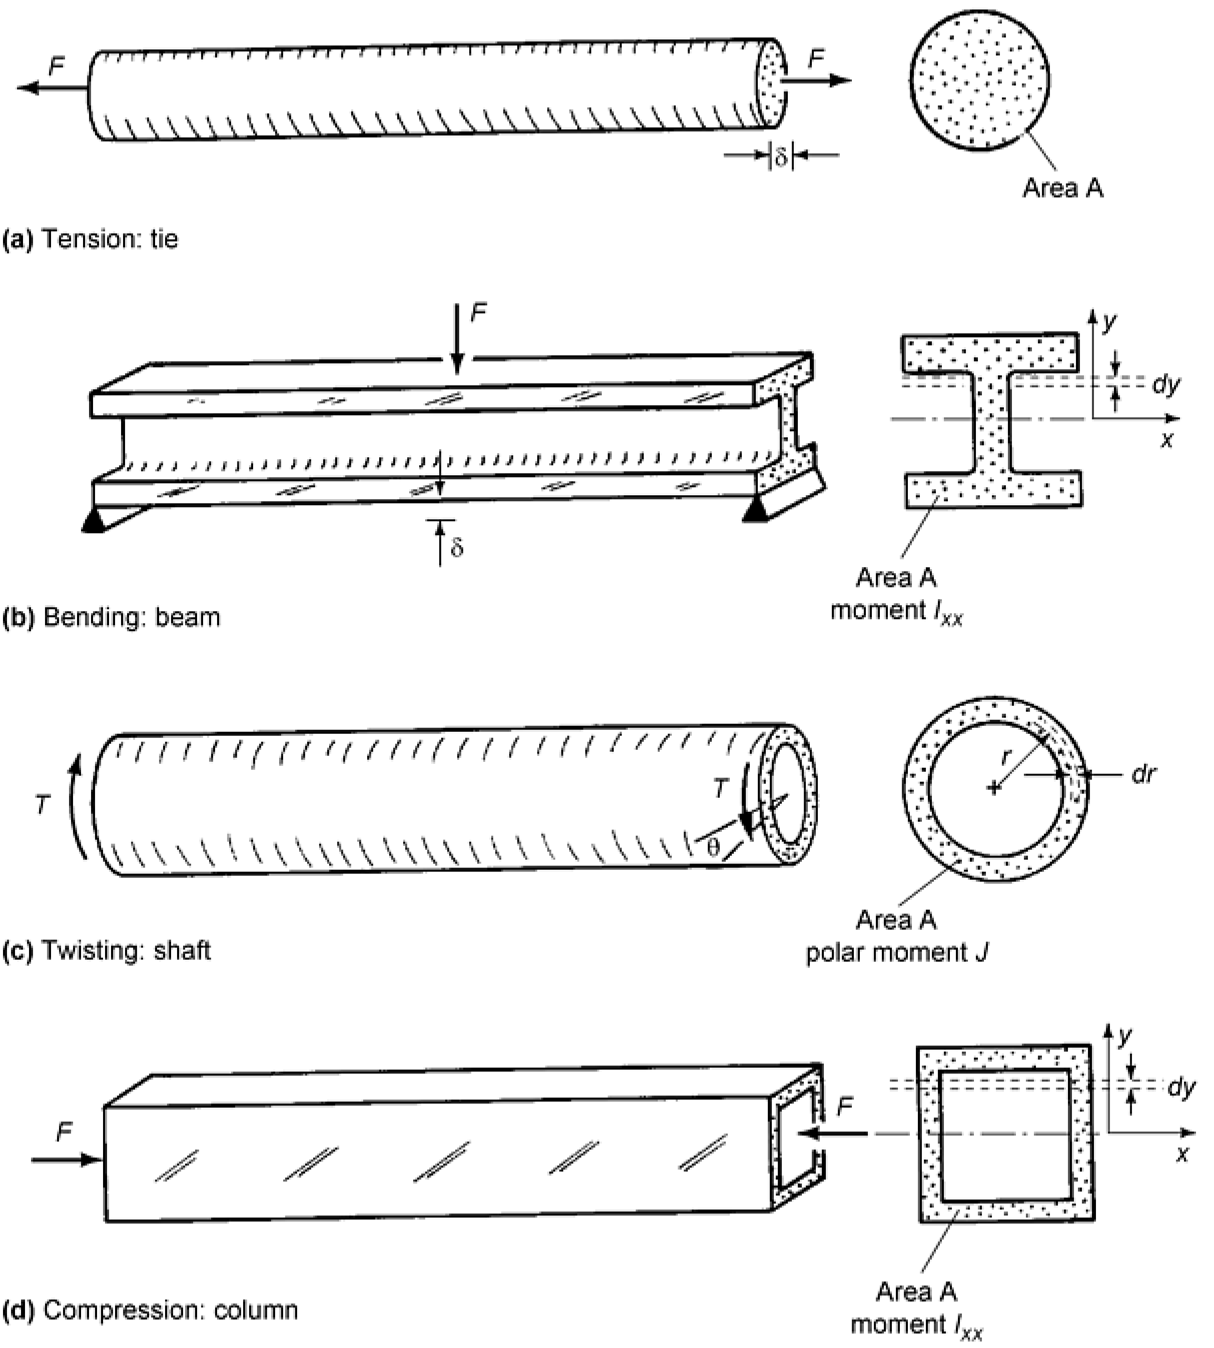

Fig. 2 A tie, a beam, a shaft, and a column. Efficient shapes are shown for each.

Consider the first of these. A material is required for a solid cylindrical tie-rod of specified length *l*, to carry a tensile force *F*; it is to be of minimum mass. Here, "maximizing performance" means "minimizing the mass while still carrying the load *F* safely"; thus the design requirements are those specified in Table 2. The mass is

$$m = A\, l\, \rho \qquad \textbf{(Eq 4)}$$

where *A* is the area of the cross section and ρ is the density of the material of which it is made. Equation 4 is the objective function--the quantity to be minimized. The length *l* and force *F* are specified and cannot be changed; the radius *r*, and thus the cross section, *A*, of the rod is free. The mass can be reduced by reducing the radius, but there is a constraint: The section area *A* must be sufficient to carry the tensile load *F*, requiring that

$$\frac{F}{A} \le \frac{\sigma_f}{S_f} \qquad \textbf{(Eq 5)}$$

where σ_f is the failure strength and S_f is a safety factor, typically in the range 1.2 to 3. Eliminating A between these two equations gives

$$m \ge (S_f F)\,(l)\left(\frac{\rho}{\sigma_f}\right) \qquad \textbf{(Eq 6)}$$

Note the form of this result. The first bracket contains the functional requirement that the specified load F is safely supported. The second bracket contains the specified geometry (the length l of the tie). The last bracket contains the material properties. The lightest tie-rod that will safely carry the load F without failing is that with the largest value of the material index

$$\mathbf{M} = \frac{\sigma_f}{\rho} \qquad \textbf{(Eq 7)}$$

The convention was adopted that indices are expressed as quantities to be maximized in order to maximize performance; that is why the material properties in Eq 6 are inverted in the definition of **M** in Eq 7. In this example, the index is the "specific strength" mentioned earlier. A similar calculation for a light stiff tie leads to the index

$$\mathbf{M} = \frac{E}{\rho}$$

where E is Young's modulus. This time the index is the "specific stiffness." If the objective is to minimize cost instead of mass, the index becomes

$$\mathbf{M} = \frac{E}{C_m \rho}$$

where C_m is the cost per unit mass of the material.

Table 2 Function, objective, and constraints for light, strong tie

Function	**"Tie" = carry tensile loads**
Objective	"Light" = minimize weight
Constraints	"Strong" = support load *F* without yield or failure

But things are not always so simple. The text example shows how this comes about.

Performance Index for a Light, Stiff Beam

The mode of loading that most commonly dominates in engineering is not tension, but bending--think of floor joists, of wing spars, of golf-club shafts. Consider, then, a light beam of square, solid section and length l (Fig. 3a) and loaded in bending, which must meet a constraint on its stiffness S, meaning that it must not deflect more than δ under a load F. The

words "light, stiff beam" prescribe a function, an objective, and a constraint (Table 3). The stiffness *S* of an elastic beam is:

$$S = \frac{F}{\delta} \geq \frac{CEI}{l^3} \qquad \textbf{(Eq 8)}$$

where *E* is Young's modulus, *C* is a constant that depends on the distribution of load and *I* is the second moment of the area of the section, which, for a beam of square section is

$$I = \frac{b^4}{12} = \frac{A^2}{12} \qquad \textbf{(Eq 9)}$$

The stiffness *S* and the length *l* are specified; the section *A* is free. The mass of the beam can be reduced by reducing *A*, but only so far that the stiffness constraint is still met. Using these equations to eliminate *A* in the objective function, Eq 4 gives

$$m \geq \left(\frac{12S}{C}\right)^{1/2} (l^{5/2}) \left(\frac{\rho}{E^{1/2}}\right) \qquad \textbf{(Eq 10)}$$

The brackets are ordered as before: functional requirement, geometry, and material. The best materials for a light, stiff beam are those with large values of the material index

$$\mathbf{M} = \frac{E^{1/2}}{\rho} \qquad \textbf{(Eq 11)}$$

Here, as before, the properties have been inverted; to minimize the mass, **M** must be maximized.

Table 3 Function, objective, and constraints for light, stiff beam

Function	**"Beam" = carry bending moments**
Objective	"Light" = minimize weight
Constraints	"Stiff" = beam stiffness is specified (a functional constraint)

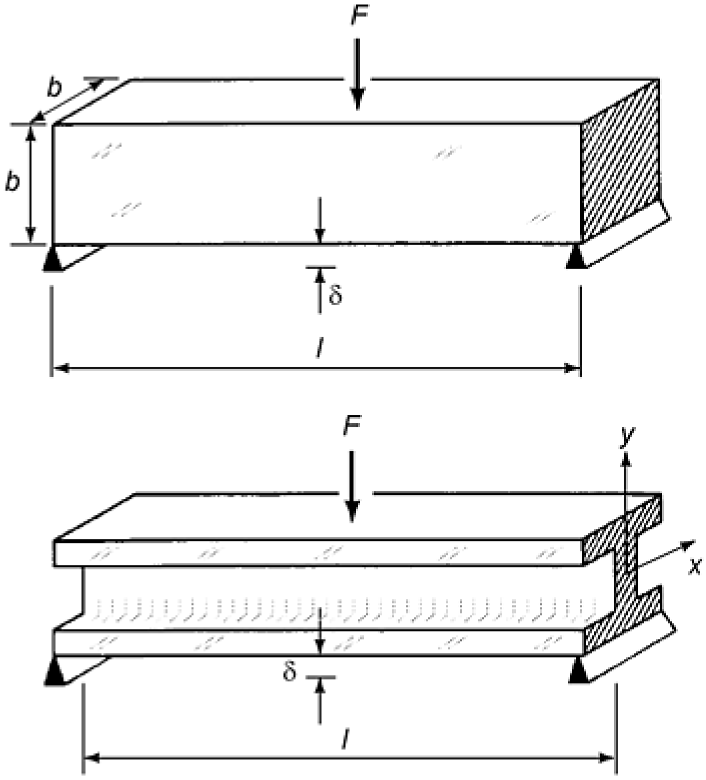

Fig. 3 (a) A solid, square-section beam, loaded in bending. (b) An I-section beam, loaded in bending

Performance Indices that Include Shape

Wooden beams sometimes have a solid, square section, but they are the exception rather than the rule. If the beam is to be efficient, it must be given an efficient shape: a tube, an I-section, or a box-section, perhaps (Fig. 2 and 3b). All of these are much lighter, for the same stiffness, than a solid, square section. To include shape, Eq 8 is used.

The second moment of area, *I*, depends on both the shape and scale (size) of the cross section:

$$I_{xx} = \int_{\text{section}} y^2 \, dA \qquad \textbf{(Eq 12)}$$

where *y* is measured normal to the bending axis and *dA* is the differential element of area at *y*, as shown in Fig. 2. It is helpful to separate shape from scale (Fig. 4). To do this, the shape factor for elastic bending is defined (Ref 4, 6, and 7):

$$\phi_B^e = \frac{4\pi I}{A^2} \qquad \textbf{(Eq 13)}$$

The second moment, *I*, has dimensions of (length)^4; so does the quantity A^2. The ratio of the two is dimensionless; it describes shape and is independent of scale. Two I-beams that have the same values of ϕ_B^e but that differ in scale have cross sections that look like photographic enlargements or reductions of each other. The factor 4π is inserted to give a solid, circular section a shape factor with a value of 1. Very efficient sections have values of ϕ_B^e as high as 100.

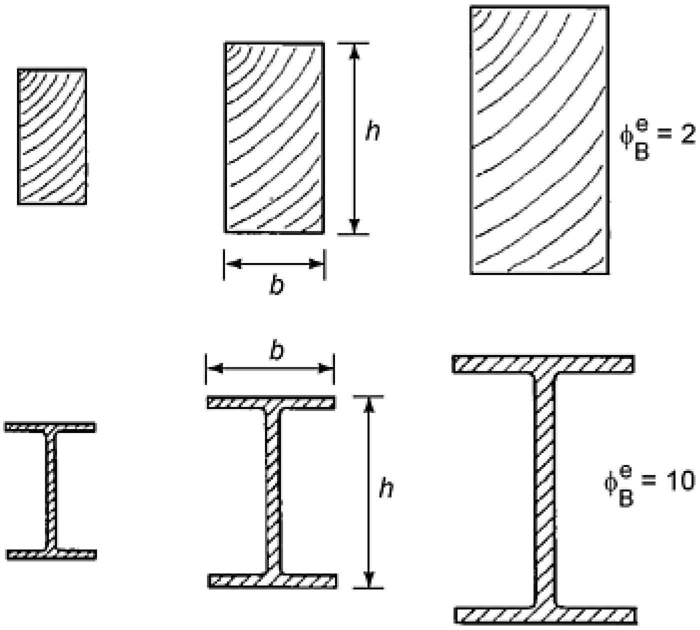

Fig. 4 The shape factor ϕ_B^e characterizes shape and is independent of scale. The shapes shown here have value of ϕ_B^e of 2 and 10. Shape factors as high as 100 are possible.

Substituting Eq 13 into Eq 8 gives

$$S = \frac{CE\phi_B^e A^2}{4\pi l^3} \qquad \textbf{(Eq 14)}$$

The free variable, *A*, in the objective function Eq 4 is now eliminated, giving

$$m = \left(\frac{4\pi S}{C}\right)^{1/2} (l^{5/2}) \cdot \frac{\rho}{(\phi_B^e E)^{1/2}} \qquad \textbf{(Eq 15)}$$

In this equation, the constant *C*, the stiffness *S*, and the length *l* are all specified by the design. For beams of a given, fixed shape, the objective function describing *m* is minimized by maximizing the same performance index **M** as before--it is that of Eq 11. However, for beams that differ in shape (as aluminum and wood beams generally do), it is minimized by maximizing a modified performance index that now includes the shape factor ϕ_B^e:

$$\mathbf{M} = \frac{E^{1/2}}{\rho} \cdot (\phi_B^e)^{1/2} \qquad \textbf{(Eq 16)}$$

Some materials--steels and aluminum alloys, for instance--are routinely formed to very efficient shapes. Others--wood, for example--are not. Performance indices like that of Eq 16 that include both material and shape allow the coupled selection of both. Further details can be found in Ref 4, 6, and 7.

Other Shape Factors

As has been discussed, a shape factor is a dimensionless number that characterizes the efficiency of a section shape, regardless of scale, in a given mode of loading. Thus, as well as the shape factor, ϕ_B^e, for elastic bending of beams

(defined above), there is another, ϕ^{e}_{T}, for elastic twisting of shafts (the superscript "e" means "elastic"). These are the appropriate shape factors when design is based on stiffness; when, instead, it is based on strength (i.e., on the first onset of plastic yielding or on fracture) two more shape factors are needed: ϕ^{f}_{B} and ϕ^{f}_{T} (the superscript "f" meaning "failure"). Finally, there is a shape factor for elastic buckling under axial compression ϕ^{e}_{E}. All five shape factors are defined so that they equal 1 for a solid bar with a circular cross section. Each is examined briefly in the following paragraphs.

In the elastic twisting of shafts (Fig. 2c), shape enters through the torsional moment of area, *K*. For circular sections it is identical with the polar moment of area, *J*:

$$K = J = \int_{\text{section}} r^2 \, dA \qquad \textbf{(Eq 17)}$$

where *dA* is the differential element of area at the radial distance *r*, measured from the center of the section. For noncircular sections, *K* is less than *J*; it is defined such that the angle of twist θ is related to the torque *T* by

$$\theta = \frac{Tl}{KG}$$

where *l* is length of the shaft and *G* the shear modulus of the material of which it is made. Approximate expressions are available to calculate *K* for common section shapes (Ref 8).

The shape factor for elastic twisting is defined by

$$\phi^{e}_{T} = \frac{2\pi K}{A^2} \qquad \textbf{(Eq 18)}$$

It, too, has the value 1 for solid circular shafts and is near 1 for any solid, equiaxed section; but for thin-walled shapes it, too, can be large. As before, sets of sections with the same value of ϕ^{e}_{T} differ in size but not shape.

Plasticity starts when the stress, somewhere, first reaches the yield strength, σ_y; fracture occurs when this stress first exceeds the fracture strength, σ_{fr}. Either one of these constitutes failure. The symbol σ_f denotes the failure stress, meaning "the local stress that will first cause yielding or fracture." One shape factor covers both. In bending, the stress σ is largest at the point y_m in the surface of the beam that lies furthest from the neutral axis; it is:

$$\sigma = \frac{M_B y_m}{I} = \frac{M_B}{Z} \qquad \textbf{(Eq 19)}$$

where M_B is the bending moment and *Z* is the section modulus ($Z = I/y_m$). The shape factor for failure in bending, ϕ^{f}_{B}, is defined by

$$\phi^{f}_{B} = \frac{16\pi Z^2}{A^3} = \frac{16\pi I^2}{y_m^2 A^3} \qquad \textbf{(Eq 20)}$$

Defined in this way, ϕ^{f}_{B} has the value 1 for a solid cylinder. It can be as high as 150 for efficient shapes.

In torsion, the problem is more complicated. For circular tubes or cylinders subjected to a torque *T* (as in Fig. 2c) the shear stress τ is a maximum at the outer surface, at the radial distance r_m from the axis of bending:

$$\tau = \frac{T r_m}{J} \qquad \textbf{(Eq 21)}$$

The quantity J/r_m in twisting has the same character as I/y_m in bending. For noncircular sections with ends that are free to warp, the maximum surface stress is given instead by

$$\tau = \frac{T}{Q} \qquad \textbf{(Eq 22)}$$

where Q, with units of m^3, now plays the role in torsion of Z in bending (details in Ref 8). This allows the definition of a shape factor, ϕ_T^f, for failure in torsion:

$$\phi_T^f = \frac{4\pi Q^2}{A^3} \qquad \textbf{(Eq 23)}$$

Like the other shape factors, ϕ_B^f and ϕ_T^f are dimensionless and therefore independent of scale, and both have the value 1 for a solid circular section.

Fully plastic bending or twisting (such that the yield strength is exceeded throughout the section) involve a further pair of shape factors. But, generally speaking, shapes that resist the onset of plasticity also resist full plasticity well. New shape factors for these are not, at this stage, necessary. The shape factor for buckling in compression (Fig. 2d) depends only on *I*. The appropriate shape factor (ϕ_B^e) has the same form as that for elastic bending (Eq 13) except that the *I* that enters is the lesser of the principal moments I_{xx} and I_{yy}, whereas in bending the loads are usually applied in such a way that the larger principal moment resists the deformation. The shape factors are summarized in Table 4. Expressions for all expressions of ϕ for common section shapes are listed in Ref 4 and 6.

Table 4 Definitions of shape factors

Mode of loading	Constraint	Section moment	Shape factor
Bending	Stiffness	I_{max} = greater of I_{xx} and I_{yy}	$\phi_B^e = \frac{4\pi I_{max}}{A^2}$
Bending	Strength	$Z = I/y_{max}$	$\phi_B^f = \frac{16\pi Z^2}{A^3}$
Torsion	Stiffness	J (circular sections) or K	$\phi_T^e = \frac{2\pi K}{A^2}$
Torsion	Strength	J/r (circular sections) or Q	$\phi_T^f = \frac{4\pi Q^2}{A^3}$
Compression	Buckling	I_{min} = lesser of I_{xx} and I_{yy}	$\phi_E^e = \frac{4\pi I_{min}}{A^2}$

The Table of Indices (Tables 5(a), 5(b), 5(c), 5(d), 5(e), 5(f), 5(g))

Tables 5(a), 5(b), 5(c), 5(d), 5(e), 5(f), and 5(g) list some 130 indices, relevant to mechanical, thermomechanical, and electromechanical design. Derivations for almost all of them, following the method outlined here, can be found in Ref 4 and 5. In most selection exercises they are used in the way described below, without consideration of shape. But in mechanical design of components loaded in bending, in torsion, or in compression such that buckling becomes a failure mode, shape and material must be chosen together. The relevant index is then a compound one, like that of Eq 16, containing both material properties and one of the five shape factors of Table 4. Worked examples can be found in Ref 4.

Table 5(a) Performance indices: stiffness-limited design at minimum mass (cost, energy)

Function and constraints[(a)]	Maximize[(b)]
Tie (tensile member)	
Stiffness, length specified; section area free	E/ρ
Shaft (loaded in torsion)	
Stiffness, length, shape specified; section area free	$G^{1/2}/\rho$
Stiffness, length, outer radius specified; wall thickness free	G/ρ
Stiffness, length, wall-thickness specified; outer radius free	$G^{1/3}/\rho$
Beam (loaded in bending)	
Stiffness, length, section shape specified; section area free	$E^{1/2}/\rho$
Stiffness, length, section height specified; width free	E/ρ
Stiffness, length, section width specified; height free	$E^{1/3}/\rho$
Column: compression strut far from buckling limit	
Stiffness and length specified; section area free	E/ρ
Column: compression strut, failure by elastic buckling	
Buckling load, length, section shape specified; section area free	$E^{1/2}/\rho$
Panel (flat plate, loaded in bending)	
Stiffness, length, width specified; thickness free	$E^{1/3}/\rho$
Plate (flat plate, compressed in-plane, buckling failure)	
Collapse load, length, and width specified; thickness free	$E^{1/3}/\rho$

Cylinder with internal pressure	
Elastic distortion, pressure, and radius specified; wall thickness free	E/ρ
Spherical shell with internal pressure	
Elastic distortion, pressure and radius specified; wall thickness free	$E/(1 - \nu)\rho$

(a) To minimize cost, use the above criteria for minimum weight, replacing density ρ by $C_m\rho$, where C_m is the material cost per kg. To minimize energy content, use the above criteria for minimum weight replacing density ρ by $q\rho$, where q is the energy content per kg.

(b) E = Young's modulus; G = shear modulus; ρ = density

Table 5(b) Performance indices: strength-limited design at minimum mass (cost, energy)

Function and constraints[(a)]	Maximize[(b)]
Tie (tensile strut)	
Stiffness, length specified; section area free	σ_f/ρ
Shaft (loaded in torsion)	
Load, length, shape specified; section area free	$\sigma_f^{2/3}/\rho$
Load, length, outer radius specified; wall thickness free	σ_f/ρ
Load, length, wall-thickness specified; outer radius free	$\sigma_f^{1/2}/\rho$
Beam (loaded in bending)	
Load, length, shape specified; section area free	$\sigma_f^{2/3}/\rho$
Load length, height specified; width free	σ_f/ρ
Load, length, width specified; height free	$\sigma_f^{1/2}/\rho$
Column (compression strut)	

Load, length, shape specified; section area free	σ_f/ρ
Panel (flat plate, loaded in bending)	
Stiffness, length, width specified; thickness free	$\sigma_f^{1/2}/\rho$
Plate (flat plate, compressed in-plane, buckling failure)	
Collapse load, length and width specified; thickness free	$\sigma_f^{1/2}/\rho$
Cylinder with internal pressure	
Elastic distortion, pressure and radius specified; wall thickness free	σ_f/ρ
Spherical shell with internal pressure	
Elastic distortion, pressure and radius specified; wall thickness free	σ_f/ρ
Flywheels, rotating disks	
Maximum energy storage per unit volume; given velocity	ρ
Maximum energy storage per unit mass; no failure	σ_f/ρ

(a) To minimize cost, use the above criteria for minimum weight, replacing density ρ by $C_m\rho$, where C_m is the material cost per kg. To minimize energy content, use the above criteria for minimum weight replacing density ρ by $q\rho$, where q is the energy content per kg. For design for infinite fatigue life, replace σ_f by the endurance limit σ_e.

(b) σ_f = failure strength (the yield strength for metals and ductile polymers, the tensile strength for ceramics, glasses and brittle polymers); ρ= density

Table 5(c) Performance indices: strength-limited design for maximum performance of components such as springs and hinges

Function and constraints	Maximize[(a)]
Springs	
Maximum stored elastic energy per unit volume; no failure	σ_f^2/E

Maximum stored elastic energy per unit mass; no failure	$\sigma_f^2/E\rho$
Elastic hinges	
Radius of bend to be minimized (maximum flexibility without failure)	σ_f/E
Knife edges, pivots	
Minimum contact area, maximum bearing load	σ_f^3/E^2 and H
Compression seals and gaskets	
Maximum conformability; limit on contact pressure	$\sigma_f^{3/2}/E$ and $1/E$
Diaphragms	
Maximum deflection under specified pressure or force	$\sigma_f^{3/2}/E$
Rotating drums and centrifuges	
Maximum angular velocity, radius fixed; wall thickness free	σ_f/ρ

(a) σ_f = failure strength (the yield strength for metals and ductile polymers, the tensile strength for ceramics, glasses, and brittle polymers); H = hardness; ρ= density. For design for infinite life, replace σ_f by the endurance limit σ_e.

Table 5(d) Performance indices: vibration-limited design

Function and constraints	Maximize[(a)]
Ties, columns	
Maximum longitudinal vibration frequencies	E/ρ
Beams	
Maximum flexural vibration frequencies	$E^{1/2}/\rho$
Panels	

Maximum flexural vibration frequencies	$E^{1/3}/\rho$
Ties, columns, beams, panels	
Minimum longitudinal excitation from external drivers, ties	$\eta E/\rho$
Minimum flexural excitation from external drivers, beams	$\eta E^{1/2}/\rho$
Minimum flexural excitation from external drivers, panels	$\eta E^{1/3}/\rho$

(a) E = Young's modulus (the yield strength for metals and ductile polymers, the tensile strength for ceramics, glasses, and brittle polymers); η= damping coefficient; ρ= density. For design for infinite fatigue life, replace σ_f by the endurance limit σ_e.

Table 5(e) Performance indices: damage-tolerant design

Function and constraints	Maximize[(a)]
Ties (tensile member)	
Maximize flaw tolerance and strength; load-controlled design	K_{Ic} and σ_f
Maximize flaw tolerance and strength; displacement-control	K_{Ic}/E and σ_f
Maximize flaw tolerance and strength; energy-control	K_{Ic}^2/E and σ_f
Shafts (loaded in torsion)	
Maximize flaw tolerance and strength; load-controlled design	K_{Ic} and σ_f
Maximize flaw tolerance and strength; displacement-control	K_{Ic}/E and σ_f
Maximize flaw tolerance and strength; energy-control	K_{Ic}^2/E and σ_f
Beams (loaded in bending)	
Maximize flaw tolerance and strength; load-controlled design	K_{Ic} and σ_f
Maximize flaw tolerance and strength; displacement-control	K_{Ic}/E and σ_f

Maximize flaw tolerance and strength; energy-control	K_{Ic}^2/E and σ_f
Pressure vessel	
Yield-before-break	K_{Ic}/σ_f
Leak-before-break	K_{Ic}^2/σ_f

(a) K_{Ic} = fracture toughness; E = Young's modulus; σ_f = failure strength (the yield strength for metals and ductile polymers, the tensile strength for ceramics, glasses, and brittle polymers); η = damping coefficient; ρ = density

Table 5(f) Performance indices: thermal and thermomechanical design

Function and constraints	Maximize[a]
Thermal insulation materials	
Minimum heat flux at steady state; thickness specified	$1/\lambda$
Minimum temp rise in specified time; thickness specified	$1/a = \rho C_p/\lambda$
Minimize total energy consumed in thermal cycle (kilns, etc.)	$\sqrt{a}/\lambda = \sqrt{1/\lambda\rho C_p}$
Thermal storage materials	
Maximum energy stored/unit material cost (storage heaters)	C_p/C_m
Maximize energy stored for given temperature rise and time	$\lambda/\sqrt{a} = \sqrt{\lambda\rho C_p}$
Precision devices	
Minimize thermal distortion for given heat flux	λ/α
Thermal shock resistance	
Maximum change in surface temperature; no failure	$\sigma_f/E\alpha$
Heat sinks	

Maximum heat flux per unit volume; expansion limited	$\lambda/\Delta\alpha$
Maximum heat flux per unit mass; expansion limited	$\lambda/\rho\Delta\alpha$
Heat exchangers (pressure-limited)	
Maximum heat flux per unit area; no failure under Δp	$\lambda\sigma_f$
Maximum heat flux per unit mass; no failure under Δp	$\lambda\sigma_f/\rho$

(a) λ= thermal conductivity; a = thermal diffusivity; C_p = specific heat capacity; C_m = material cost/kg; T_{max} = maximum service temperature; α = thermal expansion coefficient; E = Young's modulus; ρ= density; σ_f = failure strength (the yield strength for metals and ductile polymers, the tensile strength for ceramics, glasses, and brittle polymers)

Table 5(g) Performance indices: electromechanical design

Function and constraints	Maximize[a]
Bus bars	
Minimum life-cost; high-current conductor	$1/\rho_e\rho C_m$
Electromagnet windings	
Maximum short-pulse field; no mechanical failure	σ_y
Maximize field and pulse-length; limit on temperature rise	$C_p\rho/\rho_e$
Windings, high-speed electric motors	
Maximum rotational speed; no fatigue failure	σ_e/ρ_e
Minimum ohmic losses; no fatigue failure	$1/\rho_e$
Relay arms	
Minimum response time; no fatigue failure	$\sigma_e/E\rho_e$
Minimum ohmic losses; no fatigue failure	$\sigma_e^2/E\rho_e$

(a) C_m = material cost/kg; E = Young's modulus; ρ= density; ρ_e = electrical resistivity; σ_y = yield strength; σ_e = endurance limit

Applying the Indices and Limits: Property Charts

The selection is made by creating materials property charts, onto which performance indices are plotted to give a sequence of selection stages. Figure 5 shows how a single selection stage is performed. Typically, there is a performance index, **M,** made up of two or more properties p_1 and p_2 that characterize them; families of materials appear as larger bubbles. A typical performance index has the form:

$$\mathbf{M} = \frac{p_2^n}{p_1} \quad \textbf{(Eq 24)}$$

(the index $E^{1/2}/\rho$ is an example). Rearranging this gives:

$$p_2 = (p_1\mathbf{M})^{1/n}$$

Taking logarithms of the last equation gives:

$$\log p_2 = \frac{1}{n} \log p_1 + \frac{1}{n} \log \mathbf{M} \quad \textbf{(Eq 25)}$$

Because the axes of the chart are log(p_1) and log(p_2), values of **M** can be plotted on it as a family of parallel diagonal lines of slope 1/*n.* The selection is optimized by choosing the subset of materials that have the largest values of **M.** In Fig. 5, the materials near the top left are the best choice. Alternatively, the selection can be made as shown in Fig. 6. Here the index itself has been plotted on one axis, giving a bar chart of its values; the materials near the top are the best choice. Shaped materials can be plotted onto charts and selected by a similar procedure, which is illustrated more fully in the case studies that follow.

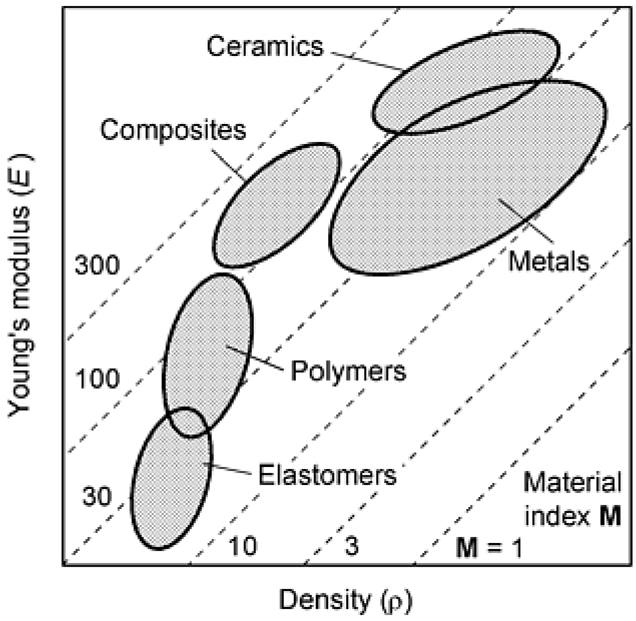

Fig. 5 A schematic *E*/ρ diagram with contours of the performance index, M

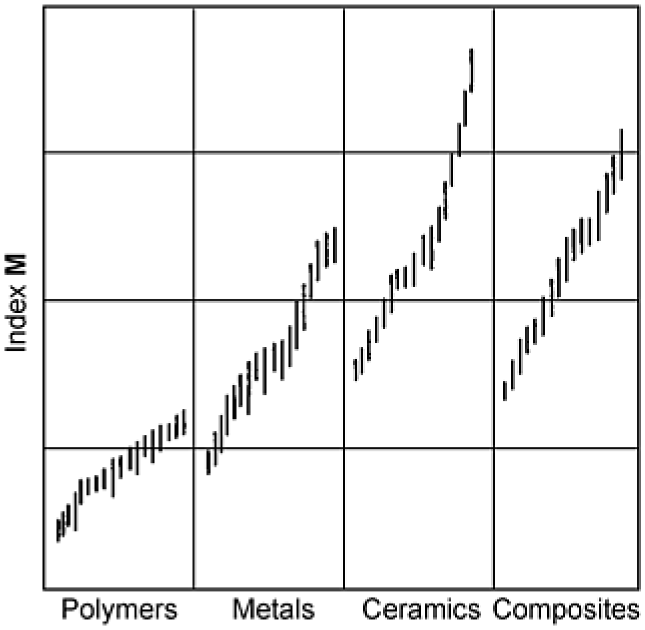

Fig. 6 A bar chart showing the performance index M

The method lends itself to implementation in software (Ref 5, 9, and 10). A full selection exercise can involve several stages in which limits are first placed on certain key properties (such as the maximum working temperature, the resistance to corrosion, toughness, or cost), and the subset of materials that pass these limits is then searched using the index-and-chart method to isolate candidates that optimally meet the objective and the constraint.

Performance Indices

M.F. Ashby, Engineering Design Centre, Cambridge University

Case Studies in the Use of Performance Indices

The two case studies that follow illustrate the use of material indices, shape factors, and selection charts to select materials.

Example 1: Materials for Springs.

Springs come in many shapes (Fig. 7) and have many purposes (Ref 11): One thinks of axial springs (a rubber band, for example), leaf springs, helical springs, spiral springs, and torsion bars. The primary function of a spring is that of storing elastic energy and, when required, releasing it again. The objective, then, is to maximize the energy that can be stored. There is a constraint: The spring, if it is to perform properly, must remain elastic; that is, the stress in it must nowhere exceed the elastic limit or, for cyclic loading, the endurance limit. Table 6 summarizes the design requirements.

Table 6 Design requirements for springs

Function	**Spring**
Objective	1. Maximize the energy stored per unit volume 2. Maximize the energy stored per unit weight 3. Maximize the energy stored per unit cost
Constraints	Must not fail by yield, fracture, or fatigue

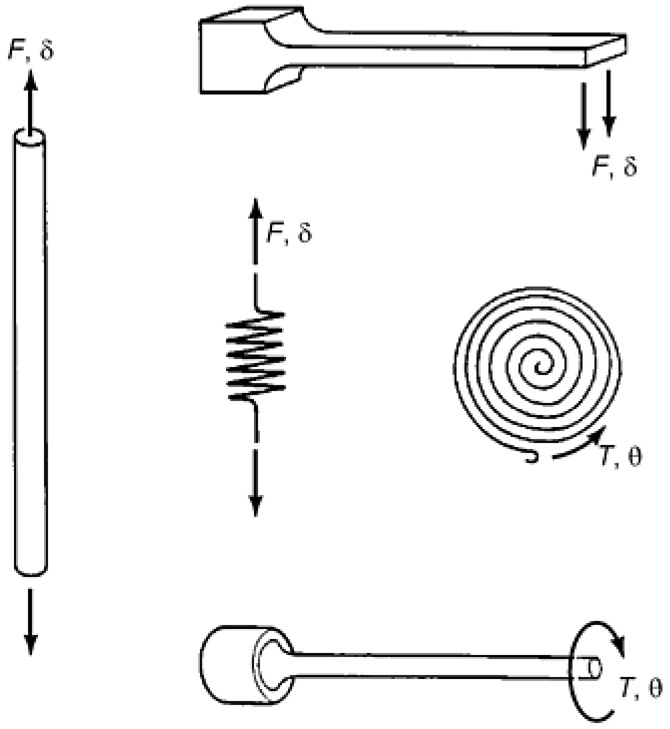

Fig. 7 Springs have many shapes, but all perform the same basic function: that of storing elastic energy.

The elastic energy W_v stored per unit volume in a block of material of modulus E stressed uniformly to a stress σ is

$$W_v = \frac{1}{2}\frac{\sigma^2}{E}$$

It is this that should be maximized. The spring will be damaged if the stress σ exceeds the elastic limit, yield stress, or failure stress σ_f; the constraint is that $\sigma \leq \sigma_f$ with an appropriate safety factor, S_f. So the maximum energy per unit volume that a spring can store is

$$(W_v)_{max} = \frac{1}{2}\frac{\sigma_f^2}{S_f E} \qquad \textbf{(Eq 26a)}$$

Torsion bars and leaf springs are less efficient than axial springs because much of the material is not fully loaded. The material at the neutral axis, for instance, is not loaded at all. For torsion bars:

$$(W_v)_{max} = \frac{1}{3}\frac{\sigma_f^2}{S_f E} \qquad \textbf{(Eq 26b)}$$

and for leaf springs:

$$(W_v)_{max} = \frac{1}{4}\frac{\sigma_f^2}{S_f E} \qquad \textbf{(Eq 26c)}$$

However, as these results show, the mode of loading has no influence on the choice of material. The best materials for compact springs are those with the biggest value of

$$\mathbf{M_1} = \frac{\sigma_f^2}{E} \qquad \textbf{(Eq 27)}$$

If weight, rather than volume, is of concern (light springs), $(W_v)_{max}$ must be divided by the density ρ (giving energy stored per unit weight) and materials must be found with high values of

$$\mathbf{M_2} = \frac{\sigma_f^2}{\rho E} \qquad \textbf{(Eq 28)}$$

Also, if it were the energy per unit cost (inexpensive springs), $(W_v)_{max}$ must be divided by cost per unit volume, $C_m \cdot \rho$ and materials must be found with high values of

$$\mathbf{M_3} = \frac{\sigma_f^2}{C_m \rho E} \qquad \textbf{(Eq 29)}$$

The selection procedure for springs of minimum volume is shown in Fig. 8 (based on Fig. 5 in the article "Material Property Charts" in this Volume), which shows the elastic limit plotted against the modulus. Rearranging Eq 27 gives:

$$E = \frac{\sigma_f^2}{\mathbf{M_1}}$$

or, taking logs,

$$\log(E) = 2 \log(\sigma_f - \log(\mathbf{M_1}) \qquad \textbf{(Eq 30)}$$

Family lines of slope 2 link materials with equal values of $\mathbf{M_1}$ = σ_f^2/E; those with the highest values of $\mathbf{M_1}$ lie toward the bottom right. The heavy line is one of the family; it is positioned so that a subset of materials is left exposed. The best choices are a high-strength steel (spring steel, in fact) lying near the top end of the line, and, at the other end, rubber. But certain other materials are suggested too: GFRP (now used for truck springs), titanium alloys (good but expensive), glass (used in galvanometers), and nylon (children's toys often have nylon springs). Note how the procedure has identified a candidate from almost every class of material: metals, glasses, polymers, elastomers, and composites. They are listed, with commentary, in Table 7.

Table 7 Materials for efficient compact springs

Material	$M_1 = \frac{\sigma_f^2}{E}$ (MJ/m^3)	Comment
Ceramics	(10-100)	Brittle in tension; good only in compression
Spring steel	10	The traditional choice: easily formed and heat treated
Titanium alloys	10	Expensive, corrosion resistant
Carbon-fiber-reinforced polymer (CFRP)	8	Comparable in performance with steel; expensive
Glass-fiber-reinforced polymer (GFRP)	5	Almost as good as CFRP and much less expensive
Glass	10	Brittle in torsion, but excellent if protected against damage; very low loss factor
Nylon	3	The least good; but inexpensive and easily shaped, but high loss factor
Rubber	20	Better than spring steel; but high loss factor

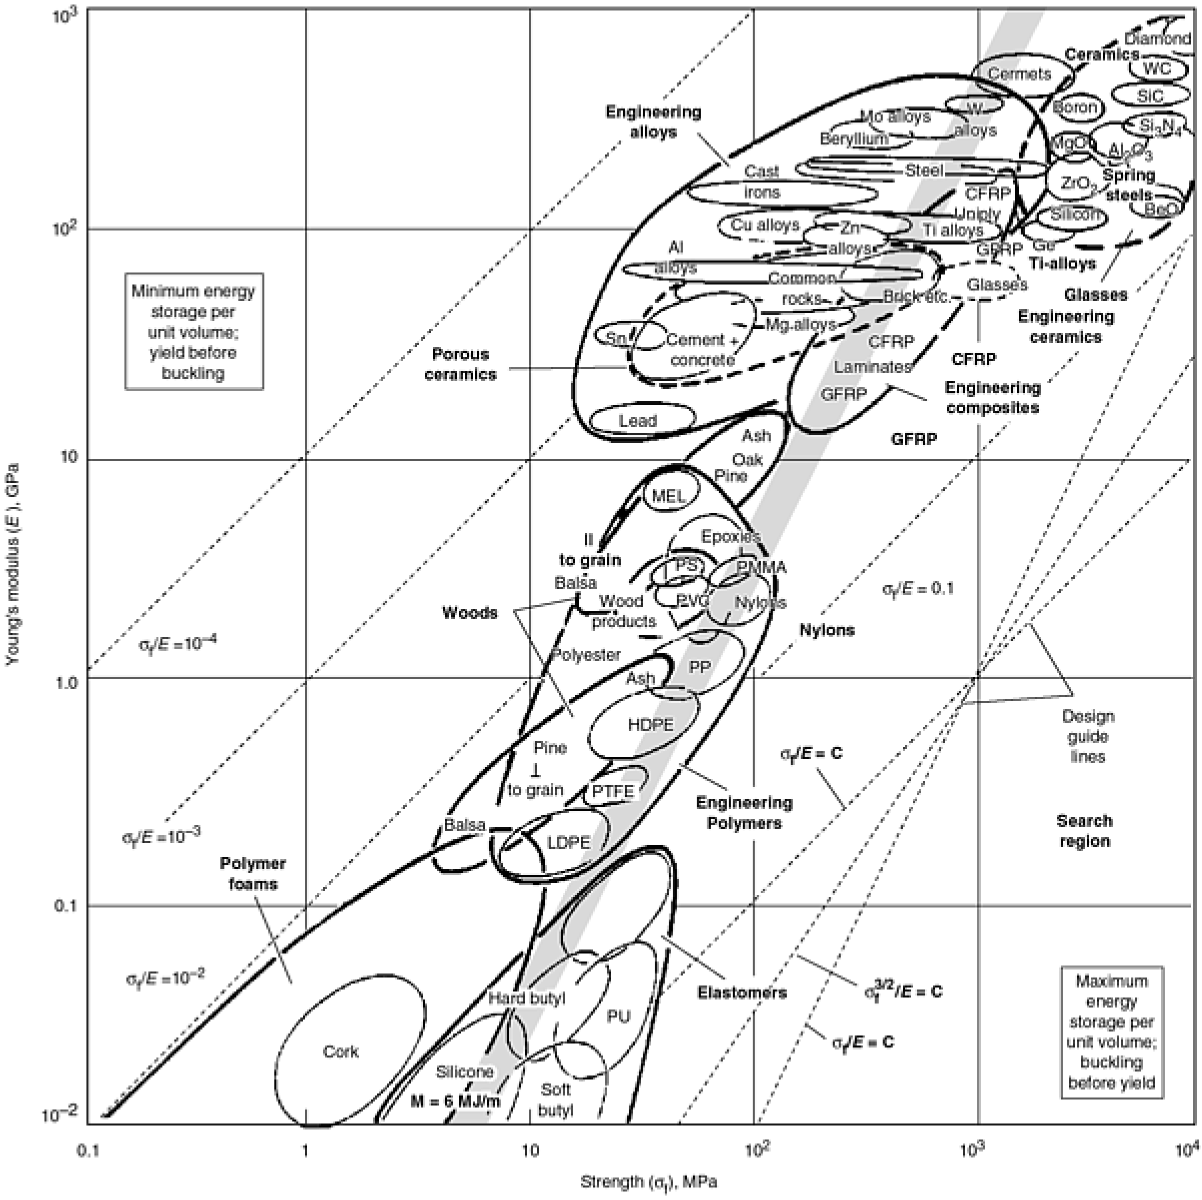

Fig. 8 A chart of Young's modulus, *E*, plotted against the elastic limit, σ_f. The diagonal line shows M_1.

A similar procedure allows materials selection for light springs using the index $\mathbf{M_2}$ and Fig. 6 of the article "Material Property Charts" in this Volume and for inexpensive springs, using the index $\mathbf{M_3}$ and an appropriate chart (Ref 5).

Other Considerations. Many additional considerations enter the choice of a material for a spring. Springs for vehicle suspensions must resist fatigue and corrosion; internal combustion (IC) valve springs must cope with elevated temperatures. A subtler property is the loss coefficient, shown in Fig. 9 of the article "Material Property Charts" in this Volume. Polymers have a relatively high loss factor and dissipate energy when they vibrate; metals, if strongly hardened, do not. Polymers, because they creep, are unsuitable for springs that carry a steady load, though they are still perfectly good for catches and locating springs which spend most of their time unstressed.

Example 2: Materials for Windsurfer Masts.

Windsurfing seems to have its origins in an eccentric idea, published in *Popular Science* in 1965 by an American, Newman Derby. It was that of the "freesail"--a board, steered by back and forward motion of the mast itself. Implementing it successfully took a further idea, that of another American, Jim Drake, who devised a universal joint that allowed a freely swiveling mast to be stuck onto a surfboard, thereby creating a new sport (Ref 12, 13). Since then the equipment (Fig. 9) has evolved, reflecting the technical influence of mechanical and materials engineering. The mast is a

key part of the rig and influences the dynamics of the sail. Masts are designed to flex under wind pressure; the flex characteristics of the mast determine sail shape and, through this, sailing characteristics. Thus the first constraint on the mast is that of a specified stiffness. While maintaining stiffness, the designer seeks to limit the outer diameter of the mast in order to reduce its influence on air flow. Also, for reasons of stability, the mast must be as light as possible. Table 8 summarizes the design requirements.

Table 8 Design requirements for windsurfer masts

Function	**Windsurfer mast (light, stiff beam)**
Objective	Minimize mass, *m*
Constraints	Stiffness *S* specified

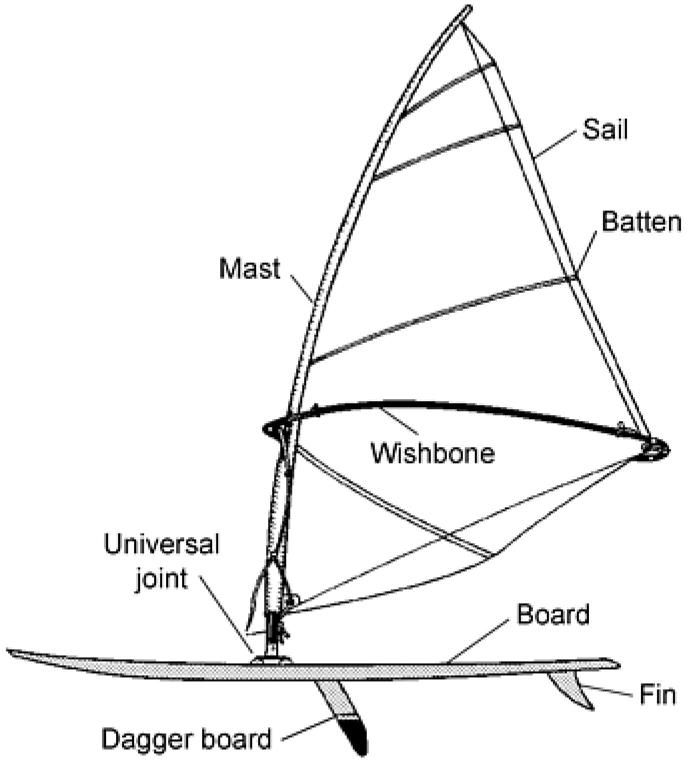

Fig. 9 A windsurfer. The flexure of the mast controls the shape of the sail; its pivoting about the universal joint controls the response of the craft.

A typical windsurfer mast has a length L of 4.6 m. Its stiffness is characterized by the International Mast Check System (IMCS) number. It is measured by measuring the deflection δ caused by hanging a weight of 30 kg at the midpoint of the mast, supported at its ends; the number is given by

$$\text{IMCS number} = \frac{L}{\delta} \qquad \textbf{(Eq 31)}$$

The values lie between 20 (a soft mast) and 32 (a hard one). Masts typically weigh between 1.8 and 3 kg. They are tuned by changing the lay-up.

The mast has length *L* and cross-sectional area *A*, and for lightness, it is hollow. The objective is to minimize its mass *m*:

$$m = A\,L\,\rho \qquad \textbf{(Eq 32)}$$

where ρ is the density of the material of which it is made. There is a constraint on the bending stiffness *S* of the mast, defined by

$$S = \frac{F}{\delta} = \frac{CEI}{L^3} \qquad \textbf{(Eq 33)}$$

where *E* is the (longitudinal) modulus of the material of which it is made, *I* the second moment of its cross section, and *C* a constant that depends only on the distribution of load; for three-point bending, as in the ICMS test, *C* = 48. The shape factor for elastic bending, ϕ_B^e, was defined in Eq 13. Because only this shape factor is needed, it shall be denoted by the symbol ϕ alone. Solving Eq 13 for *I* and substituting in Eq 33 gives an expression for the area *A* that will just provide the required stiffness *S*:

$$A = \left(\frac{4\pi S L^3}{CE\phi}\right)^{1/2} \qquad \textbf{(Eq 34)}$$

Substituting this into Eq 32 gives

$$m = \left(\frac{4\pi S L^5}{C}\right)^{1/2} \left(\frac{\rho}{(\phi E)^{1/2}}\right) \qquad \textbf{(Eq 35)}$$

the first bracket contains only quantities defined by the design. The second contains only material properties and shape. The mass of the mast is minimized, for a given stiffness, by choosing a material and shape with as large a value as possible of the performance index

$$\mathbf{M} = \frac{(\phi E)^{1/2}}{\rho} \qquad \textbf{(Eq 36)}$$

There is, additionally, a geometric constraint: The mast must not be too fat. Expressed more formally, the outer radius of the mast must be less than an upper-limiting value:

$$r \leq r_{\max} \qquad \textbf{(Eq 37)}$$

The derivation thus far has been general, applicable to any shape. This new constraint is used by employing results specific to thin-walled tubes. The shape factor for a thin-walled tube is

$$\phi = \frac{4\pi I}{A^2} = \frac{4\pi\,(\pi r^3 t)}{(2\pi r t)^2} = \frac{r}{t} \qquad \textbf{(Eq 38)}$$

This allows

$$I = \pi r^3 t = \frac{\pi r^4}{\phi} \quad \text{(Eq 39)}$$

and

$$\phi = \frac{r}{t} \quad \text{(Eq 40)}$$

Substituting this into Eq 33 gives a lower bound for the quantity E/ϕ:

$$\frac{E}{\phi} \geq \frac{SL^3}{C\pi r_{max}^4} \quad \text{(Eq 41)}$$

To make use of this, the right-hand side must be evaluated. The stiffness $S = F/\delta$ of a "medium" mast with an IMCS number of 26 is 1.7×10^3 N/m. The resulting lower limits for E/ϕ, for L = 4.6 m and three values of r_{max}, are listed in Table 9.

Table 9 Limits on E/ϕ

Maximum radius of mast (r_{max}), mm	Required minimum (E/ϕ), GPa
10	110
15	21
20	6.8

Figure 10 shows the selection. The axes are effective modulus E/ϕ and effective density ρ/ϕ. To plot the index **M,** note that

$$\mathbf{M} = \frac{(\phi E)^{1/2}}{\rho} = \frac{(E/\phi)^{1/2}}{\rho/\phi} \quad \text{(Eq 42)}$$

Solving for E/ϕ and taking logs gives

$$\log(E/\phi) = 2\log(\rho/\phi) + 2\log(\mathbf{M}) \quad \text{(Eq 43)}$$

Therefore, the tubes are treated as "materials" with effective modulus E/ϕ and ρ/ϕ, and they are plotted on the conventional E-ρ diagram together with solid materials for which $\phi = 1$. Contours of **M** appear as a family of lines of slope 2. One is shown. The lower limit on effective modulus appears as a horizontal line at the indicated value of r_{max}; only materials above the appropriate line are candidates. Among these, the most attractive are those with the largest value of the index **M.** The selection is listed in Table 10.

Table 10 Materials for windsurfer masts

Material	Shape factor, $\phi = r/t$	Index M, $GPa^{1/2}/(Mg/m^3)$	Mass (m), kg, for IMCS = 26
r_{max}= 20 mm			
CFRP	14.3	22.9	2.0
GFRP	4.3	6.2	7.3
Aluminum	8.0	8.5	5.3
Wood and (spruce)	1.7	9.0	5.0
r_{max}= 15 mm			
CFRP	4.7	12.9	3.5
GFRP	1.4	3.9	9.2
Aluminum	3.1	4.9	11.6
Wood and (spruce)	Not possible	. . .	. . .

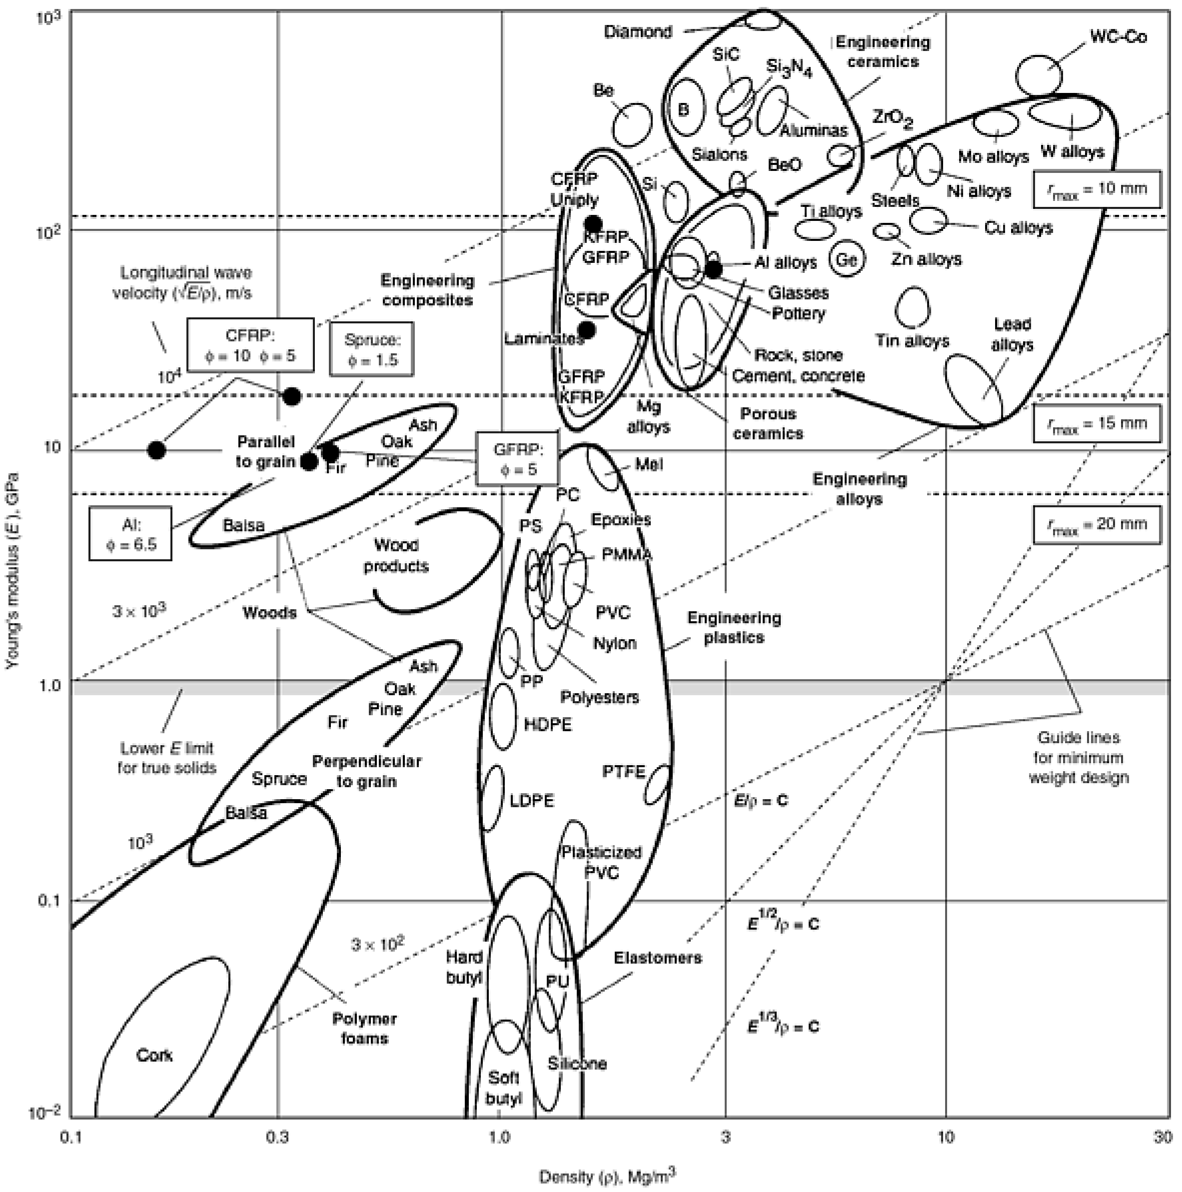

Fig. 10 A chart of Young's modulus, *E*, plotted against density, ρ. Solid materials are plotted at their (*E*, ρ) point; shaping them by a factor ϕ moves them to the point (E/ϕ, ρ/ϕ). All the previous selection strategies still apply. The diagonal line shows M; the horizontal lines shows the limits for E/ϕ.

Other Considerations. The language of windsurfer design verges on the poetic. The coupled tuning of sail and rig is known in the industry as the "integrated rig concept," a vision that focuses on the "creation of a perfect harmonic functional unit." With harmonic perfection as the criterion of success, the choice of material and overall shape is only the first (though important) step. The distribution of stiffness along the mast now becomes an issue. Masts today are tuned not only to match the weight of the surfer, but also the type of windsurfing (slalom, race, or wave). As in many other sports, the technology of the equipment has become very sophisticated.

Decision Matrices in Materials Selection

David L. Bourell, The University of Texas at Austin

Introduction

THE GOAL of any materials selection endeavor is to choose the best material for a given application. When selection is simple, involving only one or two material demands, the process is relatively straightforward. However, sometimes there are conflicting materials demands, or several individuals or groups want to have input, or the process needs to be documented. In these cases it is helpful to use a decision matrix.

In materials selection, a decision matrix method is any formalized procedure by which materials are ranked prior to a selection decision. The methods described in this article all involve construction of a table, composed of columns of potential materials and rows of important materials functions. A decision matrix is a stimulus to creative work (Ref 1), because it forces the designer to analyze the selection from different angles and to clarify the design issues. Decision matrix methods are sometimes more correctly labeled "evaluation matrix methods."

Advantages of decision matrix methods are:

- They organize and clarify the selection task, providing greater insight into the design situation and ensuring that all appropriate considerations are included.
- They improve understanding of the interactions between proposed solutions, thereby providing a means for new, synergistic solutions. For example, the need to reconcile low cost with corrosion resistance may lead to consideration of plating or surface sheet bonding.
- They provide a written record of the selection process, which can be important if the decision is reviewed or questioned later. In addition, a decision matrix can be a fruitful starting point for future materials selection for a different design with related functions.
- They are versatile, robust, and applicable during all stages of design, including conceptual and configuration design.
- They facilitate participatory decision-making by recording input from various individuals.
- They can be relatively bias-free, thus maximizing creativity and flexibility in materials selection.
- They allow the designer to include or exclude properties or features in excess of the design requirements. For example, consider an application requiring a maximum corrosion rate of 200 mm/year and a minimum yield strength of 200 MPa. Suppose two materials are considered, one with a corrosion rate of 180 mm/year and yield strength of 300 MPa, the other with a corrosion rate of 10 mm/year and yield strength of 210 MPa. Decision matrix methods allow the designer to incorporate into the decision process the relative importance of these "excess" properties and features.

Limitations of decision matrix methods include the following:

- Decision matrix methods are not completely objective. Designers must still make value judgments in comparing materials (e.g., judge the manufacturability of plain carbon steel versus that of low-density polyethylene). Sometimes they must also judge the relative importance of evaluation criteria (e.g., electrical conductivity versus castability versus strength).
- It is important to evaluate the decision matrix method during the design process. However, this "fine tuning" may be misconstrued or abused, so that the inputs are "fudged" in order to obtain a foregone conclusion.
- Often, requisite data are unknown or inaccessible in a timely manner. This is becoming less of a problem with the creation and availability of computer databases (see the article "Computer-Aided Materials Selection" in this Volume).

Alternatives, Criteria, and Weighting Factors

Three important concepts in decision making are alternatives (candidate materials), criteria (objectives), and weighting factors.

Alternatives (candidate materials) are the materials or material systems under consideration. In the conceptual design stage, an alternative might be non-heat-treatable aluminum alloy. In the configuration phase, a specific material, such as ASTM B 209 aluminum alloy 5052-H38, might be an appropriate alternative. Alternatives can be suggested by

several sources, including the design engineer's experience, materials databases, materials suppliers, an in-house list of stocked material, and Ashby selection charts (discussed in the article "Material Property Charts" in this Volume).

Criteria (objectives) are the properties or materials features that are being considered in the decision-making process. Criteria should be as specific as the design definition will allow. Early in design, the criteria might be "must be transparent," "should be easily manufactured," "must be tough," or "must have low specific modulus". During configuration design, the criteria might be "toughness exceeding 60 MPa$\sqrt{m}$," "electrical conductivity between 0.1 and 0.4 $\mu\Omega \cdot$ m," "hardening without preheat or postheat," or "weldable using gas welding techniques." Criteria generally are derived from the requirements list (also known as the specification sheet or product requirements list) that is developed early in the design process.

Weighting factors are numerical representations of the relative importance of criteria in the selection process. Assuming that all alternatives meet the design demands, weighting factors quantify the relative importance of the criteria (e.g., hardness versus castability versus density) to the overall selection. They can also be used to quantify excess properties. Generally, weighting factors for all criteria sum to unity. All decision matrix methods use alternatives and criteria, but weighting factors may or may not be used.

David L. Bourell, The University of Texas at Austin

Decision Matrix Techniques

Numerous decision matrix techniques have been developed (Ref 1, 2, 3, 4, 5, 6, 7). The three selection techniques described in this article have been chosen to demonstrate varying degrees of complexity: the Pugh method, the Dominic method, and the Pahl and Beitz method. Their key features are shown in Table 1. The Pugh method is the simplest of the three, with all criteria qualitatively evaluated with equal weight. The Dominic method provides a means for rating the relative importance of criteria by use of weighting factors. The Pahl and Beitz method is a completely numerical approach to materials selection.

Table 1 Comparison of common decision matrix methods

Methods	Type	Criteria weighting factors?
Pugh	Qualitative	No
Dominic	Qualitative	Yes
Pahl and Beitz	Quantitative	Yes

Decision Matrices in Materials Selection

David L. Bourell, The University of Texas at Austin

The Pugh Method

Description. The Pugh method (Ref 1) is one of the simplest decision matrix methods. Selection is based on qualitative comparison to a datum or reference alternative. The Pugh method is useful early in design, since it requires the least amount of detailed information. It is also useful in redesign, because the current material design serves automatically as the datum.

Method. Alternatives are listed as column headers in the decision matrix. The first column lists criteria. One alternative is selected to be the datum, perhaps the alternative that is best known and understood, or the alternative that is intuitively considered to be the best. Each blank cell is associated with a row (criterion) and a column (alternative). For each blank cell, ask, "Considering this criterion, is this alternative better (+), worse (-), or the same (S) when compared to the datum?" and fill in the appropriate symbol. When there is doubt or disagreement, use "S."

The next step is to create three more rows at the bottom of the matrix with the row headers "Σ+," "Σ-," and "ΣS." For each alternative except the datum, sum the number of "+", "-," and "S" responses in the appropriate blank. Resist the tendency to generate an overall sum for each alternative.

Analyze the results. For each alternative, consider whether some modification might mitigate its weak points relative to the datum. If so, modify the alternative, enter it as a new column on the decision matrix, and evaluate it relative to the datum. Retain the unmodified alternative.

Analyze the criteria. If the method does not adequately distinguish alternatives as strong and weak, perhaps the criteria are overly ambiguous, subject to multiple interpretations, or overlapping. Clarification of criteria may be in order.

Having analyzed the alternatives and criteria, identify the weakest alternatives and eliminate them, thereby shrinking the matrix. If more than a few alternatives appear to be strong, it may be helpful to consider each of them as the final selection, in order to produce additional criteria that will clarify the decision. It is sometimes useful to redo the decision matrix using one of the strongest alternatives as the datum.

At this point, the strongest alternatives may be selected for further development. If the selection process takes place at the final stages of design, the strongest alternative may be selected if one clearly stands apart from the others. Otherwise, it may be prudent to use one of the other, more detailed decision matrix methods.

Example 1: Use of the Pugh Method in Material Selection for Redesign of a Toy Train Spring.

The objective in this example was to reconsider selection of a helical steel spring for a child's toy train. The original material was ASTM A 227 class I steel wire, hard drawn for mechanical springs. Three alternatives were considered: a different design geometry of the same material, ASTM A 228 music spring quality steel wire, and ASTM A 229 class I oil-tempered steel wire for mechanical springs. A Pugh decision matrix appears as Table 2. Criteria are grouped by performance and cost factors.

Table 2 Pugh decision matrix for a toy train helical spring redesign

Criteria	Alternative 1 Present material, hard drawn steel (ASTM A 227)	Alternative 2 Hard drawn steel, class I (ASTM A 227)	Alternative 3 Music spring quality steel (ASTM A 228)	Alternative 4 Oil-tempered steel, class I (ASTM A 229)
Wire diameter, mm	1.4	1.2	1.12	1.18
Coil diameter, mm	19	18	18	18
Number of coils	16	12	12	12
Relative material cost (per unit weight)	1	1	2.0	1.3
Tensile strength, MPa	1750	1750	2200	1850
Spring constant	Datum	-	-	-
Durability	Datum	S	+	+
Weight	Datum	+	+	+
Size	Datum	+	+	+
Fatigue resistance	Datum	-	+	S
Stored energy	Datum	-	+	+
Material cost (for one spring)	Datum	+	S	S
Manufacturing cost	Datum	S	+	-
$\sum +$		3	6	4
$\sum S$		2	1	2
$\sum -$		3	1	2

Analysis. Both the music spring quality steel wire and the oil-tempered steel wire appeared to be superior to the current design. The modestly higher ranking of the former arises from consideration of manufacturing cost related to the heat treatment of the latter. Selection of music spring quality steel wire produced an overall cost savings of 33%.

Decision Matrices in Materials Selection

David L. Bourell, The University of Texas at Austin

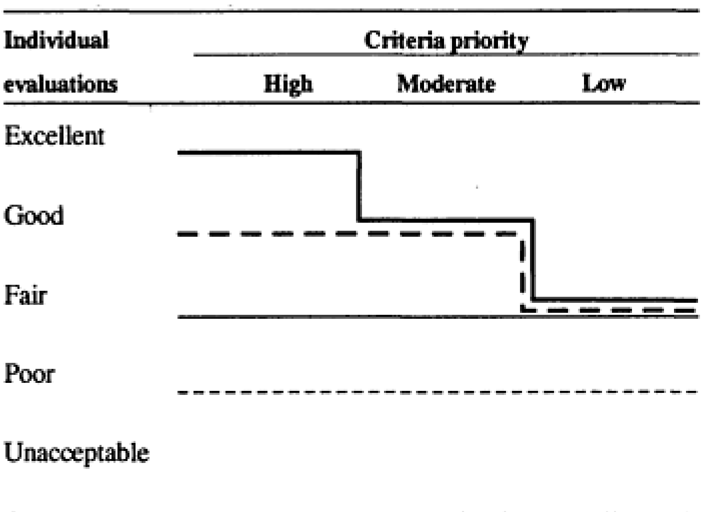
The Dominic Method

Description. The Dominic method (Ref 6) is used to evaluate alternatives using five descriptors: excellent, good, fair, poor, and unacceptable. Further, criteria are rated qualitatively as being high priority, moderate priority, or low priority. The Dominic method, like the Pugh method, is completely qualitative, but it allows for more complexity in the selection process.

Method. A matrix of alternatives and criteria is constructed as described for the Pugh method, but no datum is selected. Alternatives are labeled using capital letters ("A," "B," "C," etc.). Criteria are listed in descending order of importance to the design and are then gathered into three categories: high priority, moderate priority, or low priority (or, alternatively, "crucial," "important," and "desirable"). The matrix is completed by ranking each criterion on an absolute basis as excellent, good, fair, poor, or unacceptable for each alternative.

Once the matrix is complete, the results are tabulated using a Dominic method overall evaluation table (DMOET), Table 3. The rows are the ratings for alternatives and the columns are ratings for criteria. The blanks are filled in with the letters representing alternatives. For example, if alternative B had three "excellent" ratings in high-priority criteria, three B's would be placed in the blank cell for "High" and "Excellent." Once the DMOET is complete, alternatives are given an overall rating. All letters for an alternative must be above an overall rating line to obtain a given rating. The rating lines are shown on the DMOET. To obtain an "excellent" overall rating, the alternative must be rated as excellent in all high-priority criteria, good or excellent in all moderate-priority criteria, and fair or better in the low-priority criteria. The results of the Dominic method are analyzed as described for the Pugh method.

Table 3 Dominic method overall evaluation table (DMOET)



Overall evaluation: all above heavy solid line, excellent; all above heavy dashed line, good; all above light solid line, fair; all above light dotted line, poor

Example 2: Use of the Dominic Method for Material Selection of a Loaded Thermal Conductor in Late Concept Design.

The objective in this example was to select a mass-produced, non-heat-treatable cylindrical sheath material to conduct heat efficiently near room temperature and to withstand a static load. A heat transfer application required that a sheet of material be bent around a heat transfer medium. The sheet, whose thickness was defined by the necessary heat transfer conditions, also had to withstand a static compressive load and be resistant to denting during handling. Manufacturing issues were tooling cost and springback.

Table 4 lists the materials that were initially considered and their properties. The criteria are listed in Table 5. High-priority criteria were the amount of heat transferred (thermal conductivity, high was desirable), tooling costs (bend force index, low was desirable), and springback (index, low was desirable). Medium-priority criteria were the time to steady-state conduction (thermal diffusivity, high was desirable) and the ability to carry a static load (static load index, high was desirable). The low-priority criterion was the ability to resist denting during handling (hardness, high was desirable). The completed DMOET is shown as Table 6.

Table 4 Properties of candidate materials for the Dominic example

Properties	A 1020 steel (ASTM A 611, grade B)	B 304 stainless steel (ASTM A 666, grade D)	C 5052-H34 aluminum (ASTM B 209)	D C11000-H04 ETP copper (ASTM B 152)	E C22000-H01 commercial bronze (ASTM B 36)
Thickness (*t*), in.	0.107	0.107	0.407	0.205	0.205
Thermal conductivity, Btu · ft/h · °F · ft^2	27	9.4	80	224	109
Thermal diffusivity, ft^2/h	909	270	3750	6750	3810
Elastic modulus (*E*), 10^6 psi	30	28	10.5	17	17
Yield strength (YS), ksi	30	110	26	40	37
Hardness, HB	111	240	68	50	42
Static load index[(a)], in. · lb	3210	11,770	10,580	8200	7590
Bend force index[(a)], lb	343	1260	4310	1680	1550
Springback index[(a)], 10^{-3} in.$^{-1}$	9.35	36.7	6.08	11.5	10.6

(a) Static-load-carrying capability is proportional to YS(t), and large numbers are desirable. Bending force is proportional to YS$(t)^2$. Extent of springback is proportional to YS/(tE). Small numbers for both indices denote desirable manufacturability.

Table 5 Criteria and ratings for candidate materials for the Dominic example

Criteria	Priority	A 1020 steel (ASTM A 611, grade B)	B 304 stainless steel (ASTM A 666, grade D)	C 5052-H34 aluminum (ASTM B 209)	D C11000-H04 ETP copper (ASTM B 152)	E C22000-H01 commercial bronze (ASTM B 36)
Heat transfer	High	Good	Fair	Excellent	Excellent	Excellent
Tooling costs	High	Excellent	Good	Fair	Good	Good
Springback	High	Excellent	Fair	Excellent	Excellent	Excellent
Time to steady state	Moderate	Good	Fair	Excellent	Excellent	Excellent
Static load	Moderate	Good	Excellent	Excellent	Excellent	Excellent
Dent resistance	Low	Good	Excellent	Fair	Fair	Fair

Table 6 Dominic method overall evaluation table (DMOET) for the loaded thermal conductor

Individual evaluations	Criteria priority		
	High	**Moderate**	**Low**
Excellent	AACCDDEE	BCCDDEE	B
Good	ABDE	AA	A
Fair	BBC	B	CDE
Poor			
Unacceptable			

Overall evaluation: all above heavy solid line, excellent; all above heavy dashed line, good; all above light solid line, fair; all above light dotted line, poor

Analysis. No material received an overall "excellent" rating. Low-carbon steel, copper, and bronze had "good" ratings. Steel had the highest rating, but steel is limited by its heat transfer characteristics, a difficult parameter to improve on. Aluminum and copper are limited by the high tooling cost associated with their thickness. Because the design stage was late conceptual, it was considered reasonable to continue with low-carbon steel, copper, and bronze into configuration design.

The Pahl and Beitz Method

Description. The Pahl and Beitz method (Ref 7) allows quantitative evaluation of alternatives using weighted criteria. Because of the level of detail associated with its application and the objectivity of numerical approaches, it is particularly well suited for configuration design, using a large number of criteria that require input from technically diverse groups or individuals.

Method. Lists of criteria and alternatives are generated. The criteria are weighted numerically such that the sum of all weighting factors equals 1. (Sometimes 100 is used as the sum.)

An "objective tree" is a useful construction for assigning weighting factors (Fig. 1). The first level represents a simple statement describing the part or component being designed and has an entry value of 1.

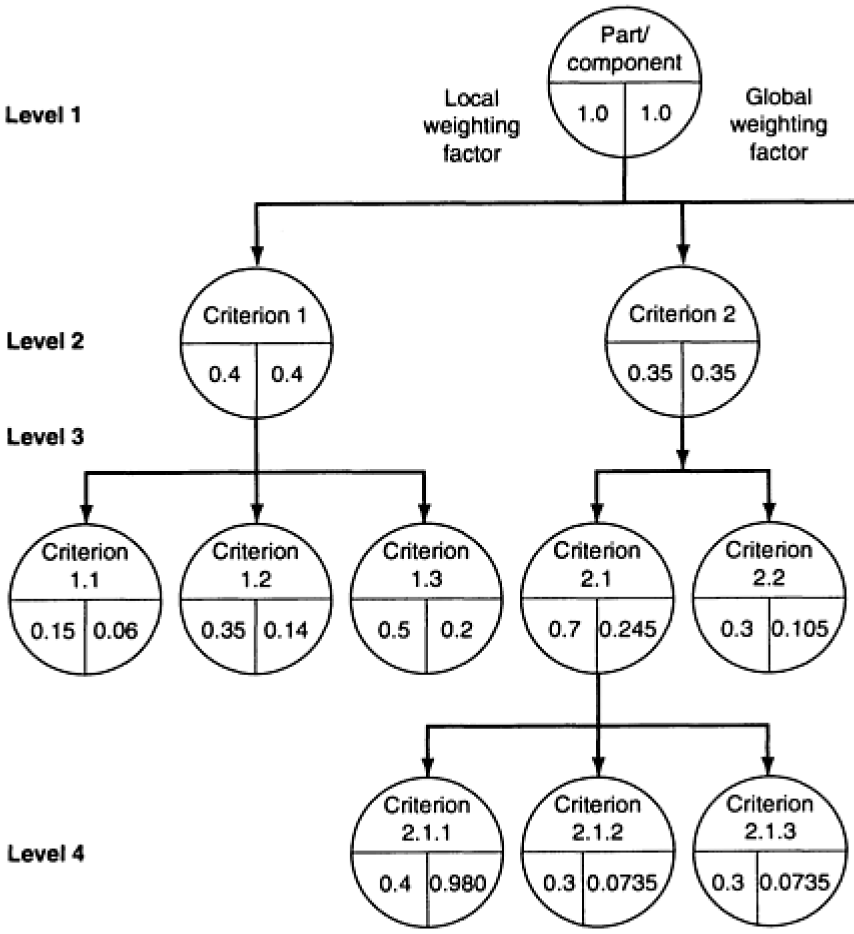

Fig. 1 Pahl and Beitz decision matrix, sample objective tree structure

The second level is a list of the most basic design requirements, usually arising from the concept design description of functional requirements. The relative value of each is assessed by assigning a fractional weighting factor such that the weighting factor sum of criteria in level 2 equals 1.

Level 3 is constructed by further dissection of each level 2 criterion. First, a level 2 criterion is selected. It is dissociated by specification of new criteria with weighting factors such that the sum of the weighting factors equals 1. This continues for each level 2 criterion. The value of these new criteria to the overall design is calculated by multiplying its weighting factor by all "upstream" weighting factors in the objective tree. For example, suppose a level 2 criterion with an assigned weighting factor of 0.4 had three level 3 refinements with weighting factors of 0.15, 0.35, and 0.5. The contribution of the first level 3 refinement to the overall design would be (0.15) (0.4) (1) = 0.06. As shown in Fig. 1, both the "local" weighting factor (0.15) and the "global" weighting factor (0.06) are tallied for each criterion.

Further refinement to additional levels may be required, depending on the complexity of the selection process. The final result is a list of the most refined criteria with global weighting factors assigned. These comprise the selection process criteria and associated weighting factors *w*. These weighting factors sum to 1.

An alternative method of establishing weighting factors is to make a pairwise comparison between all criteria, deciding quantitatively for each pair which is more important (see the article "Overview of Materials Selection" in this Volume).

A matrix of alternatives and criteria is constructed as described for the Pugh and Dominic methods. Suppose there are *k* alternatives and *n* criteria. The matrix is completed by assigning a value *v* to each criterion for each alternative. These values and their meanings come from Table 7 and may be based on either a 5- or 11-value scale (Ref 7, 8). It is sometimes expedient to search for alternatives with extremely good or poor qualities and to assign values there first. Another approach is to convert the property values for each criterion into scaled property values (see the article "Overview of Materials Selection" in this Volume).

Table 7 Value scales for the Pahl and Beitz method

Value	Meaning
5 value scale	
0	Unsatisfactory
1	Just tolerable
2	Adequate
3	Good
4	Very good
11 value scale	
0	Absolutely useless
1	Very inadequate
2	Weak
3	Tolerable

4	Adequate
5	Satisfactory
6	Good with few drawbacks
7	Good
8	Very good
9	Exceeds requirements
10	Ideal

The number of values to assign is (k)(n). Each value may be represented by v_{ij}. Once all values are assigned, the (k)(n) weighed values $(wv)_{ij}$ are computed by multiplying each value v_{ij} by the associated criteria weighting factor w_j. Summing all weighted values for alternative i produces the overall weighted value (OWV_i). This is the raw score for a given alternative. It is customary to normalize overall weighted values to 1 by dividing by the maximum value v_{max} (5 or 10, based on the value scale chosen in Table 7) and the sum of the weighting factors. The formula for this weighted rating, WR_i (also known as the weighted property index), is:

$$WR_i = \frac{\sum_{j=1}^{n} (w_j \times v_{ij})}{v_{max} \sum_{j=1}^{n} w_j}$$

where normally

$$\sum_{j=1}^{n} w_j = 1$$

The weighted ratings provide an indication of which alternatives are clearly superior or inferior. Ideally, the alternative with the highest rating would be selected. However, as mentioned above, this may be done only after analysis of the data to ensure that other alternatives cannot be improved, and after the criteria and the weighting factors have been reconfirmed to be appropriate in light of the results.

Example 3: Use of the Pahl and Beitz Method in Configuration Design Material Selection of an Epicyclic Gear.

The objective in this example was to select a mass-produced, low-cost, lightweight material for a power transmission gear component in a cordless, hand-held power screwdriver. The final design solution was a two-stage epicyclic gear assembly (Fig. 2), necessary to reduce motor rpm by 1:81 and amplify the torque from 50 mJ to over 4 J. The selection was for the three first-stage (low-torque) epicyclic gears. Geometric constraints were a maximum gear diameter of 11 mm and thickness ranging between 1 and 4.5 mm. The torque produced a gear-tooth transmitted shearing/bending force of 35 N. A safety factor of 1.5 was used for all force calculations.

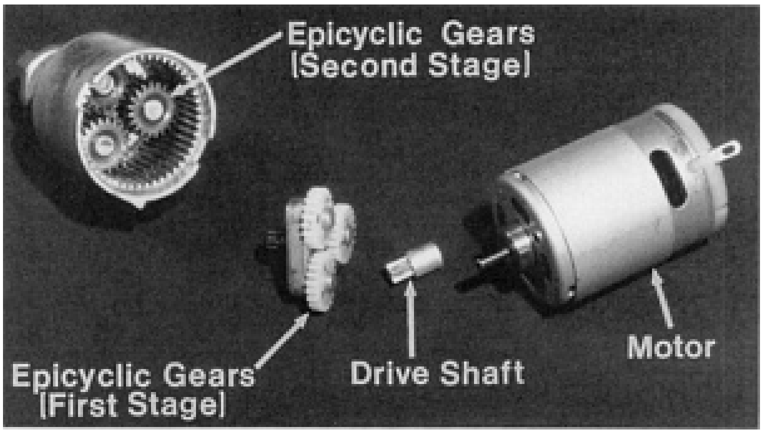

Fig. 2 Epicyclic gear train for a cordless screwdriver

Three primary considerations for selection were light weight, the ability to transmit and amplify the torque, and low component cost. Table 8 lists the nine grouped criteria based on these considerations. A four-level objective tree was constructed to generate the criteria weighting factors (Fig. 3). These weighting factors are listed in Table 8.

Table 8 Pahl and Beitz decision matrix for the selection of an epicyclic gear

Criteria				Alternative 1 30-35% glass-reinforced nylon 6		Alternative 2 40% fiber-glass-reinforced polyester		Alternative 3 Aluminum alloy 380.0-F		Alternative 4 Zinc alloy UNS 33521 (alloy 3)		Alternative 5 Magnesium alloy AZ91B-F	
Primary consideration	**No.**	**Evaluation criterion**	**Weighting factor (w_j)[(a)]**	**Value (v_{1j})**	**Weighted value (w_jv_{1j})**	**Value (v_{2j})**	**Weighted value (w_jv_{2j})**	**Value (v_{3j})**	**Weighted value (w_jv_{3j})**	**Value (v_{4j})**	**Weighted value (w_jv_{4j})**	**Value (v_{5j})**	**Weighted value (w_jv_{5j})**
Light weight (0.20)	1	Light weight	0.20	9	1.80	9	1.80	5	1.00	3	0.60	7	1.40
Amplify and transmit torque (0.3)	2	Tooth shear stress	0.12	4	0.48	3	0.36	9	1.08	8	0.96	7	0.84
	3	Tooth bending stress	0.09	4	0.36	3	0.27	8	0.72	7	0.63	6	0.54
	4	Fatigue strength	0.06	6	0.36	6	0.36	7	0.42	6	0.36	7	0.42
	5	Impact strength	0.03	5	0.15	5	0.15	6	0.18	8	0.24	5	0.15
Low cost (0.5)	6	Material cost	0.15	7	1.05	9	1.35	7	1.05	1	0.15	3	0.45
	7	Mass produced	0.20	9	1.80	6	1.20	7	1.40	8	1.60	9	1.80
	8	Wear rate	0.09	5	0.45	6	0.54	8	0.72	7	0.63	6	0.54
	9	Coefficient of friction	0.06	8	0.48	9	0.54	5	0.30	4	0.24	4	0.24
				OWV_1	6.93	OWV_2	6.57	OWV_3	6.87	OWV_4	5.41	OWV_5	6.38

OWV, overall weighted value; WR, weighted rating.

(a) Sum of all weighting factors equals 1.00.

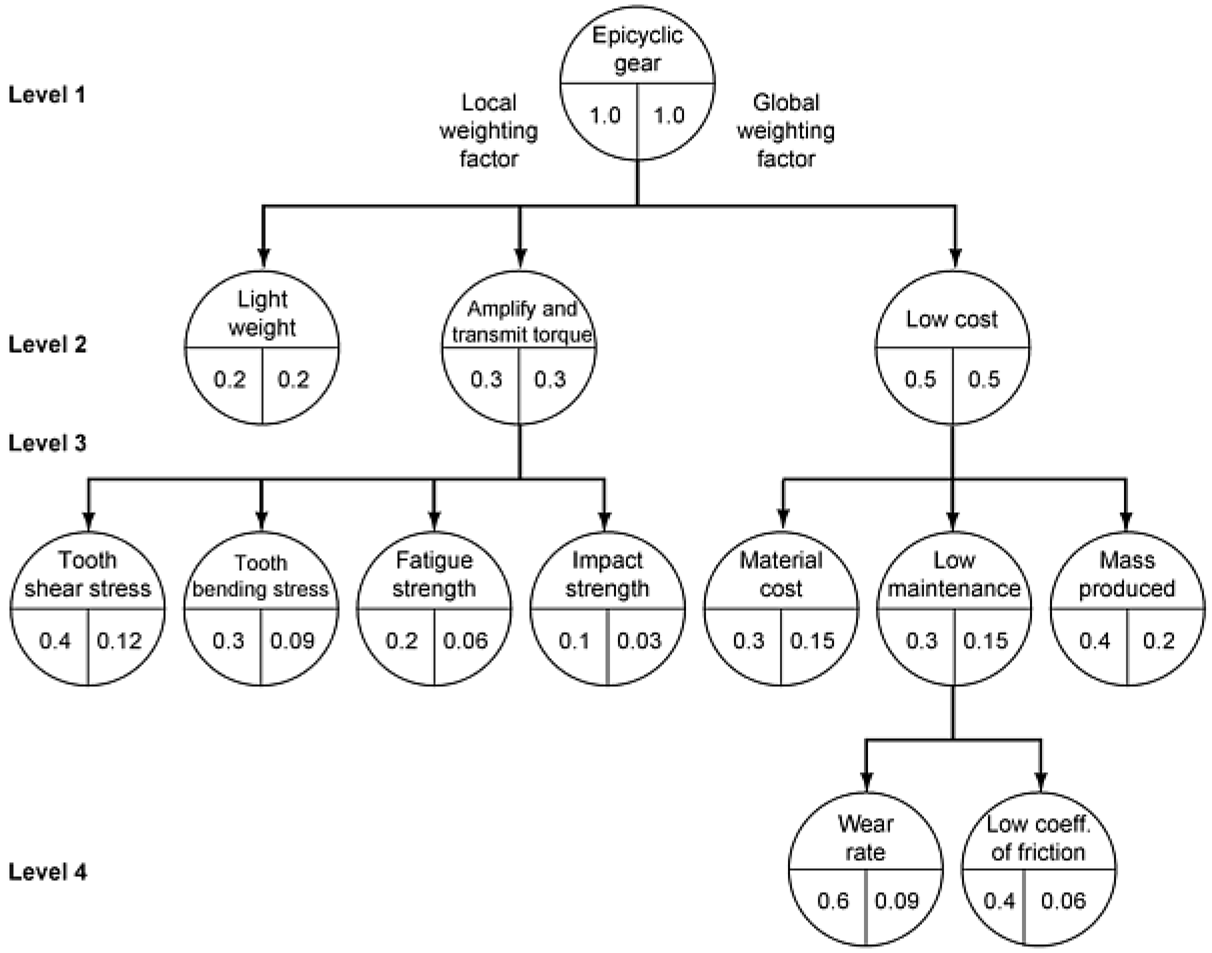

Fig. 3 Pahl and Beitz decision matrix, objective tree for epicyclic gear example

Five alternatives were considered: 30 to 35% glass-fiber-reinforced nylon 6, 40% fiber-glass-reinforced polyester, die-cast aluminum alloy 380.0-F, die-cast zinc alloy UNS 33521 (alloy 3), and die-cast magnesium alloy AZ91B-F. An 11-value scale (Table 7) was used to assign values for each alternative and criterion. Details of the engineering calculations have been omitted for the sake of clarity and brevity. Fundamental property data are compiled in Table 9.

Table 9 Materials properties for the Pahl and Beitz epicyclic gear example

Alternative	Material	Density, g/cm^3	Tensile strength, MPa	Tensile Elongaion, %	Impact strength, J/m	Cost, c/cm^3
1	Glass-reinforced (30-35%) nylon 6	1.38	165	2.2-3.6	117-181[(a)]	0.67
2	Fiber-glass-reinforced (40%) polyester	1.3	138	1.4	374[(a)]	0.32
3	Aluminum alloy 380.0-F	2.71	330	3	400[(b)]	0.51
4	Zinc alloy UNS 33521 (Alloy 3)	7.1	283	10	5800[(c)]	1.16
5	Magnesium alloy AZ91B-F	1.81	230	3	270[(b)]	0.72

(a) Izod.

(b) Notched charpy.

(c) Unnotched charpy

Overall weighted values and weighted ratings for the alternatives were computed and listed at the bottom of Table 8. Nylon and the aluminum alloy had the highest rankings, although the polyester scored well also. After analysis of the selection procedure, nylon was selected for production.

Decision Matrices in Materials Selection

David L. Bourell, The University of Texas at Austin

Conclusions

Decision matrix methods in materials selection are formalized procedures by which materials alternatives are ranked. Three common methods, Pugh, Dominic, and Pahl and Beitz, have been presented as examples of decision matrix methods of varying complexity. Factors governing which of these or other decision matrix methods to use include the complexity of the design, when in the design process the method is used, the level of participation involved in the selection process, and the completeness of the knowledge base for the material alternatives being considered. The result of proper use of a decision matrix method is a documented, bias-free materials selection based on adequate consideration of all important issues.

Relationship between Materials Selection and Processing

George E. Dieter, University of Maryland

Introduction

THE SELECTION OF THE BEST MATERIAL for a particular design is intimately associated with the decisions of how to process the material or manufacture the part. Growing concerns with world economic competitiveness have forced a renewed emphasis on manufacturing as a vital core competency for any industrial enterprise. Major attention is being given to linking product design and manufacturing in a systematic integrated approach called *concurrent engineering.* In concurrent engineering the members of the integrated product design team, from the outset, consider all elements of the product life cycle from concept through disposal, including issues of quality, cost, schedule, and user requirements. (Additional information is provided in the article "Concurrent Engineering" in this Volume.) In view of the increasing recognition of the importance of concurrency in design, there should be no excuse for selection of a material without serious consideration of the alternative manufacturing processes.

As an example, a hydraulic accumulator piston for an automotive transmission was made from a thermoplastic polymer instead of the more conventional aluminum alloy (Ref 1). Use of the glass-filled linear polyphenylene sulfide (PPS) plastic resulted in a 30% reduction in the important functional requirement of weight, coupled with a continuous use temperature of 220 °C (428 °F) and good dimensional stability. The use of precision injection molding permitted as-molded tolerances achieved only in metals with multiple machining operations, and as a bonus, the O-ring was formed into the periphery of the polymer piston. Even though the polymer resin cost more than the aluminum alloy there was a net cost reduction of 10%, due chiefly to the elimination of machining and cleaning steps. This is an example where the selection of a material allowed the use of a manufacturing process with superior capabilities and lower final cost.

As another example, consider a part to be made from an aluminum casting alloy. Three alternative casting processes are sand casting, permanent-mold (gravity-feed) casting, and die casting (see the article "Design for Casting" in this Volume).

The chief differentiating factor between these processes is the cooling rate, which varies from about 0.2 °C/s (0.35 °F/s) for sand casting to 500 °C/s (280 °F/s) for die casting. The highest cooling rate results in the finest grain size, which produces a casting with the highest yield strength and the best fatigue properties and wear resistance. Also, die casting produces the best surface finish, the tightest dimensional tolerances, and, because of pressure feeding, the ability to produce wall thicknesses as small as 1.0 to 2.5 mm. On the negative side, the rapid cooling rate may result in a greater degree of porosity. This is a typical example of how the choice of the manufacturing process can significantly influence the properties of the design. Other important factors influencing this decision are discussed below.

Relationship between Materials Selection and Processing

George E. Dieter, University of Maryland

Characteristics of Manufacturing Processes

This section describes the basic characteristics of manufacturing processes. Although the level of detail is rather elementary, this section provides sufficient detail for selection of processes at the conceptual or embodiment stages of design. For further detail, see the article "Manufacturing Processes and Their Selection" in this Volume.

Material Factors. In a very general sense the selection of a material determines a range of processes that can be used to produce parts from the material. In the article "Overview of the Materials Selection Process" in this Volume, Fig. 4 shows the common classes of manufacturing processes and Table 4 indicates the manufacturing processes used most frequently with different metals and plastics. The melting point of a material and level of deformation resistance and ductility determine these relationships. Some materials are too brittle to be plastically deformed; others are too reactive to be cast or have poor weldability.

The melting point of a material determines the casting processes that can be employed. Low-melting-point metals can be used with any of a large number of casting processes, but as the melting point of the material rises the number of available processes becomes limited. Ashby (Ref 2), has shown a correlation between the size (weight) of a cast part and the melting point of the material (Fig. 1). This plot shows the regions of size that can be handled by different casting and molding processes and shows how the available number of processes decreases dramatically for materials with high melting point. This is one of a number of process selection charts, dealing with casting, metalworking, polymer processing, power fabrication, and machining, introduced by Ashby in Ref 2 to aid in the selection of a manufacturing process in the conceptual stage of design.

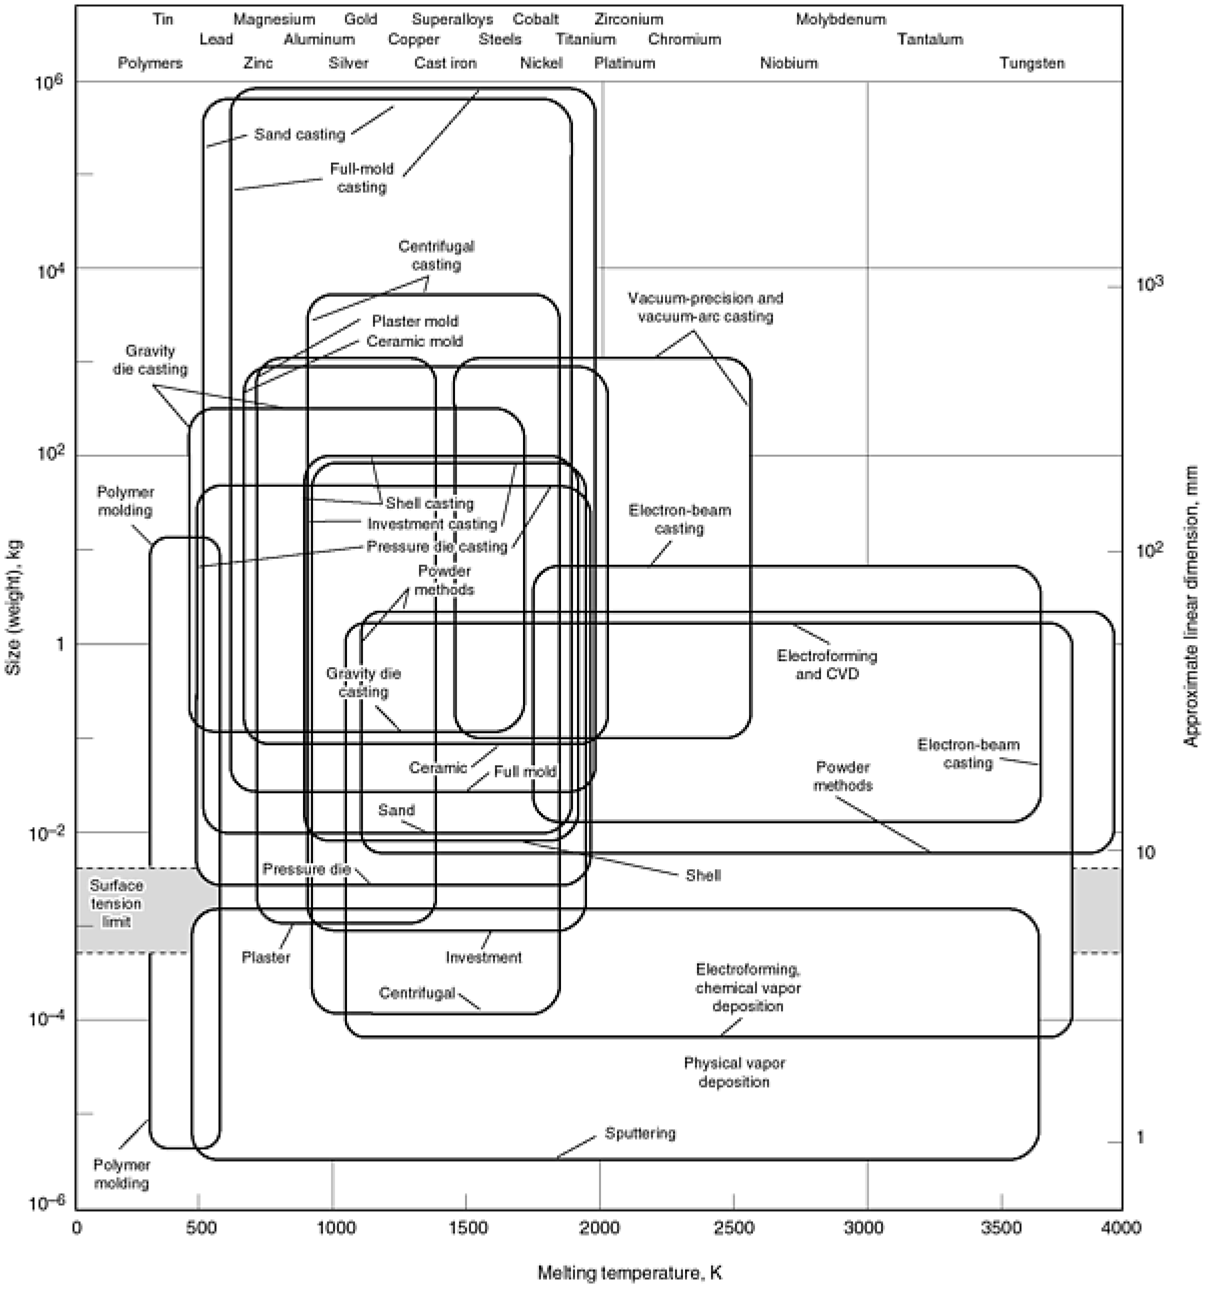

Fig. 1 Ashby process chart for casting. The size in this chart is measured by weight, *W*. It can be converted to volume via the density, ρ, or to the approximate linear dimension, *L*, shown on the right-hand-axis via $L = (W/\rho)^{1/3}$. Source: Ref 2

Similarly, yield strength, or hardness, determines the limits in deformation and machining processes. Forging and rolling loads are related to yield strength and tool life (tool load and temperature generation) in machining scales with the hardness of the material being machined. Ultimately the limit of these processes is determined by the workability of the material. See the section "Workability" in this article.

Shape Factors. Each process has associated with it a range of shapes that can be produced. Thus, the first decision in selecting a process is whether it is capable of producing the required shape. A simple classification of shape is as follows:

Two-dimensional (2D)	**Profile of product does not change along its length. Examples: wire, pipe, aluminum foil. Many 2D products are used as raw material for processes that make them into 3D shapes.**
Three-dimensional (3D)	Profile of the product varies along all three axes. Most products are 3D.
Sheet	Has almost constant section thickness that is small compared with the other dimensions.
Bulk	Has a complex shape, often with little symmetry. Solid: has no significant cavities. Hollow: has significant cavities.

Whether the process can accommodate shapes with undercuts, or reentrant angles, or parts with an element positioned perpendicular to the main die motion also must be determined.

The factors that contribute to complexity of shape are:

- The requirement to achieve a minimum section thickness
- The presence of undercuts and reentrant angles
- The presence of complex internal cavities

See the article "Manufacturing Processes and Their Selection" in this Volume for more in-depth consideration of shape and its relationship to process selection. The classification of shapes is an active field of research in manufacturing. An important application is *group technology,* which aims at utilizing the similarity of parts based on their geometrical features, because similar shapes tend to be produced by similar processing methods (Ref 3). Application of group technology requires the adoption of detailed numerical coding systems, but the benefits in design and manufacturing can be rather widespread. These include ability to generate quickly designs for similar-shaped parts, control of part proliferation and redundant designs, standardization of design features such as chamfers, corner radii, tolerances, grouping of machine tools into more productive units, development of jigs and fixtures that can accommodate different members of a part family, and the development of computer-based process selection methods.

Process Factors. Key manufacturing process factors include cycle time, quality, flexibility, materials utilization, and operating cost.

Cycle time is the time required to process one unit, once the process has been set up and is operating properly. The inverse of cycle time is production rate.

Quality is an inclusive term describing fitness for use. Included under this characteristic is surface roughness, ability to manufacture parts to a set tolerance, product integrity (freedom from voids, pores, cracks, and inclusions), and ability to produce controlled properties (microstructure control).

Flexibility in manufacturing is the ease with which a process can be adapted to produce different products or variations of the same product. In an era where product customization is becoming more important, this characteristic has gained importance. Flexibility is influenced greatly by the time to change and set up tooling.

Materials utilization measures the amount of material processed in addition to the material required in the product. Most machining operations generate 60 to 80% scrap. Net-shape forging and injection molding are at the other extreme. As materials costs become the greater part of the product cost, materials utilization becomes of greater importance.

Operating cost involves both the capital cost of plant, machinery, and tooling and the labor costs of setting up and running the process. Process selection often is constrained by the available equipment, particularly if the desired process is costly to install. In any manufacturing situation, one available decision is whether to outsource the production to a qualified subcontractor.

A rating system for evaluating these five process characteristics is given in Table 1. This is applied to rating the most common manufacturing processes in Table 2. Another system, using somewhat different process characteristics, is given in Table 4 of the article "Overview of the Materials Selection Process" in this Volume.

Table 1 Scale for rating manufacturing processes

Rating	Cycle time	Quality	Flexibility	Materials utilization	Operating costs
1	>15 min	Poor quality, average reliability	Changeover extremely difficult	Waste > 100% of finished component	Substantial machine and tooling costs
2	5 to 15 min	Average quality	Slow changeover	Waste 50 to 100%	Tooling and machines costly
3	1 to 5 min	Average to good quality	Average changeover and setup time	Waste 10 to 50%	Tooling and machines relatively inexpensive
4	20 s to 1 min	Good to excellent quality	Fast changeover	Waste < 10% finished part	Tooling costs low/little equipment
5	<20 s	Excellent quality	No setup time	No appreciable waste	No setup costs

Rating scheme: 1, poorest; 5, best. Source: Ref 4

Example 1: Selection of Plastics for an Automobile Bumper.

This hypothetical, but realistic, example is taken from Ref 4. The functional requirements for a material for a car bumper are:

- Adequate rigidity to maintain dimensional limits of the structure
- Adequate impact resistance down to -30 °C (-22 °F)
- Resistance to degradation from ultraviolet radiation and spillage of gasoline
- Dimensional stability to prevent distortion over the operating temperature range
- Ability for the plastic to be finished to match the adjoining painted metal parts

With these performance requirements of chief importance, four polymeric materials were chosen from the large number of engineering plastics:

- Polyester reinforced with chopped-glass fiber to improve toughness
- Polyurethane with glass-flake filler to increase stiffness
- Rubber-modified polypropylene to decrease the ductile-brittle transition to below -30 °C (-22 °F)
- A polymer blend of polyester and polycarbonate to combine the excellent solvent resistance of the former with the high toughness of the latter

It is important to note that, in each case, the plastic was modified in some way to improve one or more critical properties.

The processing characteristics of these polymers and considerations of the shape of the bumpers restrict the choice of manufacturing process to the four processes listed in Table 3. A comparison among the four processes shows that materials utilization and quality are not deciding factors. However, there is a distinct interaction between cycle time (production rate) and flexibility and tooling cost. Deciding on the best manufacturing process requires a more detailed examination of the relationship between production volume and cost.

Table 3 Comparison of processes for producing automotive bumpers

Process	Cycle time	Flexibility	Materials utilization	Quality	Equipment/ tooling costs
Injection molding	4	1	4	3	1
Reaction injection molding	3	2	4	2	2
Compression molding	3	4	4	2	3
Contact molding	1	4	4	2	4

Rating scheme: 4, best; 1, worst

The four processes differ mainly in the investment in mold costs and in the amount of time required to produce a part. The assumed values for these parameters are:

Process	Mold cost	Labor input/unit
Injection molding	$450,000	3 min = $1
Reaction injection molding	$90,000	6 min = $2
Compression molding	$55,000	6 min = $2
Contact molding	$20,000	1 h = $20

Then the part cost is the sum of the mold cost per part plus the labor input, neglecting material cost. The data in Table 4 indicate that this varies considerably depending on the production volume. At 1000 parts the least expensive process is contact molding. At 10,000 and 100,000 parts it is compression molding, while at 1 million parts it is injection molding. The concept of a break-even point on batch size, or economic lot size (as discussed in the article "Overview of the Materials Selection Process," and shown there in Fig. 7) is exemplified by the data in Table 4.

Table 4 Cost per part for four processes at different production levels

Process	Cost per part			
	1000 parts	**10,000 parts**	**100,000 parts**	**1,000,000 parts**
Injection molding	$451	$46	$5.50	$1.45

Reaction injection molding	$92	$11	$2.90	$2.09
Compression molding	$57	$7.50	$2.55	$2.06
Contact molding	$40	$22	$20.20	$20.02

Additional information on the selection, properties, and processing of engineering plastics is provided in the articles "Overview of the Materials Selection Process," "Effects of Composition, Structure, and Processing on Properties of Engineering Plastics," "Design with Plastics," and "Design for Plastics Processing" in this Volume.

Relationship between Materials Selection and Processing

George E. Dieter, University of Maryland

Influence of Materials on Manufacturing Cost

A major shift in manufacturing throughout this century has seen a decrease in the percent of the cost of manufactured goods attributed to direct labor from 50 to 10%, with a corresponding increase in the fraction due to materials from 30 to 60% (Ref 6). As a result, design changes that reduce the amount or cost of materials or purchased components can have a direct and major influence on profits. Figure 2 shows the buildup of cost elements that make up the selling price of a product.

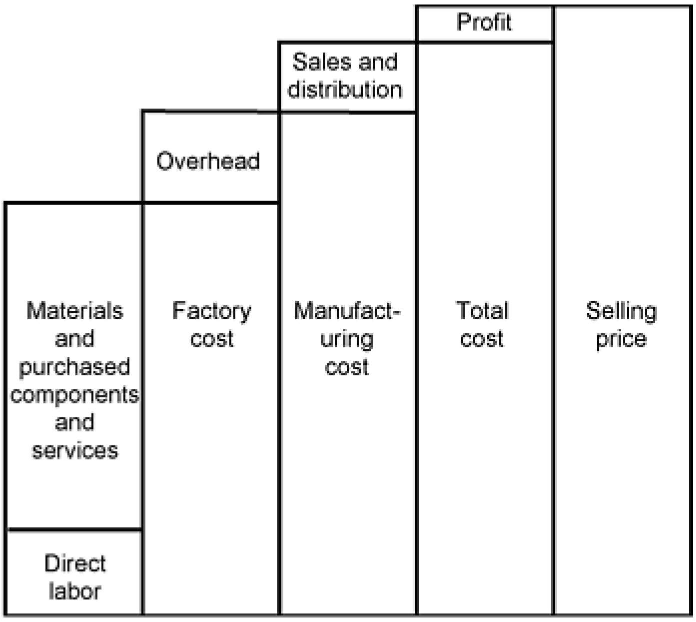

Fig. 2 Buildup of cost elements to establish selling price

Example 2: Manufacturing Cost Models.

Table 5 lists four cost models for producing a product (Ref 7). For simplicity, the selling price per unit is $100. Model A represents the current distribution between the cost elements shown in Fig. 2.

Table 5 Comparison of four product cost models

	Model A	Model B	Model C	Model D
Selling price	$100	$100	$100	$100
Units sold	100	105	100	100
Revenues	$10,000	$10,500	$10,000	$10,000
Direct labor	$1,500	$1,575	$1,425	$1,500
Materials	$5,500	$5,775	$5,500	$5,225
Overhead	$1,500	$1,575	$1,525	$10,500
Sales and distribution	$1,000	$1,050	$1,000	$1,000
Total costs	$9,500	$9,975	$9,450	$9,225
Profit	$500	$525	$550	$775

Source: Ref 7

Cost model B shows what would happen if sales were increased by 5%. There would be a 5% increase in the four cost elements, while the unit costs remain unchanged. Costs and profits rise to the same degree as sales.

Cost model C shows what happens with a 5% productivity improvement (5% decrease in direct labor) brought about by a process-improvement program. The small increase in overhead results from the new equipment that was installed to increase productivity. Note that the profit per unit has increased by 10%.

Cost model D shows what happens with a 5% decrease in the cost of material or purchased components. This could also result from a design modification that allows a change to a less-expensive material or eliminates a purchased component. In this case, barring an extensive development program, all of the cost savings goes to the bottom line and results in a 55% increase in the unit profit.

Relationship between Materials Selection and Processing

George E. Dieter, University of Maryland

Design for Manufacturability

With increased awareness of the importance of the interaction between design and manufacture a new field aimed at formalizing this relationship is evolving, called "design for manufacturability" (DFM). The DFM approach examines the product design in all aspects for ways of integrating the product and its processing so that the best match is made between product and process requirements and that the integrated product/process ensures inherent ease of manufacture. A major objective of DFM is to ensure that the product (including material selection) and the process are designed together. While DFM methods have not given much attention to the materials selection question, the ideas of DFM are important to consider when selecting a material in relationship to possible manufacturing processes. The subject is reviewed briefly here following the approach of Bralla (Ref 8). For a more in-depth consideration of DFM, see the articles "Introduction to Manufacturing and Design," "Design for Manufacture and Assembly," and "Manufacturing Processes and Their Selection" in this Volume.

Minimize Total Number of Parts. Maximum cost savings result when a part is eliminated or combined with another, rather than just being simplified. A part that is eliminated costs nothing to make, assemble, move, store, clean, inspect, rework, or service. A part is a candidate for elimination if there is no need for relative motion between the part and some other element of the design, no need for subsequent adjustment between parts, and no need for the materials to be different. However, part reduction should be taken so far that costs increase because of increased complexity or weight. The best way to achieve part reduction is to establish minimum part count as a functional requirement at the conceptual design stage. Replacing fasteners by snap fits in plastic covers and designing parts to be multifunctional by incorporating hinges, springs, guides, and bearings are good approaches. Plastic parts are particularly well suited for multifunctional integral design (Ref 9).

Standardize. Major cost savings are achieved when the design of products, subassemblies, components, modules, and individual parts are standardized. Attempts should be made to utilize standard parts and components in a line of products. Similar parts should all be shaped and dimensioned the same. Standard catalog components should be used when applicable. The goal should be to not only reduce the number of parts, but to reduce the number of part numbers, that is, the number of distinct part designs needed to produce a line of products.

Use Readily Processed Materials. The topic is addressed later in this article in considerable detail. At this point two cautions are appropriate: (1) never compromise the quality of a part by selecting a more readily processed material, and (2) it is the final part cost that counts, not the initial material cost.

Fit the Design to the Manufacturing Process. The best overall result with respect to cost, function, and quality usually is achieved when the product design is developed for the particular manufacturing process that will be used to make the part. This argues for a process-first, materials-second approach to materials selection. For the many applications where performance is not paramount or difficult to achieve, this is the approach to use. The best manufacturing economy, highest quality, and shortest time-to-market usually are achieved when the product is made using the facilities, equipment, tooling, and know-how that already exist in the company factory or that of a regular vendor.

Design Each Part to be Easy to Make. The inherent capabilities and constraints of each manufacturing process must be known and considered by the design team (Ref 10). These are expressed in the form of design guidelines, design rules, and design standards. The articles in the Section "Manufacturing Aspects of Design" of this Volume that consider each of the manufacturing processes contain much of this type of information. With this knowledge, the designer should minimize needed fixturing, specify tolerances easily met by the process, minimize secondary operations, and design so that finishing operations are not required.

Eliminate Machining and Finishing Operations. Machining and finishing operations are inherently expensive and should be eliminated provided this will not compromise quality. One way to do this is to use as-cast, as-molded, and as-formed surfaces as much as possible instead of machined surfaces. Another approach is to use near-net shape processes such as powder metallurgy, fine blanking, and investment casting.

Relationship between Materials Selection and Processing

George E. Dieter, University of Maryland

Factors in Selecting a Material for Production

The ultimate criterion for selection of materials is the cost to produce a quality part. For selection of the best material for producing a part the following factors must be considered:

- Material composition: grade of alloy or plastic
- Form of material: bar, tube, wire, strip, plate, powder, and so forth
- Size: dimensions and tolerances
- Heat-treated condition
- Directionality of mechanical properties (anisotropy)
- Surface finish
- Quality level: control of impurities, inclusions, and microstructure
- Quantity: volume of production (batch size)
- Ease of manufacture: workability, weldability, castability, and so forth
- Ease of recyclability
- Cost of material

Cost is the basis to which the above factors are reduced to reach a decision on material selection. Generally, the least expensive material consistent with achieving the required properties is selected. The selection of the grade of material will establish the composition, which along with the processing, will establish the properties (see the Section "Effects of Composition, Processing, and Structure on Materials Properties" in this Volume). The caveat should be given that it is the final part cost that must be minimized. Thus, it may well be that a more expensive material will result in a less expensive product because it can employ a more economical manufacturing process. This section discusses these kinds of trade-offs. The most common is the decision whether to use material A with process B versus material C with manufacturing process D. Methods for calculating the part or component (assembled parts) cost at an early stage in design have been developed, as described in Ref 11 and 12 and in the article "Design for Manufacture and Assembly" in this Volume. Such methods are essential for widespread adoption of intelligent decision making concerning material selection and process selection.

For geometrically simple parts, such as straight shafts, the most economical raw material form and method of manufacture are readily apparent. As the shape of the part becomes more complex, the applicability of two or more forms and methods of manufacture add complexity to the selection process. For example, a small gear may be completely machined from bar stock. However, it might be more economical to start with a close-tolerance forged gear blank, depending on the total number of parts to be produced. For a small gear the total cost of making 100 pieces might favor machining from bar. At 10,000 or more parts the forged or powder metallurgy gear blank might show an economic advantage. With a larger gear, if only 500 pieces were to be made, it might be more economical to leave the hub solid and drill the bore. At 5000 pieces it would probably pay to have the hub pierced in the forging operation.

Figure 3 shows an example where change in form resulted in economy (Ref 13). A type 321 stainless steel tube was slotted in eight locations. Milling the slots was difficult because the tube was thin, and the labor cost for removing the burrs on the inside was high. The problem was solved by changing the form of the raw material to a type 321 sheet. The slots were punched into the sheet, which was then formed and welded into the required tubular part.

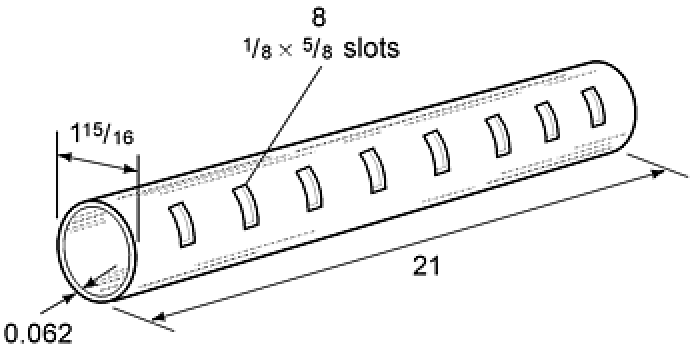

Fig. 3 Slotted tubular part. Dimensions in inches. Source: Ref 13

The workpiece should be just enough larger than the final part to allow for removal of surface defects. Thus, extra material in a casting may be necessary to permit machining a critical surface to the needed finish, or a heat-treated steel part may be made oversize to allow the removal of a decarburized layer. Often the manufacturing process dictates the use of extra material, such as sprues and risers in castings and flash in forging and injection molding. Sometimes extra material must be provided for purposes of handling, positioning, or testing the part. Even though extra material removal is costly, it usually is less expensive to purchase a slightly larger workpiece than to pay for a scrapped part.

Most engineering alloys can be purchased from the supplier in a variety of metallurgical conditions other than the annealed state. Examples include quenched-and-tempered steel, solution-treated, cold-worked and aged aluminum alloys, and cold-drawn and stress-relieved brass rod. It may prove to be more economical to have the metallurgical strengthening produced in the workpiece by the material supplier than to heat treat it separately after it has been manufactured. For example, a cap nut was machined from type 1144 steel bar, hot drawn to a yield strength of 825 MPa (120 ksi) and a hardness of 35 HRC. This material replaced 4140 steel, machined and heat treated to 30 to 35 HRC, which had resulted in as much as 40% scrap rate due to distortion (Ref 13).

A metal that has undergone a severe amount of deformation, for example from rolling or wire drawing, develops a preferred orientation, or texture, in which certain crystallographic planes orient themselves in a preferred manner with

respect to the direction of maximum strain. A cold-worked metal that has been annealed generally shows a preferred orientation (annealing texture) that is different from and stronger than the texture that existed in the deformed metal. Just as the flow stress of a single crystal varies with orientation, so the tensile properties of a metal sheet with a texture will vary with the direction the axis of the tensile specimen makes with the rolling direction of the sheet. This type of anisotropy is important in producing nonuniform deformation in deep-drawn cups (earing) and in determining the deep-drawing capability of the sheet. It is measured by the *r* value, described in the section "Formability" in this article (see Eq 6).

Another source of the variation of properties with direction of working is mechanical fibering caused by the alignment of inclusions, porosity, and second-phase constituents in the main direction of mechanical working. This kind of anisotropy is important in forgings and rolled plates. The principal direction of working is defined as the longitudinal direction. This is the long axis of a forged bar or the rolling direction of a sheet or plate. The two directions perpendicular to this direction are the transverse directions. Generally, mechanical properties are lowest in the short-transverse direction, for example, the thickness of a plate. Measures of ductility (reduction in area), fatigue, and fracture toughness properties are most affected by mechanical fibering.

In metals there is a general relationship between surface roughness and the tolerance that can be maintained. Moreover, each manufacturing process has a range of surface roughness that can be achieved without extra effort (see Figure 5 in the article "Overview of the Materials Selection Process" in this Volume). Table 6 describes the range of achievable surface roughness. In polymers, excellent surface finish is obtained with most molding processes, but the dimensional stability (tolerances) depends on the particular polymer and the processing conditions. Whatever the material, tightening the tolerances causes manufacturing cost to increase exponentially.

Table 6 Range of surface finishes

Surface finish, μin.	Description
250	Results from ordinary machining at medium feeds. Not objectionable in appearance. Can be used for surface of noncritical components.
125	Results from high-quality machining with light cuts, fine feeds, and sharp tools. Can be used for bearing surfaces with light loads and moderately stressed parts. Should not be used for sliding surfaces.
63	A high-quality, smooth machine finish. As smooth a finish as can be produced by turning or milling without a subsequent operation. Suitable for ordinary machine parts where fatigue is not a problem.
32	A fine machine finish produced by careful turning, milling, and drilling followed by grinding and broaching. Normally found in parts subjected to stress concentration and vibration, such as gear teeth and brake drums.
16	This finish is used where the surface finish is of primary importance in the functioning of the part: rapidly rotating shaft bearings, heavily loaded bearings, hydraulic applications. Produced by diamond tools or precision grinding.
8	Scratch-free, close-tolerance finish used for parts like the inside diameter of hydraulic cylinders, pistons, cam faces. Produced by diamond turning or boring, or precision grinding.
4	A mirrorlike surface that is free from visible scratch marks. Typically used in high-quality bearings. Very high cost finish. Produced by lapping, honing, and precision grinding.

The cost of the material has a major influence on the cost of a manufactured part. The cost of metals depends on the availability of the ore, the cost of mining, the cost of reduction and refining, and the supply and demand. For polymers, the cost depends on the intermediate chemicals involved in the polymerization. Because metals invariably are used as

alloys, and polymers are more frequently used as blends, the costs of the engineering material depend on what materials are combined and how this is achieved. The control of impurities often adds significantly to the material cost. Usually material costs are expressed as cost per unit weight, but often materials serve space-filling functions, so that cost per unit volume would be more appropriate. Table 7 shows a comparison of material costs based on mass and volume. Note how the relative cost of engineering polymers is reduced when expressed on a volume basis. These costs should only be used on a relative basis and then with considerable caution because not all materials are in the same stage of the materials-processing chain. Table 8 illustrates this point by showing the cost buildup in various steel products.

Table 7 Costs of some materials based on mass and volume

Material	Cost per unit mass, $/kg
Germanium	365
Silver	164
Cobalt	31

Ease of Manufacture

This section deals with the role of the material in successfully producing a quality part. Such terms as formability, workability, castability, machinability, and weldability are implied by this topic. This section emphasizes defining those material characteristics that aid or hinder the production of a part without defects. Certain characteristics of a material are inherent in the selection of the manufacturing process; for example, a molten metal that reacts strongly with the atmosphere would not be selected for casting in air, but there are more subtle issues and materials selection tests that need to be considered.

Casting of Metals

Castability deals with a complex combination of liquid-metal properties and solidification characteristics that promotes accurate and sound castings. The factors that influence castability are fluidity, shrinkage, and resistance to hot cracking.

Fluidity is the ability of liquid metal to run freely and fill a mold cavity. Because the viscosity of molten metals is very low, fluidity is determined more by the solidification dynamics of the metal and the mold. A high surface tension of the liquid metal reduces fluidity. Oxide films forming on the surface of the molten metal thus have a significantly adverse effect on fluidity. Insoluble inclusions also reduce fluidity. The pattern of solidification of the alloy is important. Fluidity is inversely related to the temperature range over which solidification occurs. Thus, pure metals and eutectic alloys, with short freezing range, have greater fluidity. Fluidity is usually evaluated by pouring the metal into a narrow spiral mold cavity and measuring the length of penetration of the metal before it solidifies.

Shrinkage is an important castability factor in deciding whether the alloy has a high tendency to form shrinkage porosity. Unfortunately, there is no standard test for shrinkage. See the article "Design for Casting" in this Volume for a discussion of how to control shrinkage porosity in casting design.

Resistance to hot cracking is the ability of the alloy to withstand stresses developed by the contraction while cooling from the hot-short temperature range.

Castability is an integrated property that combines these three factors. One way to approach this is to rate the alloys on a scale of 1 to 5 for each of the important factors, use a weighting for the importance of each factor, and use a decision matrix to arrive at a ranking for each casting alloy (see the article "Decision Matrices in Materials Selection" in this Volume). Table 9 shows typical applications for metal alloys and relative ratings with respect to castability, weldability, and machinability. Note that these are general overall ratings for a class of alloys. Within each class, different alloys vary considerably with respect to specific process characteristics (see Table 10).

Table 9 Typical applications for castings and general rating of castability, machinability, and weldability

Casting alloy type	Applications	Castability	Machinability	Weldability
Aluminum	Pistons, clutch housings, exhaust manifolds	1-2	1-2	3
Copper	Pumps, valves, marine propellors	1-3	1-2	3
Gray iron	Engine blocks, gears, brake disks and drums, machine bases	1	2	5

Magnesium	Crankcases, transmission housings	1-2	1	2
Malleable iron	Farm and construction machinery, heavy-duty bearings, railroad rolling stock	2	2	5
Nickel	Gas-turbine blades, pump and valve components for chemical plants	3	3	3
Nodular iron	Crankshafts, heavy-duty gears	2	2	5
Steel (carbon and low alloy)	Die blocks, heavy-duty gear blanks, railroad wheels	3	2-3	1
Steel (high alloy)	Gas-turbine housings, pump and valve components, rock-crusher jaws	3	3	1
White cast iron	Ball mill liners, shot-blasting nozzles, railroad brake shoes, crushers	2	4	4
Zinc	Door handles, radiator grilles, carburetor bodies	1	1	5

(a) Ability of alloy to withstand stresses from contraction while cooling through hot short or brittle temperature range.

(b) Ability of liquid alloy to flow readily in mold and to fill thin sections.

(c) Decrease in volume accompanying freezing of alloy and a measure of amount of compensating feed metal required in form of risers.

(d) Based on resistance of alloy in standard salt spray test.

(e) Composite rating based on ease of cutting, chip characteristics, quality of finish, and tool life.

(f) Based on ability of material to be fusion welded with filler rod of same alloy.

Polymer Processing

The chief material property influencing the processing of a polymer is its viscosity. Viscosity is a fluid property that relates shear stress experienced during the flow of a fluid to the rate of shear (shear strain rate). This property controls processing because most polymer processes involve the flow of the polymer melt through small channels or die openings. Because of their long-chain molecular structure the viscosity of polymers is many orders of magnitude higher than liquid metals. This means that high pressures are required to force the polymer melt into the mold cavity at a suitable rate. Polymers are non-Newtonian fluids; the viscosity usually decreases with increasing strain rate, as well as with increasing temperature. The fluidity of a polymer melt is often characterized by the melt flow index. This standardized test measures the amount, in grams, of a thermoplastic resin that can be forced through a 2.0955 mm (0.0825 in.) orifice when subjected to 20 N (2160 gf) for 10 min at 190 °C (375 °F). Polymer melts also exhibit viscoelasticity, which results in *die swell* by which the hot polymer expands and changes shape when exiting a die opening or the mold. Table 11 shows whether these and other processing characteristics of the polymer melt are important considerations in selecting a polymer process. The article "Design for Plastics Processing" in this Volume provides a more detailed description of the processes.

Table 11 Polymer melt characteristics important in various processes

Process	Viscosity	Thermoset	Thermoplastic	Melt fracture	Die swell	Rate of reaction
Blow molding	Medium		X

Deformation Processing of Metals

Two kinds of plastic deformation processes must be recognized. In three-dimensional, or bulk deformation, processes the material is deformed in all three principal directions. Here, the limit on deformation is concerned chiefly with the fracture of the material, and so ways to describe its workability are of interest. In two-dimensional, or sheet-forming, operations the deformation limit is caused by buckling, excessive thinning, or fracture; therefore, ways to describe the formability of the material are considered.

Workability is a complex technological concept that depends not only on the fracture resistance (ductility) of the material but also on the specific details (stress state) of the deformation process, as determined by die geometry, workpiece geometry, and lubrication conditions. The greater the workability of a material the greater the deformation and/or the more complex the shape that can be produced before fracture occurs. Ease of manufacture also is aided when the material has a low flow stress (yield strength) so that the force that must be applied by the processing equipment and the stresses on the dies are lower. Because flow stress decreases with increasing temperature, much plastic deformation of metals is carried out at elevated temperature (hot working).

Crack formation that limits workability is usually a form of ductile fracture. At temperatures lower than about one-half the melting point (absolute scale) this is the familiar dimple-rupture mode, but at higher temperature fracture initiated by grain-boundary sliding or cavitation can occur (Ref 18). Workability problems can also arise when deformation is localized to a narrow zone. Flow localization is caused by the formation of a dead-metal zone between the workpiece and the tooling, either because of poor lubrication or because the dies are cooler than the workpiece. Localized flow can also result from flow softening due to structural instabilities such as adiabatic heating, grain coarsening, or spheroidization.

The workability of a material is not a fixed material property. The state of stress in the workpiece imposed by the geometry of the deformation process greatly affects the workability. Stress states with high compressive components that impede crack initiation or propagation enhance workability. A general workability parameter, β, that corrects for stress state is given as (Ref 19):

$$\beta = \frac{3\sigma_m}{\bar{\sigma}} \quad \text{(Eq 1)}$$

where σ_m is the mean or hydrostatic component of stress:

$$\sigma_m = \frac{1}{3}(\sigma_1 + \sigma_2 + \sigma_3) \quad \text{(Eq 2)}$$

and $\bar{\sigma}$ is the effective stress:

$$\bar{\sigma} = \frac{1}{\sqrt{2}}\sqrt{(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2} \quad \text{(Eq 3)}$$

Figure 4 shows the strain to fracture plotted against the parameter β. The curve is determined from three basic mechanical property tests: tension, torsion, and compression. The appropriate parameters for each of these tests are given in Table 12. Also shown in Fig. 4 are the location of the most common bulk metal deformation processes in terms of the level of compressive stress state.

Table 12 Evaluation of β parameter

Test	Principal stresses	Effective stress	Mean stress	β	Strain-to-fracture measurement
Tension	σ_1:$\sigma_2 = \sigma_3 = 0$	σ_1	$\frac{\sigma_1}{3}$	1.0	$\varepsilon_f = \ln \frac{A_0}{A_n}$ at necking
Torsion	$\sigma_1 = -\sigma_2$; $\sigma_3 = 0$	$\sqrt{3}\sigma_1$	0	0	$\varepsilon_f = \frac{r\theta}{\sqrt{3}L}$
Compression	$-\sigma_1$; $\sigma_2 = \sigma_3 = 0$	σ_1	$-\frac{\sigma_1}{3}$	-1.0	$\varepsilon_f = \ln \frac{A_f}{A_0}$

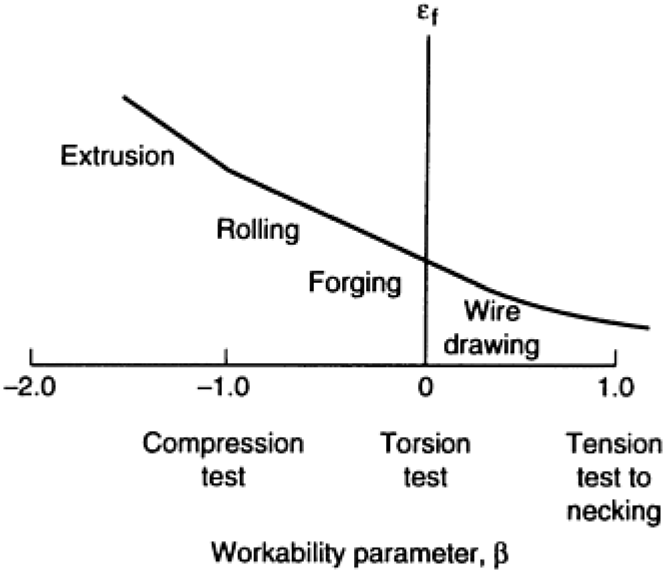

Fig. 4 Influence of stress state on strain to fracture. Source: Ref 18

One of the most successful and useful design tools to assess workability for free surface fracture is the fracture locus diagram (Fig. 5) (Ref 20). The plot shows the locus of free surface strains (one tensile and the other compressive) that cause fracture. These are obtained from tests on upset compression and bend-test specimens. For many metals the fracture locus is a straight line of slope $-\frac{1}{2}$. To use the fracture diagram, the calculated surface strains estimated to be developed during the deformation process are superimposed on the fracture locus diagram. If the final strain for processing the part lies above the fracture line for the material then part failure is expected. As shown in Fig. 5, one can either change to a material B with better workability or change the process conditions (lubrication, die design, or preform design) to reduce the level of surface tensile strain, for example, strain path b. Additional information is provided in the article "Design for Deformation Processes" in this Volume.

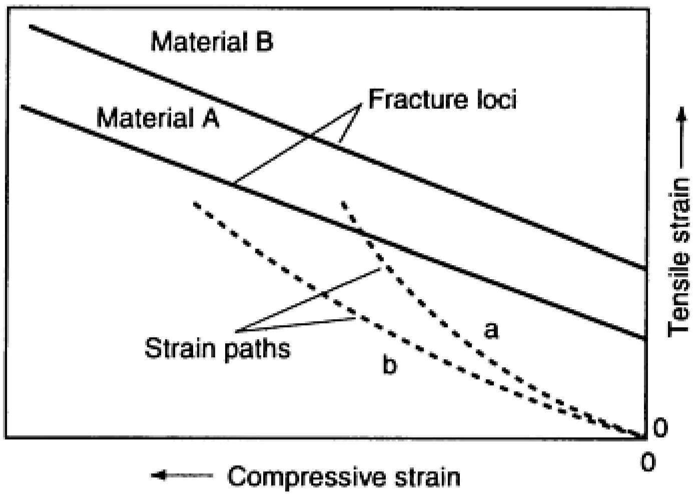

Fig. 5 Schematic workability diagram for bulk deformation processes. Strain path a would lead to failure for material A. Both strain paths can be used for the successful forming of material B. Source: Ref 20

A large number of workability tests have been developed for bulk deformation processes (Ref 21, 22). In addition to the primary tests of tensile, upset compression, bend, and torsion, there are tests such as plane-strain compression, partial-

width indentation, ring compression, and forgeability tests such as wedge forging, sidepressing, and the notched-bar upset tests.

Formability. The term formability is commonly used to describe the ability of a sheet metal to maintain its structural integrity while being plastically deformed into a shape. Failure can occur by tearing, buckling and wrinkling, or excessive thinning. An ideal material from the standpoint of formability should:

- Distribute the strain in the sheet uniformly (high *m*)
- Achieve high strain levels without necking or fracture (high *n*)
- Withstand in-plane compressive stresses without wrinkling
- Withstand in-plane shear stresses without fracturing
- Retain part shape on removal from the die
- Retain a smooth surface and resist surface damage

The strain distribution is determined by three material properties measured with the tensile test. The *strain-hardening exponent,* also known as the *n* value, is expressed as:

$$n = \frac{(\ln \sigma)}{d(\ln \varepsilon)} \qquad \textbf{(Eq 4)}$$

where σ is true stress and ε is true strain. The *strain-rate sensitivity,* also known as the *m* value, is expressed as:

$$m = \frac{d(\ln \sigma)}{d(\ln \dot{\varepsilon})} \qquad \textbf{(Eq 5)}$$

The *plastic strain ratio* (normal anisotropy), or *r* value, is expressed as:

$$r = \frac{\varepsilon_w}{\varepsilon_t} = \frac{\ln (w/w_0)}{\ln (t/t_0)} \qquad \textbf{(Eq 6)}$$

where ε_w is the true strain in the width direction of the tensile specimen and ε_t is the true strain in its thickness direction.

The *r* value is a measure of the ability of the material to resist thinning while undergoing width reduction. A high *r* value is the measure of a material with good deep-drawing characteristics. High values of *n* and *m* lead to good formability in stretching operations because they promote uniform strain distribution, but they have little effect on drawability.

A forming limit diagram has been established for sheet metals by subjecting the sheet to various ratios of major to minor in-plane strains and plotting the locus of strain ratios for which local thinning (necking) and failure occur (Fig. 6). Strain conditions on the left side, where circles distort to ellipses, represent drawing conditions, while the right side where circles distort to larger circles corresponds to stretch conditions. When the minor strain is 0 a plane strain condition is developed. A forming limit diagram for a sheet metal can be used in conjunction with a trial run of the part to determine how close the material is to failure and how lubrication or die parameters should be adjusted to take the material away from a failure condition. The surface of the sheet is covered with a grid of circles produced by electrochemical marking. When the sheet is deformed, the grid of circles distort and the ratio of major to minor strain can be determined at critical points. These strains are plotted in Fig. 6 to determine how close the material is to failure.

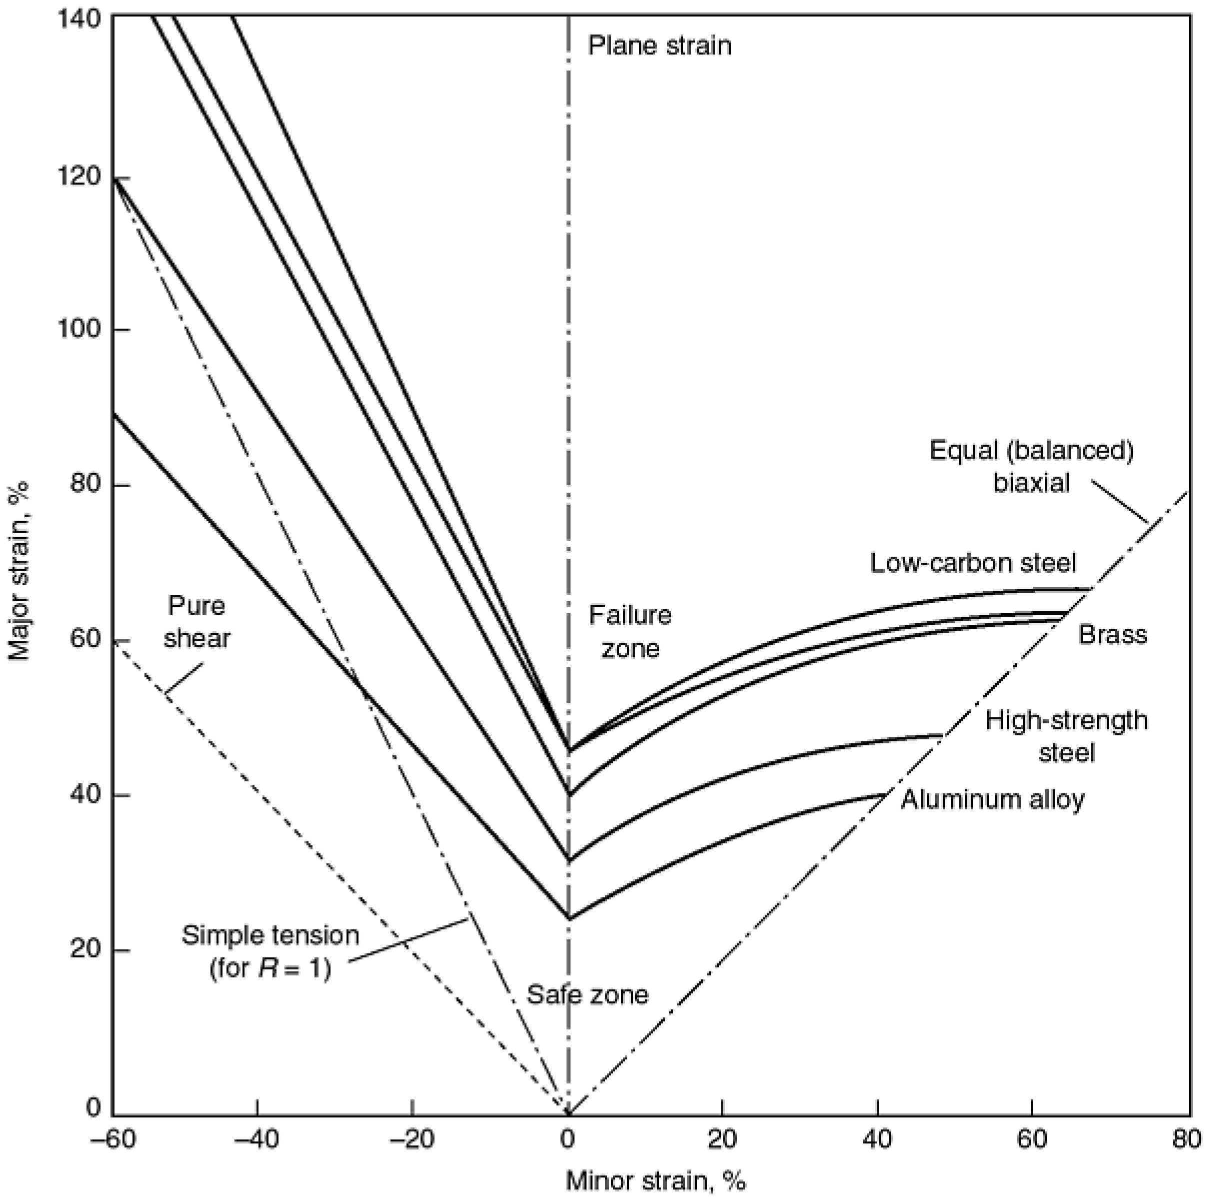

Fig. 6 Typical forming limit diagrams for different sheet metals. To use the diagram, locate the position on the chart for the major strain (always positive) and minor strain that is the most critical combination in the part to be formed. Failure will occur if the point is above the forming limit diagram for the sheet metal. Source: Ref 15

Many simulation tests for the formability of sheet metals have been developed (Ref 23). The Olsen and Erichsen cup tests and the hemispherical dome tests measure stretching, while the Swift cup test measures drawing. The Swift round-bottomed test and the Fukui conical cup tests are involved with combined stretch and drawing.

Machinability

Machinability is the relative ease or difficulty of a material to be machined. A material has good machinability if the tool wear is low, the cutting forces are low, the chips break into small pieces instead of forming long snarls, and the surface finish is acceptable. This illustrates the problem of defining machinability as a characteristic material property. Machinability is more a system property that depends on the workpiece material plus the cutting tool material and its geometry, the type of machining operation, and the operating conditions of speed, feed, depth of cut, cutting tool geometry, nature of the cutting fluid, and the rigidity of the machine tool. The one material generalization that can be applied to machinability is that the higher the hardness of the workpiece material the poorer the machinability. Even this fails at low hardness levels where soft, gummy materials develop chips with built-up edge, and lower machinability. The requirement for the material to have good machinability varies with the machining operation (see Table 13).

Table 13 Common machining processes listed in decreasing order of relative difficulty with respect to machinability of the workpiece

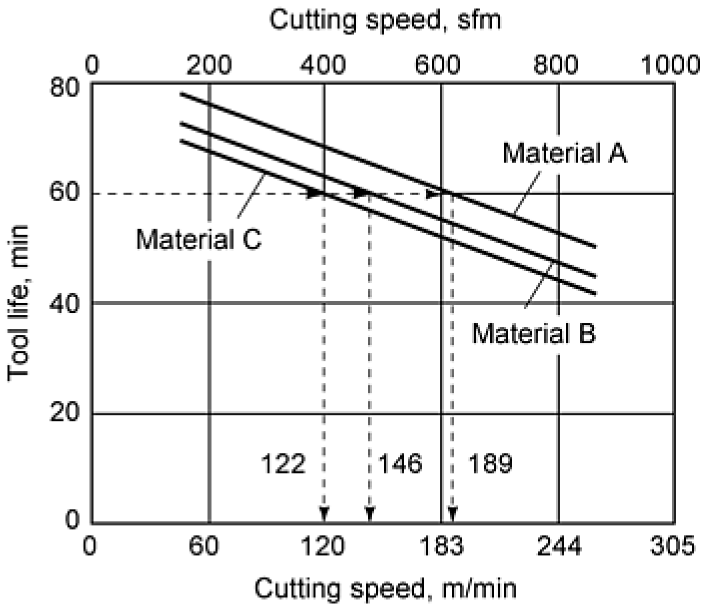
Shallow drilling
Planing and shaping
Turning with single-point tools
Sawing
Grinding

Source: Ref 24

The terms machinability index and machinability rating are used as qualitative and relative measures of the machinability of a material under specified cutting conditions. This concept was introduced early in this century when high-speed steel tools dominated the field. The tool life obtained in turning B1112 resulfurized steel with a high-speed steel tool at 180 sfm was assigned a machinability rating of 100. Suppose the tool lasted for 60 min. If in another steel the identical tool lasted for 40 min, then this material would be given a machinability rating of $(\frac{40}{60})100 = 67$. Because small changes in cutting speed produce large changes in tool life it is more practical to measure machinability as the cutting speed that causes tool failure in a specified time period, usually 60 min. This makes use of the Taylor tool life equation, that the cutting speed × tool life raised to an exponent equals a constant, (vT^n = C). The plot and method of arriving at the machinability exponent is shown in Fig. 7.



Material	Cutting speed for 60 min tool life		Machinability rating
	m/min	sfm	
A	189	620	100
B	146	480	77 $\left(\frac{146}{189}\right) \times 100$

Fig. 7 Relationship between tool life and cutting speed based on Taylor equation. Table shows how the machinability rating would be determined. Source: Ref 25

Surface finish is another criterion for evaluating machinability. The better the surface finish under a given set of conditions the higher the machinability of the material. Similarly, cutting force tests to measure the feed force under a given set of conditions are sometimes used. The most fundamental measure of machinability is the energy consumed in machining a unit volume of material (Ref 26). See Table 14 for some values. For details on conducting machinability tests, see Ref 24, 25, and 28.

Table 14 Approximate energy per unit volume requirements for machining different metals and alloys

Material	Hardness, HB	Unit energy[(a)], (W/s)/mm^3
Aluminum	50-100	0.55
Aluminum alloys	100-150	0.65
Cast irons	125-175	0.87
	175-250	1.3
Carbon steel	150-200	1.3
	200-250	1.7
	250-300	2.2
Alloy steel	200-250	1.7
	250-300	2.2
	300-350	2.8
	350-400	3.5
Copper	. . .	1.5
Brass	100-150	1.7
Bronze	100-150	1.7
High-temperature alloys	. . .	3.3-8.5
Titanium alloys	. . .	3.0-4.1
Refractory metals	. . .	3.8-9.3

(a) To convert unit energy to (hp/min)/$in.^3$ divide by 2.73.

Microstructure can have an important influence on machinability. Spheroidized carbides are more machinable than pearlite platelets. Control of the inclusions in steel through small additions of sulfur, phosphorus, or calcium can be decisive. The influence of the manufacturing process on machinability is exemplified with the aluminum-silicon casting alloy, A390. Castings made by conventional die casting are more machinable than those produced by sand casting. This is attributable to the microstructure resulting from widely differing cooling rates. The die-casting process produces very fine, evenly distributed silicon particles, while the sand casting has larger silicon particles that are less uniformly distributed.

Finally, it needs to be understood that machinability data show considerable scatter. For B1112 steel, within the composition range permitted by that grade, it was found that the machinability index varied as much as 20% below and 60% above the nominal value of 100 assigned to this grade because of unintentional variations in carbon, sulfur, and silicon content. In general, differences of 5% in machinability ratings are not likely to be significant or reproducible.

Weldability

The weldability of a particular metal combination describes the ease with which the weld can be made and the quality and soundness of that weld. All metals can be welded to themselves by at least one of the welding processes (Table 15); these processes are discussed in the article "Design for Joining" in this Volume. The primary factor that controls weldability is the composition of the base metal and the filler metal. A fusion weld cannot be made between dissimilar metals unless they have metallurgical solubility. Barring this, brittle compounds may be formed. Weldability is affected by such defects as cracking in the weld metal, porosity, or cracking in the heat-affected zone (HAZ). Weld cracking in steel can be caused by the presence of very small amounts of hydrogen, the formation of martensite in the weld, and the presence of high residual stresses. Free-machining steel with high sulfur content cannot be fusion welded without cracking due to hot shortness. Hardenable steels must be welded with caution to avoid brittle martensite formation. Preheating the weld to reduce the quench rate and postheating to temper any martensite should be practiced. To estimate whether hardenability problems are likely to affect weldability of a steel, the carbon equivalent (*CE*) is determined:

$$CE = \%C + \frac{\%Mn}{6} + \frac{\%Ni}{15} + \frac{\%Cu}{15} + \frac{\%Cr}{5} + \frac{\%Mo}{5} + \frac{\%V}{5} \quad \textbf{(Eq 7)}$$

When the *CE* of a steel is less than 0.45%, weld cracking is unlikely and no heat treatment is required.

Table 15 Weldability of specific metals and alloys

Base metals welded	Welding processes

The quality of welds is determined from a variety of tests. Tension and bend tests of specimens containing the weld are commonly used. A variety of drop weight and fracture toughness tests are used with steel welds. A large number of tests have been developed for determining the susceptibility of the weld joint to cracking during fabrication. These can be divided into restraint tests, externally loaded tests, underbead cracking tests, and lamellar tearing tests (Ref 30). Table 16 summarizes and compares these tests.

Table 16 Comparison of weldability tests for fabrication

Test	Fields of use	Controllable variables	Type of data	Specific equipment	Cost
Lehigh restraint test	Weld metal hot and cold cracks, root cracks, HAZ hydrogen cracks, stress-relief cracks	Joint geometry, process, filler metal, restraint level, heat input, preheat, postweld heat treatment	Critical restraint, or % hindered control	None	Costly machining
Slot test	HAZ hydrogen cracks	Filler metal, interpass time, preheat	Time to crack, critical preheat	None	Low cost
Rigid restraint test	Weld metal hot and cold cracks, root cracks, HAZ hydrogen cracks	Joint geometry, process restraint level, filler metal, heat input, preheat	Critical restraint	Restraint jig	Costly machining and setup
Tekken test	Weld metal root cracks, HAZ hydrogen cracks	Joint geometry, process filler metal, heat input, preheat	Critical preheat	None	Low cost
Circular groove test	Weld metal hot and cold cracks, HAZ hydrogen cracks	Process, filler metal, preheat	Go/no-go	None	Costly preparation
Implant test	HAZ hydrogen cracks, stress-relief cracks	Process, filler metal, preheat, postweld heat treatment	Critical fracture stress, critical preheat	Loading jig	Intermediate cost
Tension restraint cracking test	HAZ hydrogen cracks	Process, filler metal, heat input, preheat	Critical fracture stress, critical preheat	Loading jig	Costly machining and setup
Varestraint test	Weld metal and HAZ hot cracks	Process, filler metal, heat input	Crack length, % strain	Loading jig	Costly preparation and analysis
Longitudinal bead-on-plate	HAZ hydrogen cracks	Electrical type, heat input	% cracking	None	Low cost

test					
Controlled thermal severity test	HAZ hydrogen cracks in fillet welds	Electrical type, cooling rate, preheat	Go/no-go (at two cooling rates)	None	Costly preparation
Cruciform test	HAZ hydrogen cracks, weld metal root cracks	Process, heat input, preheat, filler metal	Go/no-go	None	Costly preparation
Lehigh cantilever test	Lamellar tearing	Process, filler metal, heat input, preheat	Critical restraint stress and strain	Loading jig	Costly specimen preparation
Cranfield test	Lamellar tearing	Filler metal	Number of passes to crack	None	Low cost
Nick bend test	Weld metal soundness	Filler metal	Go/no-go	None	Low cost

Computer-Aided Materials Selection

Volker Weiss, Syracuse University

Introduction

COMPUTERS with elaborate software programs have not only become invaluable tools for computer-aided design and manufacturing (CAD/CAM) processes, but are also emerging rapidly as potentially powerful tools for materials selection. A 1995 report by the National Materials Advisory Board (Ref 1) presented a conceptual architecture of a computer-aided materials selection expert system that is capable of interfacing with a design team and its design-specific software programs (Fig. 1). Basically, such a system consists of three closely integrated parts: databases, knowledge bases, and modeling/analysis capabilities. Databases are discussed extensively elsewhere in this Volume (see the article "Sources of Materials Properties Data and Information"). Knowledge bases include rules for materials selection, design rules, constraints, objects, taxonomies, and lessons learned. The modeling/analysis section generally consists of computer programs for finite element stress analysis, constitutive analysis, life cycle cost analysis, risk analysis, performance simulation, and so forth.

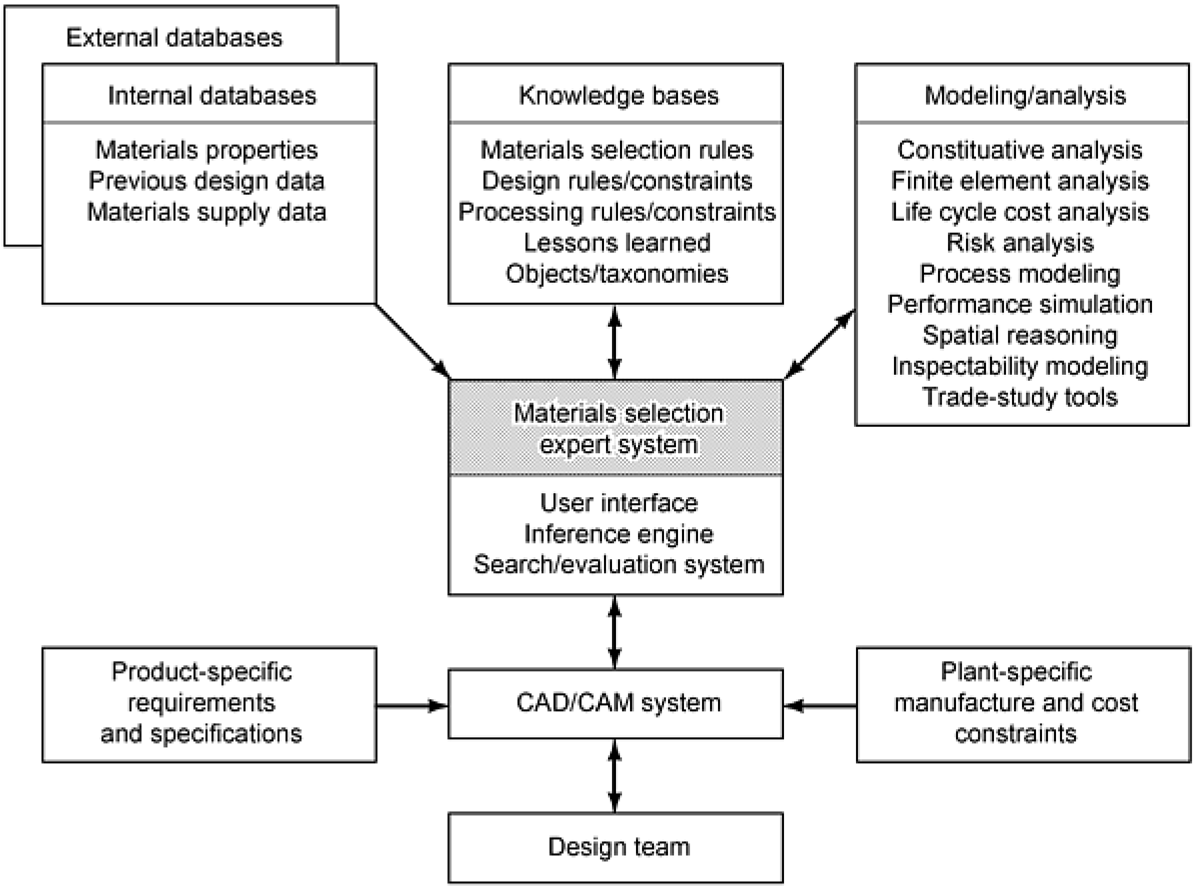

Fig. 1 Conceptual architecture of a computer-assisted materials selection system. Source: Ref 1

Computerized materials properties databases do exist at present in many companies, and some are commercially available. Much of what is routinely available in materials data handbooks is becoming available for computer use (e.g., on CD-ROMs for use on personal computers). Some computerized materials properties and cost information is beginning to become available on the Internet. The article "Sources of Materials Properties Data and Information" in this Volume provides detailed information on materials properties databases, both print and electronic.

Computerized knowledge bases are less well developed. The subject of potential knowledge bases covers the range of topics of this Section of the Handbook and beyond. The basic nature of the elements of knowledge bases are formulas (such as the calculation of the critical crack length a_{crit} from the yield strength Y and the plane-strain fracture toughness K_{Ic}, namely $a_{crit} = (\frac{1}{2}\pi)(K_{Ic}/Y)^2$), or so-called "if-then rules", or, most usually, company or plant-specific "lessons-learned" files, performance characteristics, and manufacturability information.

At present several company-specific expert systems for materials selection exist, though very few systems are commercially available. Twenty-one commercially available materials databases and selection programs are described briefly in Ref 2. Of these, only two, the Cambridge Materials Selector (CMS 2.0) and Rapa Technology's Plascam software package, a plastics materials selector, are listed as "selectors," and even these are essentially databases, not knowledge bases or expert systems. The artificial intelligence (AI) technology for developing expert systems certainly exists and has been successfully applied to the development of in-house materials selection expert systems (and others, such as failure analysis or materials characterization systems). Some companies offer expert systems for selecting products of theirs that best meet a particular set of requirements, including environmental and chemical environments and geometric compatibility; an example is the bearing design guide developed by Furon, a manufacturer of structural bearings. Generally, little published information is available about many of these excellent in-house systems. Therefore, the following descriptions of various systems for computer-aided materials selection deal primarily with promising prototypes that have emerged for various applications.

Computer-Aided Materials Selection

Volker Weiss, Syracuse University

Expert Systems: General Description

Expert systems are usually integrations of databases and knowledge bases using search and logic deduction algorithms. Once implemented, the distinction between databases and knowledge bases becomes blurred, because usually they are both treated simply as assertions, for example, "it is the case that the yield strength of 4340 steel, tempered at 400 °F, is 270 ksi." The integration of these information bases is accomplished by inference engines, typically embedded in expert system shells, or by computer languages based on some form of logic search rule (e.g., use of unification and resolution algorithms in Prolog). For all the databases and knowledge bases to be addressable by the inference engine, they have to be in an appropriate format, which is often not the case, though the situation is improving. Clearly, a fully functional computer aided materials selection system (CAMSS) will assume the character of an expert system. It has also been suggested that the CAMSS will ultimately involve not only a materials selection system, but also will be coupled, perhaps with feedback loops, to the CAD/CAM system, thus forming an integrated set of computer systems that serve the design team.

Expert systems first appeared around 1965; early systems included DENDRAL, MACSYMA, MYCIN, EMYCIN and Prospector (Ref 3). They were generally designed and programmed by one or several "knowledge engineers," who obtained the information from "domain experts" and structured a user interface that was intended to be friendly to the end user, presumably not an expert in artificial intelligence programming. The classical structure of a typical expert system is shown in Fig. 2. Prolog and LISP, and, more recently, object-oriented implementations through OOPS, Smalltalk and Java, are the languages of choice for expert system building. EMYCIN, CLIPS, KEE, ART, and NEXPERT are so-called "expert system shells," that is, empty reasoning systems to which a user can add data and rules to build an expert system. MYCIN was developed for medical diagnostic purposes. EMYCIN is "empty" MYCIN, a shell that is suitable for diagnostic reasoning (such as in failure analysis).

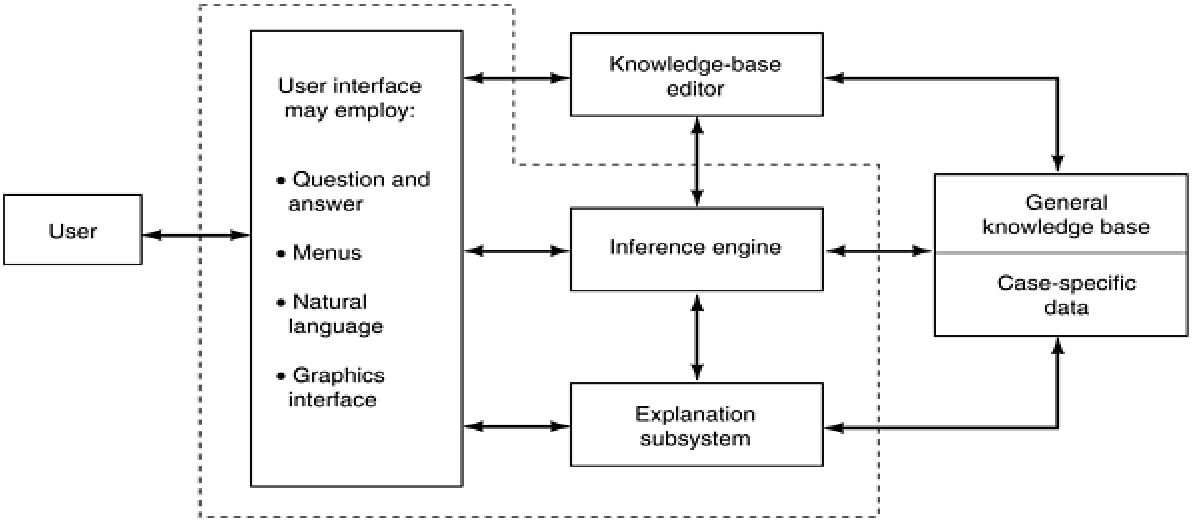

Fig. 2 Architecture of a typical expert system. Source: Ref 4

Computer-assisted materials selection, through expert or some other advanced systems, will be primarily of use for the level III and level IV design/materials selection phases (see the article "Overview of Materials Selection" in this Volume). At these stages, a design team may not be aware of, for example, all materials available in a given class (e.g., heat-resistant alloys) that also meet certain specific room-temperature requirements such as minimum fracture toughness and corrosion resistance to sea water after extended high-temperature service.

Computer-Aided Materials Selection

Volker Weiss, Syracuse University

Quantitative Selection Systems

Any useful quantitatively based expert system for materials selection depends heavily on available data and design rules. The databases must be accessible to the system structure (e.g., languages like Prolog, LISP, or a shell). The data requirement is primarily for well-analyzed and documented data of candidate materials. The application-specific knowledge base will contain the design rules, such as appropriate stress analyses, stress concentration factors, fracture mechanics formulas, creep and fatigue relationships, and so forth. For complicated geometries and critical applications, the application-specific knowledge base might be hybridized to a finite element system to perform the required stress analysis for the geometry under consideration.

The system must have access to, or incorporate, materials properties databases to be used within the reasoning structure of the expert system. For example, a simple expert system for materials selection for a tension bar of minimum weight and a diameter not to exceed a given value and to carry a given load (Ref 5) could have mechanical properties data of materials excerpted or downloaded from a database so that yield strength and density values of a sufficient number of materials are available. Rules such as:

$$\text{Load-carrying capacity} = \text{Yield strength} \times \text{Area} \times \text{Safety factor}$$

and

$$\text{Weight per unit length} = \text{Area} \times \text{Density}$$

and

$$\text{Area} = (\text{Diameter})^2 \times \pi/4$$

need to be invoked in the search through the database to select the materials that meet the requirement. This list can then be sorted in terms of weight per unit length, or yield strength/density, as desired by the designer. Inspection criteria, for example, for cracks, could be added to exclude materials for which the critical crack length is below the inspection limit; this would require fracture toughness values be included for all candidate materials. In addition, exclusion rules could be formulated that remove all materials from consideration that would experience corrosion damage above a specified limit in the service environment; for this purpose, corrosion data for the anticipated service environment would need to be available from the database. In addition, rules for other factors of concern (e.g. cost and appearance, "lessons-learned"

rules for similar designs, and "manufacturability" rules) may be formulated and invoked. The result of a query using LOG-LISP (Ref 6) and a database of several hundred materials is shown in Table 1.

Table 1 Results of LOG-LISP materials selection query

The conditions were: (1) must safely support a load of 200 ksi, (2) must have a safety factor of 1.75, (3) maximum diameter of 1.5 in., and (4) maximum weight per unit length of 0.5 lb/in.

MAT	COND	YS	DIAM	*W/L*
ST 4340	QT-400F	262	1.35	0.40
ST 4340	QT-600F	230	1.39	0.43
ST 4130	WQT-400F	212	1.45	0.46
ST 4130	WQT-600F	200	1.49	0.49

Source: Ref 6

(a) MAT, material; ST, steel; COND, condition; QT, quenched and tempered; WQT, water quenched and tempered; YS, yield strength (ksi); DIAM, diameter (in.); W/L, weight per unit length (lb/in.).

This simple example is typical of a wide variety of much more elaborate materials selection problems. Database, knowledge base, and finite element data interaction would come into play for load-carrying parts having complicated geometries. Fatigue and fatigue crack growth knowledge bases and databases will be required for applications with load fluctuations and high-temperature creep data for elevated-temperature applications. For many of these applications, closed-form design formulas will not be available; therefore, the materials selection system will have to be connected to other computer programs (e.g., finite element programs).

Information about the database quality is necessary to decide on the applicability of the materials selection system for preliminary or final design stages. For the former case, typical data, or supplier data, may suffice. For the latter, well-documented and preferably statistically analyzed data--of the type and quality characteristic of MIL-HDBK-5 (Ref 7), for example--are required. If data that include statistical information (e.g., standard deviation) are used, the knowledge base will need to have "rules" that deal with that information to determine average and (statistically defined) minimum load-carrying capacities for the structure under consideration. Iterations between design system and materials selection system should be planned for so that the designer can see if design changes also prompt material selection and other (e.g., cost) changes. It should be noted that the rules that manipulate well-defined statistical data are firm, deterministic rules that should not be confused with the application of "fuzzy logic" or "fuzzy numbers," which are addressed in the section "Qualitative and Experiential Selection Systems" in this article.

Another application for a quantitative materials selection system is materials substitution. The query to be answered would be of the type: "find materials that have the same or higher tensile and yield strength as the one currently used (e.g., SAE 4340 steel, quenched and tempered at 800 °F) but contain less chromium and nickel." In addition to calling on mechanical property databases of alloys, a (nominal) chemical composition database must be available to the "inference engine." Table 2 shows the results from the same LOG-LISP prototype expert system used for the tension member design query (Table 1).

Table 2 Results of LOG-LISP materials substitution query

Material and condition to be replaced: ST 4340, QT-800F. Critical properties to be matched or exceeded: TS, YS. Critical alloying elements to be reduced: chromium, nickel

MAT	COND	Cr	Ni	TS	YS
ST 4340	QT-800F	0.90	2.0	213	198
ST 8630	QT-400F	0.60	0.70	238	218
ST 8630	QT-600F	0.60	0.70	215	202
ST 8640	QT-400F	0.60	0.70	270	242
ST 8640	QT-600F	0.60	0.70	240	220

The prototype for a materials selection system to meet the special needs of the aerospace industry, the Intelligent Knowledge System for Selection of Materials for Critical Aerospace Applications (IKSMAT), was developed in the late 1980s (Ref 8). The plans were for an elaborate, mostly quantitative system with a front-end program for data entry and a diagnostic program to ensure that all of the important properties and characteristics of all the candidate materials are considered. The model for such a materials selection system is illustrated in Fig. 3. This model was implemented using the system architecture illustrated in Fig. 4. A "master" database facility, containing well documented and evaluated data, mostly of the type found in MIL-HDBK-5 (Ref 7), provided the input through MESSENGER mainframe software. The user interface was planned not only to allow the user to work within the existing knowledge base, but also to add data, rules, new criteria or other information, and to redefine priorities. IKSMAT was turned over to the U.S. Air Force in 1993, and it may have been discontinued due to the expense of maintaining it.

Computer-Aided Materials Selection

Volker Weiss, Syracuse University

Qualitative and Experiential Selection Systems

Qualitative and experiential materials selection systems are needed for applications that involve considerable uncertainty. In such systems, the computer code seeks to assist or even substitute for design experts. Typical examples are materials selection requirements for service in corrosive environments, for cumulative fatigue damage, and for service under thermal and load cycling. Uncertainties in such applications involve, for example, the effects of combinations of corrosive agents, effects of stress amplitude sequence in cumulative fatigue, and effects of in-phase and out-of-phase load and temperature cycling. Systems that address these problems must be able to deal with approximations, and "fuzzy numbers," and they must compare and manipulate them and present the results of such manipulations with qualifiers, which distinguish them from results obtained from "hard-number" quantitative systems. The system must allow data to be

expressed as minima, maxima, ranges, and unknowns, in addition to hard values. Different systems may, based on the underlying "fuzzy-logic" reasoning structure, come to different conclusions. For example, if the corrosion rate for material 1 in polluted harbor water is between 0.04 and 0.38 mm/yr, and that for material 2 between 0.18 and 0.28 mm/yr, which material is more corrosion resistant? Selection based on a "worst-case scenario" would lead to the selection of material 2, while a selection based on average rates would lead to the selection of material 1. For such systems it will be necessary to include the "desired scenario" in the query.

Example: Heat Exchanger Materials Selection System.

A selection system for materials subjected to service in corrosive environments is typical for this class. Specifically, Syracuse University developed a prototype materials selection system for tube (heat exchanger) applications where corrosion and erosion results from a combined effect of water chemistry and flow rate. The prototype system was implemented in Prolog on a personal computer. The knowledge base for the system consists of six components:

- A corrosion property knowledge base for candidate materials
- A fuzzy number knowledge base for reasoning with uncertain data
- An experiential knowledge base stating conditions for excluding materials
- A location knowledge base containing water analyses and derivable characteristics (e.g., Langelier and Ryzner indices)
- An installation knowledge base providing information on experience of prior installations at the same site
- A control knowledge base containing the rules that govern the selection process

The structure of this prototype heat exchanger materials selection system (HEMS) is shown in Fig. 5. The output of the system, once a location is specified, is the estimated lifetime of heat exchanger tubes, that is, time to first leak. This time is then expressed in "design life fraction" using a company-specified design life, for example, 20 years. The 12 candidate materials are then ranked in order of decreasing life expectancy. A query for tube materials for a hypothetical location (with extremely polluted, sulfide-containing harbor water) resulted in the ranking given in Table 3. It should be noted that there is considerable uncertainty about corrosion rates in the database, especially the effects of combinations of corrosive media. However, a "rule correction module" was incorporated in the knowledge base, which enabled correction of corrosion rate data on the basis of field reports. For the given location, the materials selection system indicates that only titanium tubes are suitable. For other locations, several materials may be adequate, perhaps ranging from design life fractions of 2 to 6. In such a case, the customer must weigh the generally increased cost with increasing design life of the materials, for example, copper, Cu-10Ni, and Cu-30Ni. Such cost information can readily be added to the knowledge base and incorporated in the output.

Table 3 Results of heat exchanger materials selection system query

Query: tube materials suitable for service in extremely polluted, sulfide-containing harbor water

Rank	Material	Design life fraction
1	Titanium	>5.00
2	Type 316 stainless steel	0.35
3	Aluminum bronze	0.26
4	Type 304 stainless steel	0.19
5	Aluminum brass	0.18
6	AISI/SAE 1010 steel	0.13
7	Admiralty brass	0.13
8	Red brass	0.12
9	Copper	0.11
10	Cu-10Ni	0.10
11	Cu-30Ni	0.08
12	Monel alloy	0.07

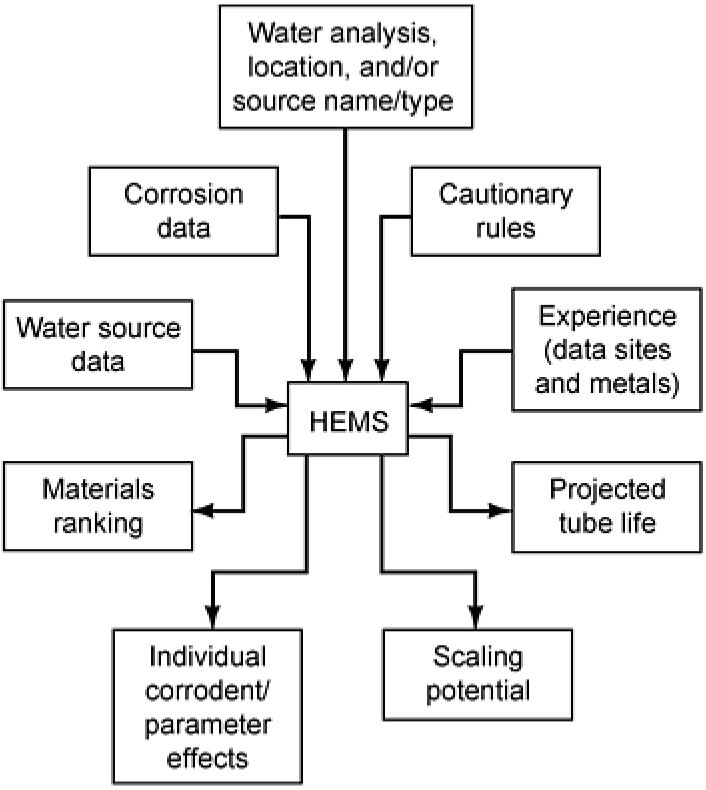

Fig. 5 Structure envisioned for the prototype heat exchanger materials selection (HEMS). Source: Ref 5

The development of a user-friendly interface is of great importance when designing expert systems. For HEMS, in the prototype version, developed in Prolog, the user-friendliness was achieved by employing a hypertext link with "buttons" on keywords that activate the appropriate Prolog queries. The following is a short excerpt from the hypertext version of the prototype HEMS system. The words in bold type are "buttons" that activate actions, either display of explanatory text or initiation of a query process, usually through query-specific windows:

> The HEMS Expert System provides help in the selection of tube materials for **centrifugal chillers, reciprocating chillers,** and **other heat exchangers.** The system consists of two major components, an **information base** and a **material selection assistant** expert system. The two components can be used independently. In most instances the user will chose the interactive mode, making use of the local water chemistry database, at least for a start, and of the water chemistry calculation program. The **materials ranking** program, partially implemented here as a prototype system, allows you to select tube materials for typical **water chemistries.**

If the user selects **material selection assistant** or **materials ranking,** windows appear that ask for location, flow rate, and updates on water chemistry and initiates the appropriate queries that result in a ranking of the type given in Table 3. Selecting other buttons provides either information about the subject or connects to databases that provide information such as water chemistries by location and corrosion rates for the candidate materials in various environments. The system was also linked to already existing FORTRAN programs that calculate Langelier and Ryzner indices from the water chemistry data.

Access was provided on two levels, general user and materials specialist. The latter group also had the capability of modifying the system, adding data and programs, and modifying corrosion rate calculations on the basis of new field data. For the materials specialist, who had some familiarity with Prolog programming, ad hoc querying of the knowledge base of the system, beyond the standard prescribed query actions offered through the windows in the general system, could readily be accomplished. To the author's knowledge, the prototype HEMS system was not used commercially.

Computer-Aided Materials Selection

Volker Weiss, Syracuse University

Object-Oriented Systems

Object-oriented computer languages, such as C++, Java, and so on, gained in popularity in the 1990s, primarily because of the way these languages allow information to be handled in a hierarchical way. Figure 6 shows how the object Al 2024-T3 is treated as a special case of various classes and subclasses. Each instance of an object or class can contain data *and* rules, or methods. Information from general classes is "inherited" to less-general classes and finally to the object. This hierarchy of the knowledge base increases its range of applicability and compactness as compared to a rule-based system operating on relational databases. Design information can be stored in a similar fashion as illustrated in Fig. 7, where the hierarchy for a specific "rod" as a subclass of a solid is presented.

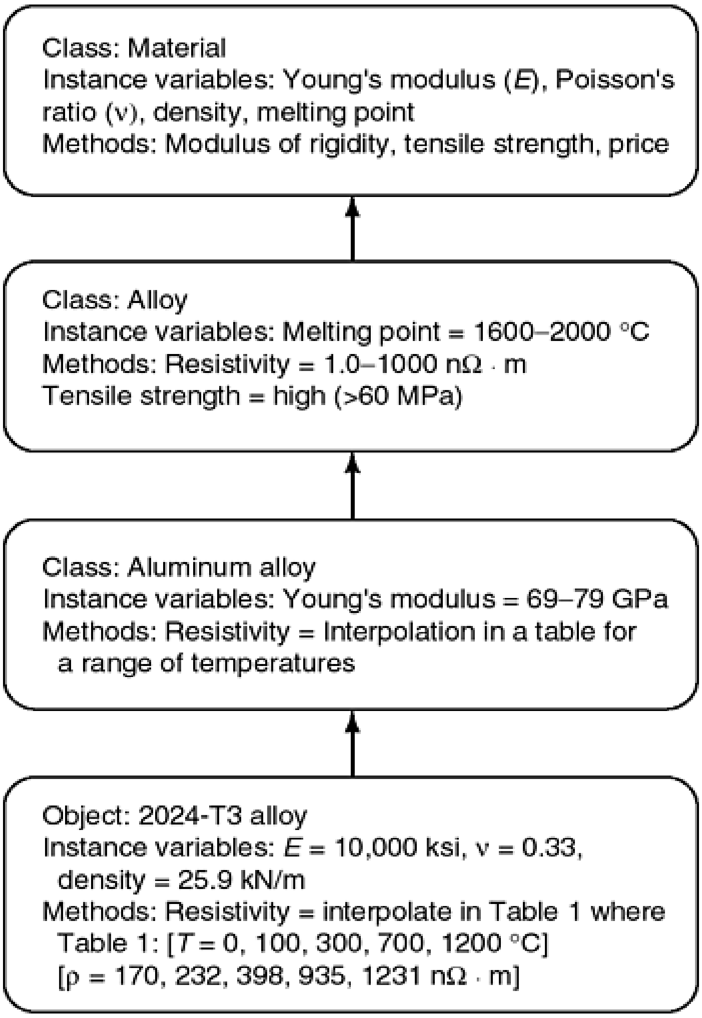

Fig. 6 Materials hierarchy in an object-oriented system. Source: Ref 9

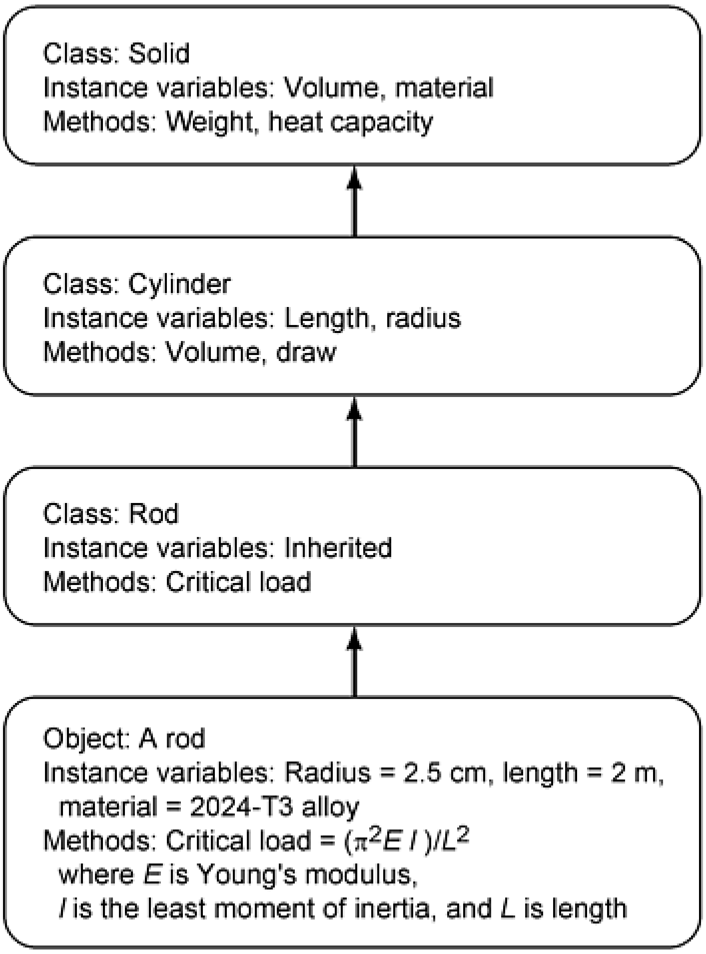

Fig. 7 Geometrical solid hierarchy for a specific rod in an object-oriented system. Source: Ref 9

Krishnamurthy and Smith (Ref 10) have developed an experimental quantitative problem solver (QPS) that is applicable to materials selection problems. Instead of asking for materials that satisfy a range of property requirements, one initiates materials selection with QPS by specifying the characteristics of the item being designed and allowing the system to specify the material query.

With increasing computing speed, object-oriented programming has become increasingly practical, even for large systems. Many of the AI languages and expert system shells are now available in object-oriented versions. Interesting new developments are the languages or programs that can interface with the Internet technologies, including the World Wide Web (WWW); two examples are Java and the EXSYS Web runtime engine (EXSYS WREN) (Ref 11). Java is an object-oriented programming language that allows the writing of small programs, called "applets," that can be embedded into a hypertext markup language (HTML) Web page. The HTML can be used to create hypertext documents that can be moved from one platform to another. Embedded applets execute on the local client workstation. Thus it is possible to use Java, or some other similarly capable program, to interact with information on the WWW to provide answers to queries subject to specified rules and constraints. EXSYS WREN (Ref 11) is an expert system development tool that, in connection with rules that can be produced by the compatible EXSYS Rule Book, acts on WWW information to respond to questions. With Java, the rules and other aspects of the applicable knowledge base have to be embedded in the applets. A simple applet may retrieve data on yield strength, modulus, and density from the Web or a database to compute the deflection of a beam of specified dimensions under its own weight. Newer versions of Java offer a new interface and greater database connectivity.

Agents. "Agents" and "agencies," (i.e. collections of "agents") are other developments worthy of consideration for use in constructing systems for materials selection. Agents are "mini expert systems" that have specific limited functions, for example, search-specified databases, or WWW files, for data on a specific subject (such as yield strength and plane strain fracture toughness) to enhance the database of the larger expert system. Agents are usually object-oriented language applications.

Data mining programs also may be useful when building knowledge bases for materials selection expert systems. These programs--some of them using object-oriented languages, some neural networks (Ref 13)--are an extended development of agents. They not only import data of interest, but also are capable of performing statistical and other operations on the data that lets the user make a judgment about their quality or even lead to predictions (perhaps via fuzzy numbers) of outcomes, for example, product demand. They generally can be applied to databases that support open database connectivity (ODBC). Typical commercially available data mining programs are "Alice" (from Isoft), "Profiler" (from Attar Software UK), "Model Quest Miner" (from AbTech Corporation), and "Predict" (from NeuralWare Inc.).

Computer-Aided Materials Selection

Volker Weiss, Syracuse University

Current Status and Outlook

At present, many components exist that can make up viable computer-based materials selection systems, though no integrated system such as envisioned by the 1995 National Materials Advisory Board study (Ref 1) has been implemented. Several user-specific, smaller-scale, special-purpose materials selector systems have been developed and are in use at various companies and institutions.

Rockwell International developed a "Materials and Process Design Advisor" based on EXSYS. It reportedly consists of expert systems for corrosion protection, adhesive selection, encapsulant selection, conformal coating selection, heat treatment of metallic materials, and selecting soldering processes. The systems are made available to the Rockwell design engineers.

Granta Design Limited is marketing the "Cambridge Materials Selector" (CMS 2.0), which was developed by the Cambridge University Engineering Department. A generic database, containing representatives of virtually all groups of engineering materials, forms the core of the system. After identifying a group of candidate materials, the user can refine the selection with the help of additional databases in the materials group of the candidate materials.

The type of use that is made of these and other emerging systems most critically depends on the quality of data available to the rule base (including design features, environment, etc.) and the inference engine. Material selection for final design of critical components will certainly only be possible if the database consulted consists of well-documented and statistically evaluated data. For materials selection for preliminary or conceptual design stages, databases containing "typical" properties data or information from the material supplier will suffice.

Expert systems for materials selection may even become useful for cases where no commercially available material can satisfy all the performance requirements specified. In such cases, it might be possible to obtain guidance toward potential materials classes by relaxing the requirements until available materials appear as possible candidates. This may lead to identification of materials in research or under development that might eventually help solve the design problem. Ultimately, it is hoped that computing programs will emerge that allow atomic modeling of new materials and their properties. A great number of combinations could be explored inexpensively and in a relatively short time. Leading

candidates could then be produced and tested in the laboratory to serve as feedback information for the atomic modeling programs and for further development.

Maintenance of both the databases and the materials selection system is also of critical importance. Initial databases should be designed to allow for efficient updates, deletions, retrieval, summarization, and reporting (see the article "Sources of Materials Properties Data and Information" in this Volume). Only databases that act predictably to queries posed through the materials selection system can be used successfully. In 1969, E.F. Codd developed a relational model and introduced the fundamental concepts for a well-organized, expandable relational database (Ref 14). To deal with these issues and keep an integrated computerized materials selection system current, it is strongly recommended that any such system be under the control of a *human* systems manager, who serves as or directs a *human* database manager specifically assigned to the maintenance, data oversight, and expansion of the knowledge base.

Finally, a note of caution is in order. The range of applicability and usefulness of these computer-aided systems for materials selection will certainly depend on the size of both the database and the knowledge base. Big systems will loose the transparency of small systems, developed by a few company engineers. Retrieval of data from the same original source, but duplicated in numerous tables and handbooks, may give a false sense of statistical security. Rules formulated for a specific case but applied as general rules may lead to wrong conclusions. And, of course, some data may be in error. While several expert systems have programs that explain the logic chain that led to the response for a specific query, these explanations deal with the logic sequences of the search (usually unification and resolution) and not with the accuracy of the assertions in the knowledge base. Therefore, the optimal benefit of these systems is expected when used by or in close association with a materials specialist well informed in the area of application.

Value Analysis in Materials Selection and Design

Theodore C. Fowler, Fowler & Whitestone

Introduction

VALUE ANALYSIS (VA) is a team problem-solving process. Its objective is to improve the value of a product from the viewpoint of the user (customer). Value analysis is applied to problems as diverse as automobile engines and gall bladder operations. It works whenever a product or process performs a function and costs money. While the method is often used to improve on present products, its greatest power is in optimizing a new design.

Throughout this article, the word *product* will be used to describe either a product or a process for which a purchaser, customer, or user can be identified. To be fully effective, VA should be applied to a complete product, not simply to a part or activity or other subelement.

Value Analysis versus Total Quality Management

The past twenty years have seen the development of a number of problem-solving systems. Many of these use teams in the same way VA uses teams. A popular current management philosophy is called total quality management (TQM). Rather than a set of procedures or a methodology, TQM is a state of mind for the modern organization. While it does apply several tools to accomplish its aims, for example, statistical process control (SPC), relations diagrams, quality function deployment (QFD), and policy deployment (PD), it makes primary use of two viewpoints or principles:

- It is customer focused. It concentrates on understanding and satisfying customer needs.

- It treats any endeavor in terms of process (check points) instead of just results (control points). Total quality management adherents follow the precept that approximately 90% of all variation from intended results is caused by problems with the process and only 10% is the result of worker actions. Statistical tools are applied to analyze data with the objective of minimizing variation and improving process.

The two key features distinguishing TQM from VA are:

- TQM presumes that the process under study is needed by the user. Value analysis involves first measuring the user attitude, then defining the user need, and finally applying the VA method.
- The VA procedure starts with the conversion of the product or process into its essential functions. It then establishes the most efficient manner of accomplishing those functions.

The VA process relates the cost of a product to the functions performed by that product. Because product cost is made up of material and labor, the typical ratio being 60 to 40, the VA process places a natural emphasis on the material cost content of a product. (The term material cost as used here includes costs of both raw and fabricated materials.)

Value Analysis in Materials Selection and Design

Theodore C. Fowler, Fowler & Whitestone

Background and General Concepts

Value analysis was developed by Lawrence D. Miles at the General Electric Company in the late 1940s. Most of the newer quality systems and techniques, such as quality circles, poka yoke, grid organization development, Kepner-Tregoe, QFD, brainstorming, continuous systematic improvement, and TQM are team problem-solving systems. What is so special about VA?

The special power of VA comes from a technique called *function analysis*, which dramatically shifts the viewpoint of problem solvers from concrete issues to abstract concepts. When Miles first developed VA, function analysis was its only unique element, and this technique has been the source of all of the breakthroughs that can be attributed to VA.

In addition to function analysis, current VA practice involves several other key attributes, concepts, and activities:

- *Function cost:* A measure of the effort (in dollars, hours, personnel, etc.) spent on each function
- *Function worth:* An analysis of the degree to which a function fulfills the needs and wants of the user
- *Create by function:* A process that forces the problem solver to focus creative effort on abstractly defined customer needs rather than on hardware or activities
- *Value targeting:* A process that directs the problem solver toward areas where function cost does not match what the user/customer says the function is worth
- *Job plan:* A structured approach to implementing VA to maximize output
- *The team:* A multidisciplinary group representing the major aspects of the product under study that carries out the VA activity
- *Ownership:* The concept that each VA proposal must have an owner or "champion" to be successfully implemented

These items are discussed in greater detail in the section "The Value Analysis Process" in this article.

In the fifty years since VA was developed, it has changed mightily. Users have modified the process to fit their requirements. A modified version of the process is in heavy use in the U.S. government, where it is called value engineering (VE). The construction industry has followed their lead with a few further modifications. Their version is also

called VE. In the automotive industry, the VA process is sometimes called value management. Each of these names refers to the same basic system. While the fundamental elements of all the systems are similar, there are nevertheless significant differences in focus, procedure, and effectiveness.

Value Engineering in U.S. Government Contracts. For most government products, the design and its related costs are established by contractors outside the government. To apply effective VA to these products, the Department of Defense created a mechanism called the Value Engineering Change Proposal (VECP).

The VECP is a motivational device. Contractors are not normally inclined to recommend changes in the design of their products. The government specification is commonly rigid and detailed. Though a change to some element of the specification might benefit the product and/or decrease the cost of the product, contractors have discovered through experience that either (1) the government will reject a proposal for change for reasons of varying validity, or (2) the government will accept the proposal and reduce the price of the product. Neither outcome is likely to motivate the contractor to apply the effort required to prepare proposals for change.

A clause is, therefore, inserted in any government contract over $100,000 in total value. This clause encourages submittal of contractor-initiated changes. The contractor is promised a share of the dollar savings for any accepted proposal for change. This motivates the contractor to search out change and motivates the government to submit such proposal to serious evaluation. This VECP clause has been somewhat effective, but it has one very unfortunate unintended effect. It implies that VE is focused only on cost reduction. The "function" element in the value equation is commonly ignored, compromising the VA effort. This misimpression that VA is cost reduction tends to carry over to nongovernment activities and has severely degraded many commercial VA efforts.

Nevertheless, the application of VE in the government is undergoing a rapid expansion since the issuance in 1996 of Public Law 104-106, which requires VE by all units of the U.S. federal administration.

Value Engineering in the Construction Industry. The design of buildings and other civil engineering works follows a rigid and historic contractual path. To accommodate these constraints, VA in construction has also taken a rather different approach.

There has been a drift toward a second-guessing or critique mode. It has proved difficult to reconcile the historic contractual arrangements between owner, architect, engineer, and construction manager with the VA requirement that each team member must be a decision maker whose assignment presently includes responsibilities on the product under study. This has led to a form of VE in which Blue Ribbon Teams of outside experts critique the efforts of the original designers. While this causes some emotional and practical blocks, the process of construction value engineering is developing an impressive record of cost reduction.

Some projects have achieved significant cost reductions (an average of 15 to 20%) and/or significant quality improvements. Material selection in this sector is an important aspect of cost and needs satisfaction and is always analyzed during a VA session. Issued in 1995, ASTM E 1699 provides guidelines for VA as used in construction projects.

Theodore C. Fowler, Fowler & Whitestone

The Value Analysis Process

Value analysis begins with implementation planning. This is in keeping with Leonardo da Vinci's famous exhortation, "Think of the end before the beginning." Before starting the study, the team prepares a list of all of the possible areas in which they might anticipate their results to fall. They then list all of the roadblocks that they might expect to face in implementing the results. Next, they list all actions that must be considered during the study to circumvent those roadblocks. These lists are updated throughout the study (a sample is provided in "Example 1: Value Analysis of a Coolant Level Sensor" in this article). This commonly results in very few surprises during the later effort to implement the results of the study. Implementation rates of a properly conducted VA study can approach 100%.

The VA system developed by Miles followed a rigorous procedure he called the *job plan.* Others have varied the job plan to fit their particular constraints. A modern version has eight phases:

1. Preparation
2. Information
3. Analysis
4. Creation
5. Synthesis
6. Development
7. Presentation and report
8. Implementation and follow-up

Each of these phases is described in the following sections.

The Preparation Phase

This phase organizes the study. First, the mandate must be clearly outlined, the objectives set and the logistics established. It is here that the multidisciplinary team is selected. The ideal VA team comprises five experts on the product under study, each from a different discipline. For a complex product, several five-person teams may be appropriate. Each member must be a person whose job includes responsibilities on the product under study. The prime requirement is that each member be a decision maker in the organization. These are referred to as the organization's "movers and shakers." The following capabilities must be included in the team:

- *Design:* Project engineer, chief draftsperson, designer, or materials engineer (ideally, the engineer responsible for design of the product)
- *Operations:* Factory supervisor, industrial engineer, manufacturing engineer, construction supervisor, or methods engineer
- *Cost:* Cost estimator, industrial engineer, or accountant
- *Outreach:* Marketing, sales, field service, purchasing
- *Catalyst:* A constructive troublemaker, possibly an engineer, product manager, marketing person, or construction manager

The team meetings are facilitated by a VA specialist whose role is to ensure that the methodology is followed.

The Information Phase

The information phase includes function-analysis, function-cost, and function-worth activities.

Function Analysis. In the process of function analysis, the product or process under study is first converted into a number of verb-noun pairs. They describe what the product does for the user. The participants in the following phases will then concentrate on those word pairs rather than on the concrete product or process.

The specific form used for these word-pairs is called the *functive.* Each word pair comprises one verb and one noun. Each noun is ideally a parameter or measurable quantity, and each verb is ideally demonstrable on a nonverbal level. One verb and one noun make up one elemental sentence. Therefore, when the key VA question, "What does it do?" is asked of a product or process, the answers become a series of two-word sentences. The number of these sentences could run from forty to eighty for even a simple product or process. In their totality, these two-word statements are a complete and interrelated description of the functions of the product or process. Value analysts call this group of statements a *function analysis.*

By concentrating all their problem-solving effort on these two-word functions, the team minimizes what Miles called "functional fixedness." It is clearly possible to be more creative when tackling a problem defined in terms of improving the function "remove pollutants" than one defined in terms of "make a better catalytic converter." Miles defined this

creative focus of function analysis in terms of the technique he called "create-by-function" (see the section "The Creation Phase" in this article).

Function analysis also serves to refocus the team from cost improvement to value improvement. This is accomplished through a fundamental relationship of VA called the *value formula.* It is a simple and elemental relationship and is usually expressed as:

$$\text{Value} = \frac{\text{Function (satisfaction of needs)}}{\text{Cost}}$$

When function is improved, value rises. On the other hand, when cost is reduced, value also rises. If function and cost both increase, value rises if function increases relatively more than cost. This relationship controls all VA and commonly results in designs that optimally satisfy all of the valid needs of the user at minimum cost. This is defined as optimum value.

Function analysis enables the team to capture the essence of a complex product or process on one page of unambiguous statements. Figure 1 is a simplified function diagram of an automobile as developed by a VA team studying the bumpers of a proposed 1992 model of a mid-sized automobile. This structure is called a function analysis system technique (FAST) diagram. Sixty-three functions were identified and arranged in the original diagram, in conformance to a cause/effect logic.

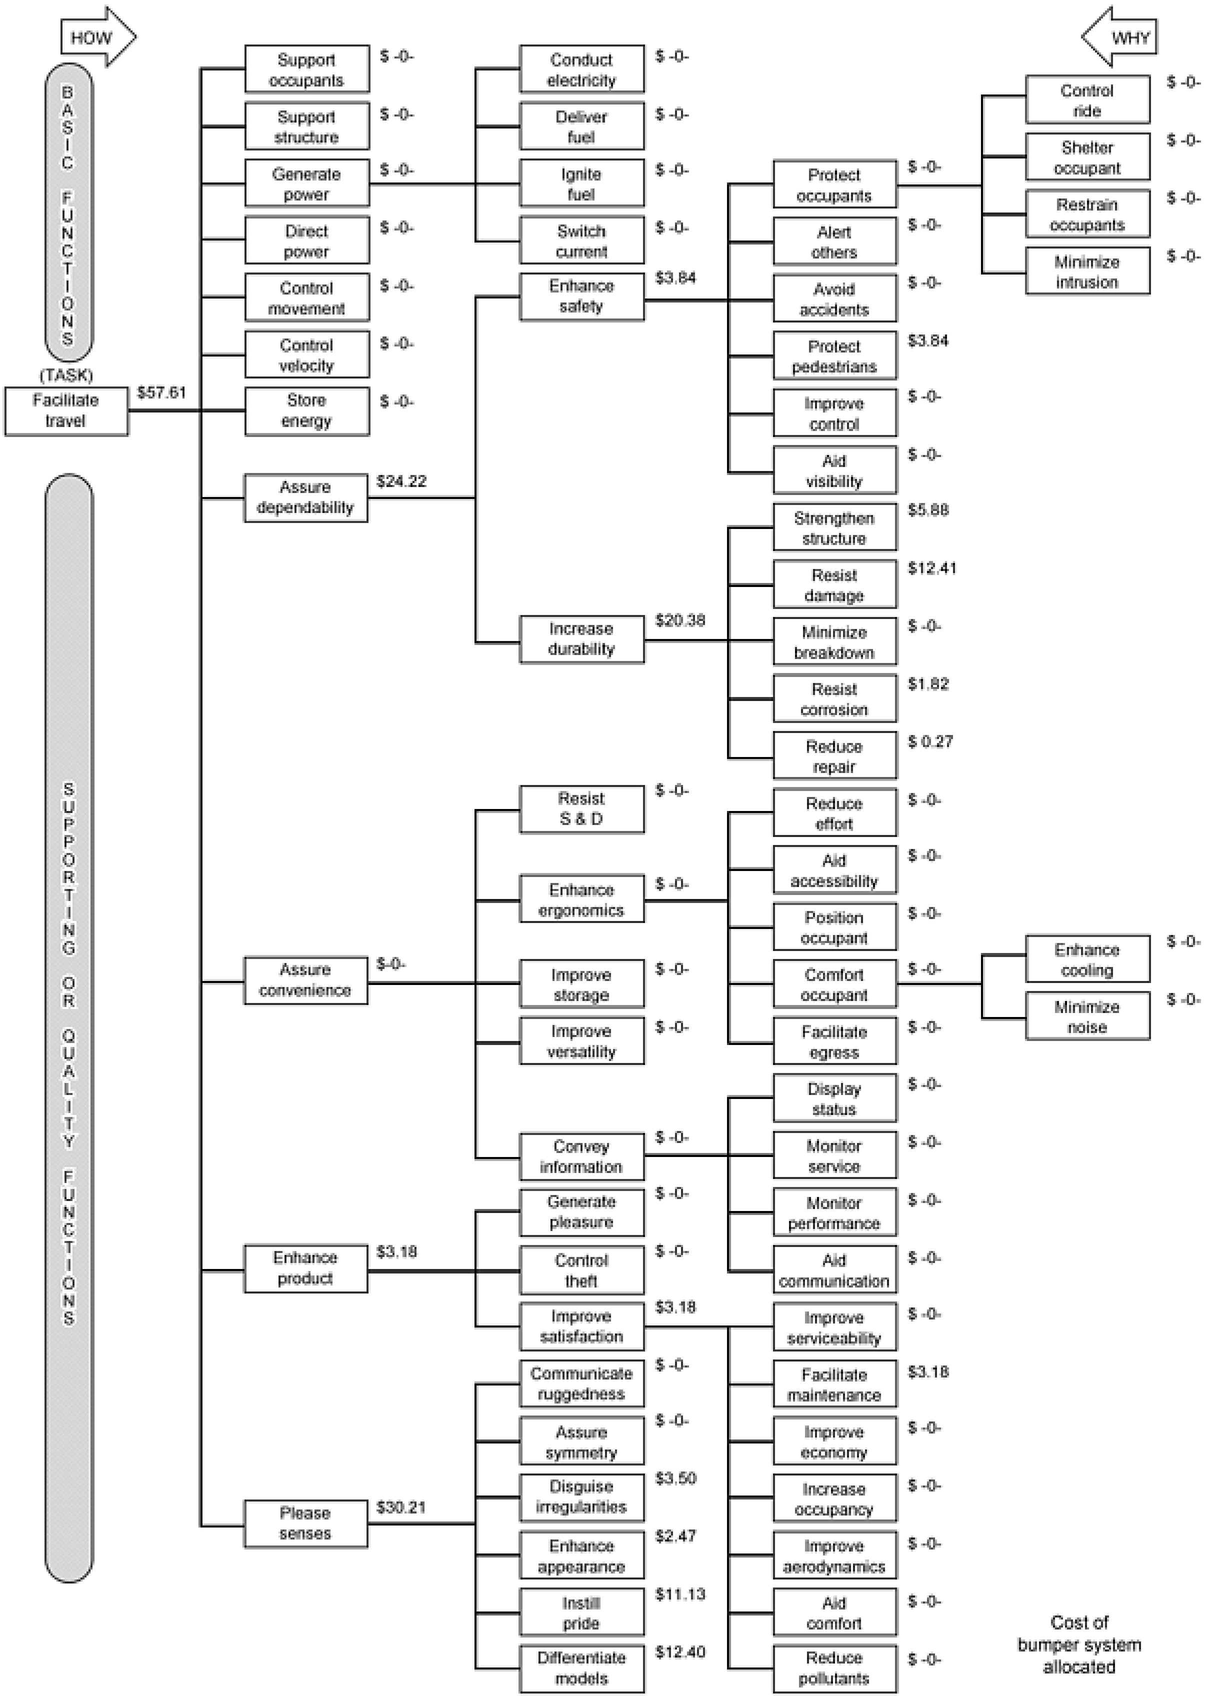

Fig. 1 Simplified function diagram of an automobile

A FAST diagram is a functional model of the product under study. Reading it from left to right takes the reader from the main objective of the product to the details of how the objective is performed. Every function to the right answers the

HOW of the function placed to the left of it. Conversely, reading from right to left validates the needs for the detailed functions by answering WHY. For example, in this diagram, one could read:

- HOW do you enhance product? By improving satisfaction.
- HOW do you improve satisfaction? By facilitating maintenance.
- WHY do you facilitate maintenance? To improve satisfaction.
- WHY do you improve satisfaction? To enhance product.

While the focus of a VA study may be only a part of a complete product, for example, a bumper system, the FAST diagram must always describe the complete product, in this instance, the automobile as purchased by a user or customer. This ensures that all evaluation will be related to the wants and needs of the user.

The FAST diagram is a precise analog of the product under study, expressed in the unconstrained language of function. It contains no references whatever to the product hardware or its labor content. It is, thus, the "new viewpoint," which is the underlying basis for all VA.

Function Cost. While the FAST diagram permits team members to create freely in the absence of the constraints represented by drawings, specifications, and bills of material, it is as yet incomplete. The next step turns the costed bill of materials into a costed bill of functions, where costs of items are attached to their respective functions. The procedure is called function-cost allocation.

The VA team allocates the costs of the product or process to the function diagram, resulting in a hierarchical structure called a costed FAST diagram. The team now has a totally new viewpoint, that of function-cost, to replace its customary viewpoint of hardware-cost. Their solutions therefore typically reach far closer to the limits of the envelope of practicality. In the diagram of the motor vehicle, the VA team allocated the cost data to their FAST diagram by assigning each line item of the bill of materials to the function(s) which it performs. The result is a costed bill of functions, the ideal basis for unconstrained, but focused, creativity.

When the VA effort is directed toward the design and development of a new product, a base reference case must first be prepared. This comprises a set of sketches and a pro forma costed bill of materials. The costs are then allocated to the FAST diagram in the same manner as for an existing product.

Function Worth. It is also desirable to add to the FAST diagram data on the needs and desires of the users/customers. To ensure that these data are carefully structured, but unconstrained in viewpoint, they are collected by simply asking a valid sample of users two nonleading, open-ended questions about the product: "What do you like?" and "What do you dislike?" The resulting data are used to assign a function worth to each of the functions.

When the VA effort is being directed toward the design and development of a new product, the collection of user attitude data is focused on currently available versions of the proposed product. In some specific cases, cost and worth in dollars can be replaced by duration, manpower, reliability, or any other criteria worthy of optimization.

Table 1 shows the results of data collected during value analysis of a gas-operated home furnace. The data are a selected sample of the 76 responses collected in a one-day target opportunity panel where 16 users and producers of the home furnace were repeatedly asked, "What do you like about your furnace?" and then, "What do you dislike about your furnace?" The unconstrained responses were rated on a scale of 1 to 10 (10 being highest) on their importance or seriousness. The ratings are of the mode or the "most frequent" value.

Table 1 Ratings of likes and dislikes of a gas furnace

Example of data collected to establish function worth during value analysis

Likes (features or characteristics)	Importance (most common vote of the users)
Heat exchanger is cast iron for long life	8
Block vent switch is prewired	5
Temperature/pressure gage is easy to read	9
Furnace is low in height	9
Flame rollout location minimizes burnout	5
Dislikes (faults or complaints)	Seriousness (most common vote of the users)
Draft hood outlet is too high	8
Pump is in wrong area for transportation	8
Standing pilot rating is not high enough	4
Plastic drain valve handle is too brittle	1

The Analysis Phase (Identification of Value Targets)

Knowing the cost and the worth of each function permits the VA team to identify and focus on only those functions where solutions are required, that is, where there is a mismatch between the two parameters of function cost and function worth. In effect, these are functions where cost does not match what the customers say the function is worth to them.

The FAST diagram for the bumper system of a 1992 mid-sized automobile is shown in Fig. 1. The $57.61 total cost is shown allocated to the functions performed by the bumper system. If the team's knowledge is limited to these data--that is, if all they know is cost--they might choose to focus their problem-solving effort simply on the higher cost functions, in accordance with the list shown in Table 2.

Table 2 Analysis of cost elements from the FAST diagram for an automobile bumper system (Fig. 1)

Priority (according to cost)	Function	Cost, %
1	• Please senses o Disguise irregularities o Enhance appearance o Instill pride o Differentiate models •	52
2	• Ensure dependability o Enhance safety § Protect pedestrians o Increase durability § Strengthen structure § Resist damage § Resist corrosion § Reduce repair o •	42
3	• Enhance product o Improve satisfaction o Facilitate maintenance •	6

A review of this priority list will quickly indicate that the use of cost alone as a criterion would lead the team to apply their redesign effort to functions where the opportunity for increased value is minimal. Fortunately, the VA team had access to data from a target opportunity panel, which shifted their focus from the functions that were simply high cost to those where the function cost failed to match the function worth as measured by the data from the panel. On the basis of these data, they chose to apply their creativity and their synthesis effort to the functions that differentiate models and enhance appearance instead. This demonstrates the importance of good function analysis. Teams often focus on cost reduction only and neglect function enhancement as a method of increasing value.

The Creation Phase

In the creation-phase team session, the focus is on function. This function focus maintains the critical perspective of what it does for the customer, rather than what it is in the mechanical or operational sense. Over the years, the best practitioners of VA have fully understood customer focus and have applied the concept of "create-by-function."

The literature on human creativity comprises hundreds of volumes and thousands of articles in a wide variety of periodicals. The methods and the results described have a common root: brainstorming, a system of creative problem solving developed in the 1940s by Alex Osborn, a New York advertising executive. He successfully used it to generate new approaches to marketing products. When Lawrence Miles was developing VA, he took advantage of Osborn's work and found that the fit between function-oriented problem solving and brainstorming was nearly perfect.

During the creation phase, the VA team simply places the name of a function at the top of an easel pad and calls for an unconstrained outpouring of "thoughts and things." The automobile team described above first listed the function *enhance appearance.* More than 100 words and phrases were generated and listed on the easel pad. The rules of brainstorming require the deferring of judgment. As a result, the listed items are seldom solutions, or even ideas. They are merely words, that is, verbalizations of often unconscious mental images. Table 3 shows a partial list of words that were triggered in the minds of the automobile bumper VA team members by the function *enhance appearance.*

Table 3 Example of creative brainstorming results for the function *enhance appearance*

• **Blend colors** • **Use makeup** • **Use translucent materials** • **Illuminate** • **Smooth surfaces** • **Integrate accessories** • **Frame highlights** • **Brush hair** • **Electrify** • **Imply motion** • **Clip fingernails** • **Coordinate dress** • **Attract eye** • **Generate emotion** • **Round edges** • **Polish**

Note that most of these words or phrases have no relationship to an automobile or a bumper. This is the secret of effective brainstorming in VA. Team members consciously avoid generating solutions. They play the function-oriented brainstorming game in its pure sense. The list of words/phrases is a result of their focus on the function *enhance appearance* and not on their ultimate task of improving the value of the bumper system.

The secret to effective VA at this stage is to treat a function in its purely semantic sense. The team must rigorously resist reverting to simply creating solutions to the problems of the product under study. Developing this viewpoint is not an easy task and requires much coaching and practice. It is in the later synthesis phase, described below, that the team re-addresses the bumper problem. The unconstrained words/phrases of the creation phase trigger solutions, often unconsciously, in the minds of the expert team members.

Additional information about brainstorming and other methods for spurring creativity is provided in the article "Creative Concept Development" in this Volume.

The Synthesis Phase

A word is not a solution. The words on a brainstorming list are a far leap from a solution that can be implemented. For that reason, VA provides a method for breaking the journey into a series of steps:

Word → Idea → Concept → Solution

The team carefully nurses each word or phrase from its brainstorming list up this ladder of abstraction until an idea, concept, or solution emerges. If the exercise is not successful, that word is deleted and the elevation effort is applied to the next word on the list. The question asked of each word/phrase is "how can I use it?"
